ORGANIZED BY

Collaboration Program on Heat Pumping Technologies (TCP HPT) by International Energy Agency Technology (IEA)

CO-ORGANIZED BY

Air-Conditioning, Heating & Refrigeration Institute

American Society of Heating, Refrigerating and Air Conditioning Engineers
Preface
This conference was carried out within the Technology Collaboration Programme on Heat Pumping Technologies (HPT TCP), which is a Technology Collaboration Programme within the International Energy Agency, IEA.

The IEA
The IEA was established in 1974 within the framework of the Organization for Economic Cooperation and Development (OECD) to implement an International Energy Programme. A basic aim of the IEA is to foster cooperation among the IEA participating countries to increase energy security through energy conservation, development of alternative energy sources, new energy technology and research and development (R&D). This is achieved, in part, through a programme of energy technology and R&D collaboration, currently within the framework of nearly 40 Technology Collaboration Programmes.

The Technology Collaboration Programme on Heat Pumping Technologies (HPT TCP)
The Technology Collaboration Programme on Heat Pumping Technologies (HPT TCP) forms the legal basis for the implementing agreement for a programme of research, development, demonstration and promotion of heat pumping technologies. Signatories of the TCP are either governments or organizations designated by their respective governments to conduct programmes in the field of energy conservation. The Programme is governed by an Executive Committee, which monitors existing projects and identifies new areas where collaborative effort may be beneficial.

Disclaimer
The HPT TCP is part of a network of autonomous collaborative partnerships focused on a wide range of energy technologies known as Technology Collaboration Programmes or TCPs. The TCPs are organised under the auspices of the International Energy Agency (IEA), but the TCPs are functionally and legally autonomous. Views, findings and publications of the HPT TCP do not necessarily represent the views or policies of the IEA Secretariat or its individual member countries.
Abandoned mines as a source of heat and cold

Abstract

Mining has influenced and shaped the development of humankind for many thousands of years. After closure, these mines are often flooded and then offer a very high potential as a regenerative energy source for heating and cooling. Due to the almost constant temperature between about 10 to 30 °C throughout the year, an independent source of energy is permanently available, which can be brought to the necessary temperature level with heat pumps. In total 116 existing, planned and decommissioned systems were found worldwide. The observation of monitoring results of an example mine (“Reiche Zeche” in Freiberg/Germany) and a comparison to three other locations shows that the parallel use of mine water for heating and cooling can achieve coefficients of performance of the overall system of up to 10. Even with high electricity prices, operation costs for geothermal mine water energy of between 5 and 10 ct/kWhheat are possible. Compared to fossil fuels, at least 50 % CO₂ emissions are saved.

Keywords: mine water, geothermal energy, heat pump monitoring, district heating and cooling

1. Introduction

Mining is changing worldwide, e.g. in Germany the last hard coal mine was closed in 2018, brown coal is to be mined until 2035 at the latest [1]. In the Czech Republic, coal mining is planned to be finished in 2033 [2], similar to the situation of Canada, where coal mining is to end in 2030 [3]. The closure of the mines will inevitably lead to structural changes in the affected regions. Jobs in the mining sector will disappear and former mine sites will be renaturalized.

But these abandoned mines also offer potential: they can be used as a regenerative, geothermal energy source to provide heating and cooling. In most cases, abandoned mines are flooded and thus function as huge heat reservoirs. Depending on the location, the water temperatures are usually between 10 and 30°C. By using heat pumps, the temperature level necessary for the consumers can be provided. In the following, the basic structure of a typical geothermal mine water plant is presented and the current worldwide status quo is reviewed. Subsequently, the monitoring results of one plant in Germany are examined in more detail and compared to other plants located in Germany, the USA and Great Britain. Finally, the ecology and economy as well as identified problems are discussed.

2. Technological basics

The principle structure and possible extraction and return points of geothermal mine water systems are shown in figure 1. Firstly, the mine water is pumped to a heat exchanger (a) where heat is extracted (heating case) or supplied (cooling case) to a second fluid cycle. Afterwards, the heat will be transported in that intermediate circuit (b) to the heat pump (c), whereby the necessary temperature level is provided. If the temperature level is suitable for direct use as a heat sink for cooling, no heat pump is necessary. After heat is...
extracted (heating case) from the mine water or supplied to it (cooling case), it is returned to the mine building. Depending on the location, other plant designs are also possible. [4, 5]:

- At pumping stations where mine water has to be pumped continuously, e.g. to protect groundwater level, and is discharged into surface waters, the pumped water can be used directly above ground, which is then transferred to surface waters. The same principle can be applied to active opencast mines where sump water is discharged.
- In the past, drainage galleries were built to transport the mine water out of the mines. Energetic utilisation is then also possible at the mouth holes, which avoids additional expenditures, e.g. for drilling.
- If there is enough space, it is also possible to install a closed loop system in the mine water, e.g. pipe bundles which are submerged in the mine water.

3. Current overview of geothermal mine water systems worldwide

In order to get an overview of the worldwide status quo of mine water geothermal systems, systems were searched in English and German literature, and a total of 42 active plants were founded worldwide. There are studies and construction plans for many more plants; a total of 116 plants could be found worldwide. Figure 2 gives an overview of the plants in Europe (up) and North America (down). It is clear that most plants are located in old mining areas in Germany, Great Britain, the USA and Canada. Outside these regions, only plants in China could still be found. However, there is also potential in other locations in South America and South Africa. Possible reasons for the lack of studies and planning for example could be a lack of investors or other, better available or cheaper renewable energy resources.
In order to give an overview of the amount of energy that is available through the geothermal energy of mine water, figure 3 shows the number of geothermal mine water plants built, planned and closed, summarized into freely chosen power classes. It can be seen from this that many existing plants worldwide are in smaller output ranges (below 200 kW), but new plants are more likely to be planned for larger output classes (over 500-1000 kW), or studies are being prepared for this. This is also evident in the projects currently planned and implemented in Europe:
• In Mieres in Spain, a large geothermal mine water plant is already in operation. There, mine water with a temperature of 23°C is used to supply various buildings, e.g. a university, with heat. The mine water is cooled down about 5 K, thus a heating power of about 4 MW is currently available after the heat pumps. In a further expansion stage, it is planned to increase it up to 6 MW.
[7]
• Another big mine water project is also being planned in Germany: at the "Haus Aden" water extraction site (mine water must be pumped out permanently to protect the groundwater level) in Bergkamen in the Ruhr region, a new urban district is to be built on the former mine site and supplied proportionally with geothermal mine water energy. A mine water volume flow of about 1000 m³/h at about 20 °C is continuously available. This means that there is a theoretical potential of 30.6 MW, which will be exploited to set an example of how to safely supply renewable heat energy by mine water to urban districts. [8 bis 10]

4. Monitoring results

In 2013, a geothermal mine water system was put into operation at the former silver mine "Reiche Zeche" in Freiberg, Germany. In the current expansion stage, with a heating capacity of 175 kW and a cooling capacity of 100 kW it can supply several buildings at the university (offices, class rooms, laboratories, server rooms). The basic system design is shown in figure 4. The special feature here is that there are the three options for providing heating and/or cooling:
• Variant A ("Rothschönberger Stolln"): The mine water here is taken from the main drainage gallery of the Freiberg mining district, the “Rothschönberger Stolln”. This has a water temperature of about 14 °C.
→ Variant A is used when there is a predominant demand for cooling.
• Variant B (Shaft “Reiche Zeche”): Alternatively, the mine water can also be taken from the “Reiche Zeche” shaft, where the mine water has a temperature of about 19 °C due to rising deep water.
→ Variant B is used when there is a predominant demand for heating.
• Variant C (intermediate circuit): Only the fluid in the intermediate circuit between the heat exchanger at a depth of 228 m and the heat pumps on the surface is circulated. In the case of low heating or cooling requirements, the heat from the rock (Gneiss) that surrounds the intermediate circuit can be sufficient for heating and cooling.
→ Variant C is used when there is a low heating or cooling demand.
This results in a total of 10 possible operating modes: for each of the three extraction options heating only, cooling only or combined heating and cooling can be selected. The 10th operating mode is "out of operation", e.g. because the system is being serviced. The diagram in figure 4 on the right top shows the proportions of the operating modes over an observation period of 3 years. Heating and cooling are used simultaneously for the most part; heating alone was only recorded in 1% of the observation period. The reason for this is the basic cooling load that is necessary at the site for cooling the server and laboratory rooms. In most cases, there is also a need for cooling in the winter. Only on a few very cold winter days there is no cooling necessary for individual hours. Otherwise, cooling-only mode was only required in about a quarter of the period under review, and this was mainly the case during the warm summer months. This is also shown in the diagram of the amount of heat and cold shown in figure 4, bottom right. Until mid-April, the heat quantity is significantly higher than the amount for cooling. Afterwards the amount of cooling gets into the predominant position. In addition to direct heating and cooling operation, a cold storage tank is integrated in the system whereby the return flows from the heating circuit can be used for cooling. The cold flow from the cold storage tank is also mainly used until mid-April, as the storage tank is then no longer “loaded” due to the low heating requirements.

The almost continuous cooling demand has a significant influence on the efficiency of the overall system see figure 5. A representative summer and winter week is shown. As expected, the heating demand is predominant in winter, with overall system performance factor per hour (HPF_{HC4}) of about 3.5 to 4.5 (notation according to [11]). This also takes into account the expenditure for electricity of mine water pumps, pipeline pumps and the measurement equipment of the monitoring system. In comparison, significantly higher HPF_{HC4S} are achieved in summer. As can be seen in Figure 5, where the minimum HPF_{HC4S} ranges between 5 and 6 but can also amount up to 10 in a representative summer week.

The reason for these HPF_{HC4S} is the predominant cooling demand. The mine water can be used directly as a heat sink and the electricity demand for the heat pump is omitted most of the time, unless there is a heat demand for hot water. The consideration of these two example weeks shows clearly that cooling can significantly increase the efficiency of geothermal mine water plants and thus make economic operation possible in the long term and in a stable manner. This issue is discussed in more detail in section 5.
In addition to the geothermal mine water system at the “Reiche Zeche”, other systems will be considered in the following:

- Since 2012, mine water from the former coal mine in Markham (Great Britain) has been used to heat company buildings. This system is an open system with mine water pumping to the surface. The mine water with an approximate temperature of 14 to 15 °C passes through the tubular heat exchanger within the mine water circuit, which heats the fluid in the intermediate circuit for a 20 kW heat pump. Due to the increased mine water level, the water extraction point was changed in 2015 so that water with a temperature between 13 and 14°C is now used.[12 bis 14]
- In Butte (Montana, USA), buildings at Montana Tech University are supplied with heating and cooling from mine water. The system uses water from the Orphan Boy shaft with a water level of 33.5 to 36.6 m below ground. The closed system includes a 175 kW heat pump that is connected to the building’s heating or cooling loop, depending on the outdoor temperature. [15, 16]
- In Ehrenfriedersdorf in (Saxony, Germany) the buildings of the visitor mine are heated since 1992. The system has a total output of about 120 kW. The heat exchanger mine water–closed intermediate circuit is located at a depth of 110 m. Therefrom the heated fluid is pumped inside the intermediate cycle to the heat pump in the buildings [17]

Table 1 provides an overview of the seasonal performance factors (SPFs) of the presented individual systems and their operating modes. It is clear that for all systems, a SPF\textsubscript{H1} of the heat pump of over 3 is achieved. In addition, the comparison of the SPF\textsubscript{H C4} of the total system also shows except from location Markham for all other systems high SPF\textsubscript{H C4}. Furthermore it’s obvious how worthwhile the combination of heating and cooling is (see “Reiche Zeche”), so that HPF\textsubscript{H C4}s of over 5 can be achieved for the entire system over longer periods of time also in winter.

The coefficient of performance of the entire system in Markham is below 2. The main reason for this is probably the energy-intensive pumping of the mine water above ground in an open system. At the other sites, the mine water is pumped over lower altitudes and the heat is then transported in a closed system.

5. Economic and ecological consideration

In addition to the investment costs, the operating costs during the operating period are a decisive factor in assessing the economic viability of geothermal mine water plants. Decisive influencing factors here are:

- Electricity price for the energy required for the heat pump, pumps, etc.
- SPF of the total system
- Costs for maintenance, servicing, etc.

Figure 6 shows the operating costs of a geothermal mine water system as a function of the electricity price in EURct/kWh and the SPF of the system. The operating costs can be read off from the sloping lines on the upper and right axes (in blue).

![Operating costs of a geothermal mine water system as a function of SPF and electricity price for various example plants compared to costs of other energy sources in the USA (grey dotted lines) and Europe (black dotted lines) data, pictures: [12, 14, 15]](image)

The other costs, e.g. for maintenance, are included in the calculation as a percentage. The monitoring results presented in section 4 are integrated in figure 6, with country-specific electricity prices always converted to euros. It can be seen, that geothermal mine water energy is more economical than comparable fossil energy sources at all locations under the current framework conditions (as of November 2022). It can be seen that with high SPFs through combined heating and cooling, even with electricity prices above 30 EURct/kWh, working costs of the geothermal mine water system of about 5 EURct/kWh can be achieved. Favorable electricity prices, e.g. through special heat pump tariffs, as in the case of the plant in the Ehrenfriedersdorf visitor mine (Germany), then enable economic operation even with lower SPFs. The cost level of fossil fuels is always a decisive factor. The strong increase in the price of gas in Europe in 2022 is also shown in the diagram. With maximum gas prices of over 30 EURct/kWh, the energetic use of mine water is always more economical and might even present advantages in the short-term. In summary, at a current electricity price in Germany of 32 EURct/kWh, a working coefficient of the overall system of about 3 must be achieved in order to be cheaper than all comparable fossil energy sources. With an electricity price in the USA of the equivalent of 17 EURct/kWh, the systems are already more economical than fossil systems, also for e.g. gas prices in the USA. In a nutshell, the American plant in Butte must achieve a SPF of at least 2.5 in order to be cheaper than fossil
fueled on the American market. In addition, electricity costs can be further reduced through local combination with the yields of e.g. photovoltaic or wind power plants. It should be noted, however, that the above consideration refers only to the operating costs; the investment costs of the systems are not integrated in this consideration. Depending on kind of construction activities are necessary (e.g. drilling), these can amount to several million euros.

In addition to the economic advantages, the use of geothermal mine water energy can also offer an ecological advantage by reducing CO\textsubscript{2} emissions. Figure 8 shows a comparison of the CO\textsubscript{2} equivalent of geothermal mine water systems compared to other energy sources. It is obvious that compared to the use of fossil fuels like brown coal or natural gas, CO\textsubscript{2} emissions can be reduced by 75\% and by at least 56\%, respectively. This factor will play an even greater role for the climate and economically in the future if CO\textsubscript{2} taxes are introduced or increased. The emissions that occur during the construction and operation of a geothermal mine water plant were considered in more detail in [18]. In summary, it is clear that emissions from geothermal mine water plants are mainly due to the electricity purchased and the refrigerant used in the heat pump, which in the future both will fall in their emission impact due to the rise of renewable electricity generation and natural refrigerants. [18]

![Comparison of CO\textsubscript{2} equivalent of geothermal mine water systems to other energy sources](image.jpg)

**Fig. 7** Comparison of the CO\textsubscript{2} equivalent of geothermal mine water systems to other energy sources (data: [19], study for Germany)

6. Identified problems

One problem to be solved when using geothermal mine water energy is the formation of fouling/depositing in the heat exchanger or pipelines. Depending on the site location, the mine water carries various loads, e.g. bacteria, dissolved and undissolved substances and other suspended matter. These substances can be deposited in the heat exchanger and thus significantly influence the plant efficiency. Even a biofilm of 250 \(\mu\)m can reduce the amount of heat transferred by 50\% [20]. In addition, the pressure loss across the heat exchanger increases, and the costs for maintenance also rise because cleaning is necessary. Furthermore, other sources of energy have to be used to compensate the resulting lack of heat. This also has a major impact on the SPF\textsubscript{H\textsubscript{C}}\textsubscript{4}s of the plants, which can also be reduced by up to 50\% due to fouling. The TU Bergakademie Freiberg is currently researching optimized heat exchanger design to reduce fouling/depositing and increase the time between cleanings. [21]

In addition, there were problems in monitoring because the system at the “Reichen Zeche” was partially shut down due to technical defects and construction work in the mine, so that longer measurement periods could not be recorded.

Furthermore, depending on the system design, winter operation may be subject to low efficiencies. A possible solution for this could be the integration of a seasonal heat storage. Currently, only a cold storage facility is used in the “Reiche Zeche” system, but this already makes the potential visible. Seasonal storage in mine water, e.g. of heat dissipated for cooling purposes in summer which can be utilized in winter, would be
desirable. Two current projects, WINZER (Funding reference number: 03G0912C) and MineATES (Funding reference number: 03G0910A) are investigating the seasonal storage of heat and cold in mine water.

7. Conclusion and outlook

An evaluation of 116 geothermal mine water sites worldwide with plants and studies on the energetic use of mine water shows that these are mainly concentrated on locations in North America and Europe. 42 currently active plants are findable (German/English). Most of them are in the power range below 200 kW; new plants are planned mainly in a higher power range above 1 MW. The results of monitoring data at the "Reiche Zeche" plant in Freiberg, Germany, show that the geothermal use of mine water by means of heat pumps is ecological and economical favorable. The combined use of mine water for heating and cooling regularly achieves high annual averaged coefficients of performance of over 7. A comparison with three other systems worldwide shows annual averaged $\text{SPF}_{\text{HC}}$ of at least 3.5 can also be achieved in pure heating mode. Under the current purchase prices for alternative energy sources, geothermal mine water energy is already cheaper for a $\text{SPF}_{\text{HC}}$ of 2 to 2.5, and with more favorable electricity prices, as in the USA, even more economical, also mode for fossil fuel prices in the USA. However, the partly high investment costs for development of mine water resources are not included in the direct operating costs and must be considered during the pre-planning phase before investment decisions. From the ecological point of view, the energetic use of mine water can save $\text{CO}_2$ emissions between 56 % up to 75 % compared to natural gas heating. In future a task to be solved is the location-dependent formation of fouling in the heat exchangers and components in contact with water due to the chemical composition of the mine water and its (un-)dissolved substances. This reduces the usable heat output and thus decreases the efficiency of plants. Research into optimized heat exchangers and plant design must be intensified in the future and adapted to the respective locations. In addition, intelligent monitoring is recommended for the plants currently planned and under construction in order to be able to monitor the actual efficiency and to compare it to other running mine water systems.

Acknowledgements

We would like to thank the German Federal Ministry of Education and Research and the project management organisation Jüllich for their financial support of the WINZER (Funding reference number: 03G0912C) project. In addition, thanks go to all the technicians and students involved, especially: J. Balski, U. Fleischmann and R. Klink.

Decarbonizing Steam Generation with High Temperature Heat Pumps: Refrigerant Selection and Flowsheet Evaluation

Christoph Höges\textsuperscript{a, *}, Valerius Venzik\textsuperscript{a}, Christian Vering\textsuperscript{a}, Dirk Müller\textsuperscript{a}

\textsuperscript{a} Institute for Energy Efficient Buildings and Indoor Climate, Mathieustr. 10, 52074 Aachen, Germany

Abstract

High temperature heat pumps have a high potential to reduce carbon emissions in industrial processes by replacing conventional heating systems for low-pressure steam generation. However, heat pump performance is sensitive to the selected refrigerant, flow sheet, and operating conditions complicating the design process. Thus, we conduct a refrigerant selection and evaluate five flow sheets for a low-pressure steam application, which heats liquid water from 80°C at 1.5 bar to 120°C steam. First, refrigerants are screened to identify suitable low-GWP (<150) refrigerants. We find 15 alternative refrigerants. Second, the performance of the selected refrigerants is evaluated in five flow sheets, including two vapor injection and a parallel-compression configurations. R717 outperforms all other solutions concerning cycle efficiency and heating capacity for all investigated cycles. However, R717 leads to high compressor discharge temperatures limiting the applicability with compressor lubricant. Here, lubricant-free technologies such as turbo compressors are promising. Besides R717, the investigation shows further solutions with high efficiencies. Most promising refrigerants, however, have a double bond in their molecule structure, reducing their chemical stability. Furthermore, the cycle configuration using vapor injection in combination with an internal heat exchanger yields the highest cycle efficiencies. Compared to the simple flow sheet, more than 20% of improvements are possible.

1. Introduction

To achieve the goals of the Paris Climate Agreement, carbon emissions have to be reduced. One main source of carbon emissions is the combustion of fossil fuels in heat generation with conventional systems, e.g., a gas boiler [1]. Heat pumps are a possible solution to replace conventional systems in heat generation. Heat pumps use ambient or waste heat combined with electric power to provide the necessary heat demand. Thereby, the emissions of the heat pump depend on the specific emissions of the necessary power demand and the emissions related to refrigerant leakages on-site.

In industrial processes, heat over a wide range of temperatures is needed to satisfy all demands [2]. A large share of the necessary heat is utilized at temperatures below 200 °C, which current heat pumps can provide. Thus, a considerable reduction of carbon emissions is possible that be utilized with heat pumps [3].

For many industrial processes (e.g., drying, refining, and food processing), steam is used to distribute the heat due to its high heat capacity and good transfer properties. In addition, due to its high latent heat, a large amount of heat can be provided while keeping the temperature constant. However, the literature on steam generation using a heat pump is limited. Furthermore, steam generation is especially challenging due to the high isothermal heat demand, which leads to a more complex secondary temperature curve in the condenser.

In contrast to conventional heating systems, heat pump efficiency strongly depends on the operating point. Additionally, the selected refrigerant and cycle configuration influence operational performance, leading to lower efficiency or a reduced operating range. For refrigerants, current regulations regarding a low global
warming potential (GWP) and a zero ozone depletion potential (ODP) should be met [4]. Additionally, the refrigerant is subject to thermodynamic requirements regarding the critical temperature, the isobaric heat capacity, and the latent heat to achieve high efficiencies. Furthermore, the molecule has to offer long-term chemical stability to ensure a safe and efficient operation. Thus, the number of potential refrigerants is limited on the one hand, and the identification is more complex compared to the residential heat pumps on the other hand.

Besides the refrigerant [5, 6], the cycle configuration, i.e., the selected components [7, 8] and flowsheet [9, 10], has a significant influence on the overall cycle performance and the operating envelope. In contrast to residential heat pumps that are well known, industry heat pumps have a much higher heating capacity, which can exceed several Megawatts. Furthermore, due to the high energy flows, the overall share of the operation period is significantly higher than conventional, small-scale heat pumps. Thus, improving the efficiency as much as possible is one key aspect when designing large-scale heat pumps, resulting in a broader number of possible cycle configurations.

In this work, we investigate the potential of heat pumps to generate steam at 1.5 bar pressure and analyze the influence of the refrigerant and the selected flowsheet on the overall cycle performance. First, a refrigerant selection based on thermodynamic and ecologic properties is conducted for the defined application. The selection leads to 14 refrigerants that are not toxic and have GWP below 150. Additionally, ammonia (R717) and R245fa are included due to their wide usage. Furthermore, we include a zeotropic mixture based on R600a and R601a to analyze the potential of zeotropic mixtures for the defined application. Second, a case study is conducted that heats liquid water from 80 °C to steam at 120 °C. The investigation uses five cycle configurations to analyze their influence on the optimal refrigerant. Third, the present study’s findings are discussed, and future research aspects are mentioned that should be directed in the future.

2. Methodology

The following sections present the used cycle models and the use case parameter. First, the general evaluation procedure is presented. Afterward, the component modeling followed by the investigated cycles is shown. Finally, section 2.4 presents the parameters of the case study and the selected refrigeration of the investigation.

2.1. Modeling approach

We use consistent thermodynamic models to predict the heat pump cycle behavior. The expansion valve is isenthalpic. Piping and all further components have no pressure and heat losses. For modeling the heat exchangers, a pinch model is used, enabling to determine the evaporation and condensation pressures related to the heat source and sink. Fig. 1 shows the temperature curves of the heat source (blue) and heat sink (red). The heat source uses sensible heat with a constant heat capacity resulting in a linear curve. The heat sink is split into a sensible part (preheating liquid water), a latent part (evaporation of water), and a sensible part (superheating of water).

Further degrees of freedom of the process are the superheating $\Delta T_{SH}$ at the compressor inlet and the subcooling $\Delta T_{SC}$ at the condenser outlet.

Fig. 1: Temperature curves of sink water (red) with cyclobutene (black) as the refrigerant and a heat source (blue).
As the main deviation from the standard heat pump model, the compressor efficiencies are calculated through a loss-based model of a reciprocating compressor [11]. The model calculates the isentropic and volumetric compressor efficiencies as a function of the operating point and the refrigerant. Equation (1) shows the general definition of the isentropic compressor efficiency \( \eta_s \).

\[
\eta = \frac{\dot{m}_{\text{refrigerant}} \cdot \Delta h_{\text{rev}}^{\text{comp}}}{P_e}\]

(1)

The model includes multiple loss mechanisms within a compressor and combines them with analytical definitions of compressor efficiencies. Thereby, friction (parameter \( a \)), flow losses (parameter \( b \)), and electrical (parameter \( c \)) losses are considered. The model leads to the following expression for the isentropic compressor efficiency:

\[
\eta = \frac{V_{\text{cyl}} \cdot n_{\text{cyl}} \cdot f_{\text{mech}} \cdot \rho_{\text{in}} \cdot \eta_{\text{vol}} \cdot (h_{\text{out}}^{\text{is}} - h_{\text{in}})}{V_{\text{cyl}} \cdot n_{\text{cyl}} \cdot f_{\text{mech}} \cdot \rho_{\text{in}} \cdot \eta_{\text{vol}} \cdot (h_{\text{out}}^{\text{is}} - h_{\text{in}}) + a + b \cdot \rho_{\text{in}} \cdot (V_{\text{cyl}} \cdot n_{\text{cyl}} \cdot f_{\text{mech}} \cdot \eta_{\text{vol}})^2} (1 - c)
\]

(2)

The volumetric compressor efficiency \( \eta_{\text{vol}} \) is approximated as a function of the pressure and refrigerant properties

\[
\eta_{\text{vol}} = 1 - \frac{k_1}{H_{\text{ref}}} \cdot \left( \frac{p_{\text{out}} + k_2 \cdot \rho_{\text{in}}}{p_{\text{in}}} \right) \frac{c_v}{c_p}
\]

(3)

with \( k_1 \) and \( k_2 \) being fitting variables. Additionally, Roskosch et al. [11] proposed an approach that scales the loss parameters of friction (\( a \)) and flow losses (\( b \)) by the compressor geometry (piston diameter \( D \) and stroke \( H \)). We will use this scaling approach in our study to design the compressor geometry specifically for each refrigerant concerning the desired heating power of the heat pump.

For the cycle calculation, we use an optimization approach. As a result, each investigated flowsheet’s coefficient of performance (COP) is maximized. Equation (4) states the optimization problem based on boundary conditions \( \dot{\theta} \).

\[
\begin{align*}
\text{max } COP (\dot{x}, \dot{\theta}) \\
\text{s. t. } & g(\dot{x}, \dot{\theta}) \geq 0 \\
& \dot{x}_{\text{min}} \leq \dot{x} \leq \dot{x}_{\text{max}}
\end{align*}
\]

(4)

The optimizer permutes the optimization variables of vector \( \dot{x} \), which depend on the flow sheet (see section 2.2). To speed up the calculation, reasonable lower and upper limits \( \dot{x}_{\text{min}} \) and \( \dot{x}_{\text{max}} \) are defined, respectively. Additionally, the cycle calculation is subject to multiple inequality constraints \( g(\dot{x}, \dot{\theta}) \) that ensure a physical operation.

The inequality constraints \( g \) ensure a physically and technically feasible operation and include three main constraints. The first constraint prevents supercritical operation [12]. The second constraint verifies that no wet compression occurs, i.e., liquid droplets during compression [13]. The compression is discretized in thirty steps, and the respective specific enthalpy is compared to the dew line enthalpy. The third constraint is part of the pinch model and ensures that a minimum approach temperature within all heat exchangers (condenser, evaporator, internal heat exchanger) is kept.

2.2. Investigated flowsheets

The present work investigates five flowsheets. Fig. 2 shows their schematics. In the following subsections, their general modeling assumptions are presented. A detailed description can be found in [14]. To calculate the individual fluid properties, the REFPROP fluid database [15] is used.
2.2.1. Simple cycle (Fig. 2a)

The cycle simulation of the simple cycle uses four degrees of freedom, which are defined by equation (5).

\[ \mathbf{x}_{\text{simple}} = [p_{\text{eva}}; p_{\text{con}}; \Delta T_{\text{SH}}; \Delta T_{\text{SC}}]^T \]

Here, the evaporation pressure \( p_{\text{eva}} \), the condensation pressure \( p_{\text{con}} \), the superheating \( \Delta T_{\text{SH}} \) at the compressor inlet, and the subcooling \( \Delta T_{\text{SC}} \) at the condenser outlet need to be defined. As the main assessment criterion, the \( \text{COP} \) is the ratio of transferred heat within the condenser and the electric power demand in the compressor. Equation (6) shows the formulation for the simple cycle assessment.

\[ \text{COP}_{\text{simple}} = \frac{\dot{Q}_{\text{con}}}{P_{\text{el}}} = \frac{h_2 - h_3}{h_2 - h_1} \]

2.2.2. Internal heat exchanger cycle (Fig. 2b)

For the internal heat exchanger, we assume that a heat transfer from the condenser outlet realizes the entire superheating at the compressor inlet. Therefore, the refrigerant leaves the evaporator as saturated vapor and the condenser already as a subcooled liquid while it is superheated and further subcooled in the internal heat exchanger. Overall, the degrees of freedom, as well as the target function \( \text{COP} \), are the same compared to the simple cycle (c.f. equation (5) and (6)). Here, we assume that the internal heat exchanger is designed ideally for the application. Thus, we optimize the transferred heat and do not use an efficiency based modeling approach.

2.2.3. Vapor injection cycle (Fig. 2c)

For the vapor injection (vi), a two-stage compression is used. After the first stage, the condenser outlet is split, and a partial mass flow rate \( \dot{m}_{\text{inj}} \) (state 5) is injected into the compressor. Due to the vapor injection, the cycle includes additional degrees of freedom. Thus, the intermediate pressure \( p_{\text{int}} \) of states 4 and 5 is optimized. The injection ratio \( y \), which is the ratio of injected vapor \( \dot{m}_{\text{inj}} \) and total mass flow rate in the condenser \( \dot{m}_{\text{con}} \), is included.

\[ y = \frac{\dot{m}_{\text{inj}}}{\dot{m}_{\text{con}}} \]

\[ \mathbf{x}_{\text{vi}} = [p_{\text{eva}}; p_{\text{con}}; \Delta T_{\text{SH}}; \Delta T_{\text{SC}}; p_{\text{int}}; y]^T \]

The injected mass flow rate is at state 5 always saturated vapor. Due to the two-step compression and vapor injection into the compression chamber, the cycle efficiency calculation is more complex than the simple heat pump cycle. Equation (9) shows the definition of the \( \text{COP} \) for the vi cycle.

\[ \text{COP}_{\text{vi}} = \frac{h_2 - h_3}{(1 - y) \cdot \Delta h_{\text{com,step1}} + \Delta h_{\text{com,step2}}} \]

2.2.4. Vapor injection in combination with the internal heat exchanger cycle (Fig. 2d)

The fourth cycle combines the advantages of the internal heat exchanger cycle (cf. section 2.2.2) and the vapor injection cycle (cf. section 2.2.3). Degrees of freedom, and the \( \text{COP} \) calculation, are similar to the vapor injection cycle (cf. equation (8) and (9)).
2.2.5. **Parallel compression cycle (Fig. 2e)**

The parallel compression cycle (pc) functionality is similar to the vapor injection cycle. However, instead of a two-stage compression process with injection in a single compressor, the flowsheet includes two individual compressors. In parallel compression, the split and preheated mass flow rate (state 6) is not injected into the main compressor but compressed by a second compressor (state 7). Here, state 6 needs the minimum amount of superheating to ensure the compressor's safe operation. Afterward, compressor outlets are mixed (state 3) and enter the condenser. Overall, the degrees of freedom is similar to the vapor injection cycle (cf. section 2.2.3). However, the calculation of the COP deviates:

\[
COP_{pc} = \frac{h_2 - h_3}{y \cdot \Delta h_{com,67} + \Delta h_{com,12}}
\]  

(10)

2.3. **Case study**

The present investigation aims to cover the following research questions:

1. Which refrigerants show high efficiency and are suitable for a steam generation?
2. Which flowsheet shows the overall best performance?
3. How do the results regarding the optimal flowsheet deviate for different refrigerants?
4. How does the source temperature influence the overall results?

To do so, the investigation focuses on steam generation where liquid water enters the condenser at 80 °C and 1.5 bar and leaves the condenser as superheated vapor at 120 °C and 1.5 bar. Five different inlet temperatures are investigated for the heat source, ranging from 40 to 80 °C. For each temperature, the temperature difference of the source is set to 10 K. Fig. 1 shows the temperature curves in both heat exchangers for the sink, source, and refrigerant.

For the defined application, a fluid selection is conducted. The fluid selection accounts for global warming potential (GWP) limits and the minimum operating pressure at an evaporation temperature of 30 °C. Additionally, the filter only includes non-toxic fluids and limits the operation to subcritical. Thus, refrigerants with a critical temperature below 130 °C are dropped. As a result, 14 refrigerants satisfy the defined constraints. For some selected refrigerants, though, the actual GWP value is low. Since all of them are isomers of known hydrocarbons, their expected GWP value should be below 150. Therefore, in addition to the selected refrigerants, ammonia and R245fa are added: Ammonia due to its high performance in the literature and R245fa as a reference refrigerant. Lastly, a zeotropic mixture based on R600a and R601a with a molar composition of 75/25 is included to analyze the potential of zeotropic mixtures for steam generation. Table 1 shows the selected refrigerants and their properties.

**Table 1:** Fluid properties of preselected pure refrigerants. Some fluid properties are not given in the literature, and their value is set to not available (n.a.).

3. Results

The following section presents the results of the conducted investigation. The study includes all refrigerants mentioned in Table 1. However, the figures in this work show only a selected number of refrigerants that represent the overall findings. Table 3 in the attachment shows the complete results for all mentioned cycle configurations and refrigerants for the operating point W80/W120.

Fig. 3 shows the results for the COP for a sink and source inlet temperature of 80 °C. Starting with the simple cycle (red bars), ammonia (R717) shows the highest efficiency at 5.75, and R1336mzz(E) shows the lowest efficiency at 3.41. Besides ammonia, cyclobutane shows similar high efficiencies. However, all other refrigerants lead to significantly lower efficiencies.

![Fig. 3: COP of selected refrigerants with a sink and source inlet temperature of 80 °C.](image)

Using the advanced flowsheets, ammonia and cyclobutane still lead to the highest efficiencies. The highest efficiency of 6.03 (R717) is reached when the vapor injection cycle, in combination with an internal heat exchanger, is used, leading to improvements of approximately 5 %. For both refrigerants, the improvements are relatively small compared to the other refrigerants. In contrast to both high-performance refrigerants, the efficiency of the zeotropic mixture based on R601a and R600a depends much more on the selected flowsheet. Here, the efficiency improves by up to 33 % with the advanced flowsheet vi-ihx. Thus, one observation is the strong interdependency of the refrigerant and the selected flowsheet.

The vi-ihx flowsheet leads to the highest overall efficiencies for all studied refrigerants, combining the ihx and the vi flowsheet. Additionally, the ihx flowsheet shows the second-highest efficiencies except for ammonia and cyclobutane. In the ihx flowsheet, the amount of superheating is shifted from the evaporator into the internal heat exchanger. Consequently, two effects occur for a perfect counterflow evaporator, which is assumed in the present work. First, the pinch-point shifts from the refrigerant outlet to the refrigerant inlet for a pure refrigerant. As a result, the lower pressure level increases, resulting in lower pressure ratios and, thus, higher efficiencies. Second, the heat that can be utilized in the evaporator increases due to the heat recovery
rate and the resulting lower vapor quality at the evaporator inlet. The heat recovery rate results from the higher superheating of the ihx cycle. Hence, the share of the provided heat received by the heat source increases, leading to higher efficiencies. However, one negative aspect is the increased maximum process temperatures (compressor discharge temperatures) due to the higher inlet temperatures in the compressor.

Fig. 4 shows the maximum process temperatures. Regarding the differences between the selected flowsheets, the ihx cycle shows the highest outlet temperatures for all refrigerants, followed by the vi-ihx cycle (except for ammonia). Due to the higher temperatures, the operating envelope of the compressor can be reduced. Thus, the overall operating range must be checked when selecting the compressor in combination with the flowsheet. On the other hand, the vi cycle leads to the lowest maximum temperatures. For the refrigerants, ammonia shows the highest process temperatures for all cycles, exceeding values above 160 °C.

![Fig. 4: Maximum process temperature for selected refrigerants in all cycle configurations for a source inlet temperature of 80 °C.](image)

Besides the mentioned effects in the ihx cycle, the vi-ihx cycle adds the advantages of vapor injection to the ihx cycle, resulting in even higher efficiencies. When using vapor injection, the compressor outlet temperature decreases due to the injection of steam at a lower temperature. The lower compressor outlet and, thus, condenser inlet temperature leads to a lower mean temperature difference between the refrigerant and the secondary fluid (in this case, water) in the condenser, reducing the entropy production during the heat transfer and, thus, leading to higher efficiencies. Additionally, the throttling losses are reduced since only a partial mass flow rate is expanded to the evaporation pressure, whereas the other part only expands to the intermediate pressure. Thus, the overall losses can be reduced.

However, the amount of loss reduction when changing the flowsheet depends on the refrigerant. Thus, not all refrigerants show the same results. In this case, the most significant improvement when changing the flowsheet occurs for the zeotropic mixture. Here, up to 33 % improvements are presented when changing the flowsheets from the simple to the vi-ihx cycle. The main reason is the even higher effect of the internal heat exchanger for zeotropic mixtures. For pure fluids, the pinch point in the evaporator is located at the evaporator inlet in case no superheating is provided in the evaporator. For zeotropic mixtures with a temperature glide that perfectly matches the source temperature difference, however, the pinch point can still be located at the evaporator outlet. Thus, the evaporation pressure can rise even further when using an internal heat exchanger, leading to higher efficiency improvements.

Nevertheless, the zeotropic mixtures still show far lower efficiencies than high-performing refrigerants like ammonia. The main reason here is the mainly latent temperature curve of the sink water in the condenser. In the condenser, the temperature glide can not be utilized due to the mainly isothermal heat transfer to the sink water. Therefore, the mean temperature difference between refrigerant and water increases if the refrigerant has a temperature glide. Once the mean temperature difference increases, the losses due to heat transfer also increase, resulting in lower overall efficiencies. Thus, zeotropic mixtures are not suitable for the generation of steam. However, azeotropic mixtures with similar behavior to pure fluids could increase efficiency since their overall fluid properties can be tailor-made by adjusting the mixture composition. Thus, azeotropic mixtures should be investigated further for applying steam generation heat pumps.

When comparing the pure refrigerants given in Fig. 3, most refrigerants show similar behavior when adjusting the flowsheet. Ammonia, however, deviates from the general performance adjustments. To analyze the effects further, Fig. 5 compares the results for all flowsheets for five source temperatures for the refrigerants ammonia (R717 – left) and butane (R600 – right). For both refrigerants, all flowsheets show the highest
efficiencies for the highest source temperature, which is the fundamental phenomenon related to the Carnot principle. The performance of the individual flowsheets, however, changes significantly. The pc, vi, and vi-ihx cycles for ammonia show similar efficiencies for all operating points.

Additionally, the ihx and simple cycle show similar performances but lower than the other three flowsheets. For butane, the vi-ihx cycle leads to the highest efficiency for all source temperatures, followed by the ihx, vi, and pc. However, the performance ranking of the ihx, vi, and pc flowsheets depends on the operating point. For high source temperatures (lower temperature lifts), the ihx flowsheet is superior to the other two. With decreasing source temperature and, thus, increasing temperature lift, the vi and pc flowsheet's potential increases, outperforming the ihx cycle's potential. Once again, the simple cycle shows the lowest efficiencies.

![COP results for ammonia (R717 – left) and butane (R600 – right).](image)

The main differences between ammonia and butane result from two aspects: First, ammonia has far higher compressor discharge temperatures (cf. Fig. 4). Second, butane – similar to the other hydrocarbons – has a dewline with a comparably low slope. Thus, the amount of superheating at the compressor outlet and the condenser inlet is relatively low for most operating points and flowsheets. Both effects can improve or reduce the effects mentioned by the individual flowsheets and will be evaluated in the following.

In the ihx flowsheet, the main improvements result from the higher superheating at the compressor inlet and, thus, the higher degree of subcooling at the inlet into the expansion valve. Therefore, the potential can be fully utilized for butane with a low compressor discharge temperature. Furthermore, the improvements in additional heat in the condenser are greater than the additional compressor work due to the higher temperature at the compressor inlet, leading to efficiency improvements. For ammonia with a very high discharge temperature, however, the improvement in additional heat in the condenser is lower compared to the increase in compressor work. Thus, the optimizer does not increase the superheating at the compressor inlet compared to the simple cycle. Hence, the efficiencies are similar.

In the vi cycle, the compressor's discharge temperature can be reduced due to the injection of refrigerant vapor at a lower temperature. For ammonia, the throttling losses and the losses due to heat transfer in the condenser can be reduced. Similar effects occur for butane. However, since butane has a low amount of superheating at the compressor outlet (in the simple cycle 6 K for a source temperature of 80 °C), the overall possible improvement is limited. Additionally, the pinch-point temperature is influenced negatively, leading to higher condensation pressures (19.6 bar in the simple cycle compared to 20.5 bar in the vi cycle). In the vi cycle, the pinch-point is located in the superheated region of the sink water. In the simple cycle, the pinch-point is located at the evaporation region of the sink water. Hence, the sink temperature at the pinch-point is higher, leading to higher necessary refrigerant temperatures to satisfy the second law of thermodynamics. This effect negatively influences the overall performance of vi. Hence, vi shows greater improvements for refrigerants with moderate compressor discharge superheating. For lower source temperatures, the amount of discharge superheating at the compressor increases for butane. Therefore, the performance of the vi flowsheets increases also.

The pc flowsheet shows similar effects to the vi cycle. The main difference is the location where both enthalpy flows are mixed. In the vi cycle, the mixing occurs in the compressor leading to a mixing entropy production in the compressor. Simultaneously, the compressor is cooled, leading to lower maximum process temperatures. In the pc flowsheet, the mixing occurs after both compressors. Hence, two effects occur. First,
the maximum process temperature is not influenced compared to the simple cycle since a partial mass flow rate still overcomes the total pressure ratio (cf. Fig. 4). Second, the entropy production due to mixing does not influence the compression process since it occurs after both compressors. Due to the second effect, the efficiencies of pc flowsheet are overall slightly higher compared to the vi flowsheet.

For the vi-ihx flowsheet, the mentioned effects for vi and ihx are combined. However, in the case of ammonia, the ihx does not offer any improvement. Hence, the results of the vi and vi-ihx flowsheets are similar.

Fig. 6: COP for vi-ihx cycle for selected refrigerants.

Finally, Fig. 6 shows the best-performing flowsheet (vi-ihx) results for all refrigerants in dependency on the source inlet temperature. The COP increases when the sink inlet temperature increases for all refrigerants. However, the overall refrigerant ranking is not affected by the adjustment of the source temperature. Thus, ammonia and cyclobutene show the highest performances still. Nevertheless, the investigation could only cover some potential refrigerants for applying a steam generation heat pump. Thus, ammonia or cyclobutene are not necessarily the best possible refrigerants. Further research should investigate the possibility and the potential of tailor-made azeotropic mixtures that offers fluid properties for a defined application.

In the following section, the results of the present investigation are discussed.

4. Discussion

The previous section shows the results of the analysis of several refrigerants in five possible cycle configurations for the application in high temperature heat pumps to generate low-pressure steam. Regarding cycle efficiency, ammonia and cyclobutene show the highest values. Additionally, combining an internal heat exchanger and vapor injection in one flowsheet leads to the highest efficiencies for all refrigerants.

Besides the cycle efficiency, however, several further aspects must be addressed when selecting a refrigerant and a flowsheet for an application. One aspect is the long-term chemical stability of refrigerants. In high temperature applications, the refrigerant has to withstand the continuously high temperature compared to conventional heat pump systems (e.g., for space heating). However, long-term stability tests have yet to be conducted for many refrigerants. Thus, the long-term stability is unknown. However, one possible indicator is the molecule structure of a refrigerant. In this regard, double and triple bonds tend to be less chemically stable than regular bonds. Table 1 shows, there a refrigerant molecule includes at least one double or triple bond. Besides the natural refrigerant R717 (ammonia) and the hydrocarbons R600, R600a, and R601a, all investigated refrigerants have at least one double or triple bond. Hence, their chemical stability cannot be guaranteed, and further studies are necessary. Thus, ammonia is preferable to cyclobutene since its long-term stability has been tested widely already.

Ammonia is a toxic and moderately flammable (B2L) refrigerant. Therefore, additional safety measures are necessary, leading to higher costs and a more prolonged designing phase since many regulations must be satisfied. Furthermore, stainless steel is necessary for ammonia, resulting in higher investments. Additionally, processing stainless steel is more challenging and expensive compared to conventional materials for heat pumps, e.g., copper, making the construction part more challenging.

Besides the general fluid properties, ammonia has a critical temperature of 132.4 °C. Since the application of this paper is the generation of low-pressure steam with a water vapor outlet temperature of 120 °C, ammonia operates relatively close to the critical points. In case of higher dynamics or oscillations during the operation,
the critical point might be reached, leading to an unstable operation. Thus, ammonia might not be applicable for the given use case. Ammonia is applicable for lower sink temperatures with a sufficient difference from the critical temperature. Nevertheless, ammonia leads to very high operating pressures due to its high critical pressure of 112.8 bar. For operation closer to the critical temperature, there are limited components available to utilize ammonia’s potential. Especially the compressor with its sealings leads to challenges regarding the design of new components.

Additionally, ammonia leads to very high discharge temperatures compared to other refrigerants (cf. Fig. 4), which can negatively affect the lubricant in the compressor. Therefore, oil-free compressor solutions, e.g., turbo compressors, can be possible when handling high temperatures. However, turbo compressors need several compression stages due to the high occurring pressure ratios and the simultaneously only limited pressure ratio a compression stage can overcome. Hence, additional investments are necessary for the system.

Nevertheless, ammonia has been applied in heat pumps for several decades. Thus, the mentioned challenges are well known, and possible solutions have been prepared and proven sufficient for a safe and efficient operation. Also, ammonia has the advantage of high volumetric heat capacities due to its high operating pressure. Due to the high volumetric heat capacities, the components of the heat pumps can be designed smaller, leading to more compact systems. Especially for large-scale heat pumps with heating demands in the range of several megawatts, compact systems are necessary due to the high demand for space. Thus, ammonia shows a high-performance solution for compact heat pump systems with solvable challenges regarding its safe operation.

Regardless of the high performance of ammonia, further research should still be conducted regarding possible alternatives. For example, for steam generation, zeotropic mixtures are not suitable due to the negative effect of the temperature glide. Tailor-made azeotropic mixtures optimized for the individual application, however, might improve the overall cycle performance (efficiency, volumetric heat capacity, maximum process temperature) further, leading to a further reduction in power demand and, thus, carbon emissions.

5. Conclusions

The present investigation analyzes the applicability of heat pumps for the generation of low-pressure steam. For the application, the water enters the heat pump condenser at 80 °C, evaporates at 1.5 bar (approx. 111 °C), and leaves the condenser at 120 °C as superheated vapor. First, a refrigerant selection is conducted to analyze the applicability of heat pumps. We identify 14 refrigerants that are not toxic and have a GWP below 150. Additionally, ammonia is included due to its high performance in existing heat pumps, and R245fa is added as a reference refrigerant. Second, we evaluate the performance of the refrigerants in five flowsheets and analyze the influence of shifting the source temperature from 40 °C to 80 °C.

The results show that ammonia and cyclobutene lead to the highest efficiencies with COPs of up to 6. Cyclobutene, however, has a double in its molecule structure and might be less chemically stable than ammonia. Hence, ammonia is to be preferred. Regarding the cycle configuration, a combination of vapor injection and an internal heat exchanger shows the highest efficiencies for all investigated refrigerants. For ammonia, however, the potential is similar to a basic vapor injection cycle since the potential of the internal heat exchanger cannot be utilized due to the high compressor discharge temperatures of ammonia.

Finally, the results are discussed. Due to its toxicity and flammability, additional safety measures are necessary when using ammonia as a refrigerant. Nevertheless, ammonia has been used in heat pumps for decades, showing its potential and solution when dealing with additional safety regulations. Additionally, ammonia leads to compact systems due to its high volumetric efficiency. Hence, ammonia is a performance solution, especially when combined with advanced flowsheets like a two-stage compression. So overall, ammonia is a high-efficiency replacement for conventional refrigerants such as R245fa. However, further research regarding the potential of tailor-made azeotropic mixtures should be conducted since the individual fluid properties can be optimized for generating low-pressure steam, improving the cycle efficiency even further.

Abstract

Driven by China's dual-carbon goals and the national strategy of clean heating, the application of air source heat pump heating is growing rapidly. So the determination of the equilibrium point in the heating design of the air source heat pump has an important influence on the determination of unit capacity, system heating performance and investment and operation cost. This paper analyzes the influence of the equilibrium point temperature selection of low ambient temperature and conventional air-source heat pump heating products in different regions, different energy-saving grades and different building types on the system performance. The results show that there is an obvious difference in the equilibrium point temperature corresponding to the optimal performance of air source heat pump heating in different regions. The equilibrium point temperature of different building types in the same region is different. In the same application situation, the equilibrium point of the low ambient temperature heat pump is generally lower than or equal to the conventional heat pump, the coefficient of performance of the heating season is higher, and has better application performance.

Keywords: Air source heat pump heating; Equilibrium point; Heating season performance factor;

1. Introduction

In order to improve the atmospheric environment in northern China, the government has put forward a clean heating strategy, combined with the dual-carbon goals of “carbon peaking and carbon neutrality”, and adopted electrified terminals to transform the seriously polluted bulk coal heating mode. Air source heat pump has the advantages of easy availability of low heat source and flexible installation\(^{[1]}\). Driven by demand, it continues to improve the applicability of low temperature and has become the dominant way of “electricity instead of coal”. The current market scale is close to 7 billion yuan.

For the air source heat pump, the heating capacity and performance are positively correlated with the ambient temperature, that is, the higher the ambient temperature, the greater the heating capacity of the air source heat pump, the better the performance; for the user side, the indoor heat load is negatively correlated with the ambient temperature. when the indoor design temperature is the same, the higher the ambient temperature is, the lower the indoor heat load is, and the lower the outdoor temperature is, the higher the indoor heat load is.

The heating capacity of air source heat pump and building heat load have the opposite trend with the ambient temperature. When they are equal, the corresponding ambient temperature is the equilibrium point temperature. When the outdoor temperature is higher than the equilibrium point temperature, the heat pump unit runs under partial load, resulting in a decrease in the coefficient of performance; when the outdoor temperature is lower than the equilibrium point temperature, it is necessary for the auxiliary heat source to bear part of the heat load, which can’t give full play to the energy-saving role of the air source heat pump. Therefore, a reasonable

\(^{*}\) Corresponding author. Tel.: +86-15901118986.
E-mail address: yly8111@163.com
equilibrium point temperature can improve the coefficient of performance of the unit and give full play to the advantages of air source heat pump.

There have been many researches on the equilibrium point temperature of air source heat pump at home and abroad. Jiang’s team[2-6] took the lead in putting forward the concepts of the optimal energy efficiency equilibrium point and the optimal energy equilibrium point, and took specific cities as examples to carry out relevant calculations. The research direction abroad is mostly focused on the method of determining the capacity of auxiliary heat source, including the difference of equilibrium point temperature when using different heating methods such as electric heating or gas heating as auxiliary heat source, which is also based on the temperature theory of heat pump equilibrium point.

The above research uses more steady-state calculation methods in the calculation of indoor heat load. With the development of computer technology, much simulation software has been developed to simulate indoor heating and cooling load, such as TRNSYS, DeST and so on. TRNSYS has the advantages of convenient use and flexible calculation, so this study uses TRNSYS software to simulate the cooling and heating load of different energy-saving buildings in different regions, and then uses the simulated indoor hourly heat load to calculate the optimal equilibrium point temperature of low ambient temperature air source heat pump(LATASHP) and conventional air source heat pump(CASHP).

2. Methods

The determination of the equilibrium point temperature depends on the choice of the final optimization objective. At present, there are two kinds of optimization objectives: the economic goal and the system performance goal. Using the annual cost value or the whole life cycle cost as the objective function to find the best economic equilibrium point temperature, its purpose is to ensure that the sum of the initial investment and operation cost of the heating system is the lowest. Using the seasonal coefficient of performance of the system heating HSPF or the seasonal coefficient of performance of the air source heat pump unit SCOP as the objective function to find the best performance equilibrium point temperature, the goal is to optimize the overall heating performance. The primary energy utilization coefficient of the air source heat pump and the primary energy utilization coefficient of the boiler are also used as the objective function, that is, when the heating energy utilization coefficient of the heat pump is equal to that of the auxiliary boiler, the primary energy efficiency of the heating system is the highest[7]. This paper mainly studies the balance point whose ultimate optimization goal is the system performance goal.

2.1. Optimal performance equilibrium point temperature of heating system

\[
HSPF = \frac{\sum_{i=1}^{T_{\text{max}}-T_{\text{min}}} Q_{i1}}{\sum_{i=1}^{T_{\text{max}}-T_{\text{min}}} W_{i} + \sum_{i=1}^{T_{\text{max}}} P_{i} T_{i}} = \frac{\sum_{i=1}^{T_{\text{max}}} Q_{i1}}{\sum_{i=1}^{T_{\text{max}}} COP_{i} + PLF + \sum_{i=1}^{T_{\text{max}}} P_{i}}
\]

(1)

In the formula:
- \(Q_{i1}\) is the indoor heat load when the outdoor air temperature is \(i\), kW;
- \(W_{i}\) is the power consumption of the heat pump when the temperature is \(i\), kW;
- \(Q_{hi}\) is the heat consumption of the auxiliary heat source when the temperature is \(i\), kW;
- \(T_{i}\) is outdoor calculation temperature for design conditions for use region, °C;
- \(T_{\text{min}}\) is the higher value of the minimum outdoor temperature that can be operated for the heat pump unit and the outdoor calculated temperature under the design condition, °C;
- \(T_{\text{max}}\) is the highest outdoor temperature for heating operation of a heat pump unit, °C;
- \(COP_{i}\) is the coefficient of heating performance of heat pump unit;
- \(PLF\) is the COP correction factor of partial load heat pump unit;
- \(P_{i}\) is the energy consumption conversion coefficient of auxiliary electric heating equipment, and the electric heating equipment generally takes 1:

\[
PLF = \frac{PLR}{1 - e_{d}(1 - PLR)}
\]

(2)

In the formula:
- \(PLR\) is the partial load rate, which is defined as the ratio of actual heating capacity to the rated capacity of
the equipment;

\( C_d \) is the attenuation coefficient of heating performance of heat pump under partial load, which is generally 0.9;

\[
Q_{ho} = \frac{Q'_0}{K_1 K_2}
\]  

(3)

In the formula:

\( Q'_0 \) is the heat output of the heat pump unit at the preset equilibrium point temperature, kW;

\( K_1 \) is the correction coefficient of heat pump unit at preset equilibrium point temperature;

\( K_2 \) is the defrosting loss coefficient of heat pump unit at preset equilibrium point temperature;

\[
Q_h = K_1(T)K_2(T)Q_{ho}
\]  

(4)

In the formula:

\( Q_h \) is the heat produced by the heat pump unit at a certain outdoor temperature during the heating period;

\( K_1(T) \) is the ambient temperature correction coefficient of a heat pump unit during the heating period;

\( K_2(T) \) is the defrosting loss coefficient of the heat pump unit at a certain ambient temperature during the heating period;

\[
Q_{fi} = Q_{hi} - Q_{hi}
\]  

(5)

When the heat load of the building, the air source heat pump unit and the auxiliary heat source are determined, HSPF is only a function of the equilibrium point temperature, so by changing the preset equilibrium point temperature, the curve of HSPF change can be obtained, and the equilibrium point temperature corresponding to the maximum value of HSPF is the optimal performance equilibrium point temperature.

2.2. Load simulation

Building energy efficiency in China is based on the building energy consumption in 1980-1981. It is a stage to improve energy efficiency by 30% on the basis of the previous stage in each step, that is, to save energy by 30%, 50%, 65% and 75% respectively compared with the benchmark building. On the basis of 65% energy saving rate, buildings that can save 60% - 75% more energy are near zero energy consumption buildings. On the basis of 65% energy saving rate, buildings that can save 60% - 75% more energy are near zero energy consumption buildings. Using TRNSYS to simulate the load of different types and different energy-saving buildings, the relevant parameters are based on the building energy efficiency standard system, and the residential building area is 2000 square meters, the office building area is 4000 square meters, and the commercial building area is 10000 square meters. The thermal disturbance factors such as enclosure structure, fresh air demand and internal personnel lighting are stipulated in the "Energy efficiency Design Standard of Public buildings GB 50189-2015" and the energy efficiency design standards of residential buildings in various areas(JGJ 26-2018, JGJ 134-2010, JGJ 75-2012). The following is an example of residential buildings in Beijing to analyze their load characteristics. It can be seen from Fig.1 that there is a linear relationship between indoor heat load and ambient temperature. The higher the energy saving level is, the lower the indoor heat load is at the same ambient temperature. Because of the interference of different factors, the relationship between indoor heat load and ambient temperature is not completely linear, and the fitted linear formula can be used to replace it in practical application. However, hourly heat load is used to calculate the energy consumption of air source heat pump in this study. For near-zero energy consumption buildings, the indoor heat load is basically less than 10W/m², and the performance of the building envelope is excellent, so the ambient temperature is only one of the factors affecting the indoor heat load, and the internal heat source also has a great influence on the indoor heat load, so the linear characteristic between the indoor heat load and the outdoor air temperature is not obvious. For near-zero energy consumption buildings, the heating load has almost no linear correlation with the outdoor temperature, and the building use mode and operation strategy have a decisive influence on the equilibrium point temperature, so it
is necessary to discuss everything in the application of near-zero energy consumption projects. According to the specific building demand, the equilibrium point is determined by calculation.

Fig. 1. Indoor heating load of residential buildings in Beijing.

2.3. Performance of air source heat pump

Through market investigation, the heating products of air source heat pump in the market are classified, and the representative ordinary air source heat pump products and jet enthalpy quasi-two-stage compressed LATASHP products are selected for performance analysis. The heating system is fixed as air source heat pump + fan coil end, and the water supply temperature is 41℃. The heating capacity and performance of the product are fitted by regression. As shown in Table 1, according to the heating capacity of the two products and the regression fitting formula of COP, we can know the change of the heat production of the air source heat pump with the outdoor temperature.

3. Results and discussion

The calculation results are analyzed from four directions: different climatic regions, different building types, different energy saving grades and different types of heat pumps.

3.1. Optimal performance equilibrium point in different climatic regions

Select typical cities in different climate zones: Harbin, Beijing, Wuhan. Harbin is located in a severe cold region, Beijing is located in a cold region, and Wuhan is located in a hot summer and cold winter region. The
buildings of the three are residential buildings, and the heat pump type is LATASHP. The current building energy efficiency in Harbin and Beijing is 75%. The current building energy efficiency rating is 50%.

It can be seen from the Fig.2 that there is an obvious inflection point in the performance equilibrium point. The optimal performance equilibrium point in Harbin is -22°C, the optimal performance equilibrium point in Beijing is -8°C, and the optimal performance equilibrium point in Wuhan is -1°C. The reason why HSPF first increases and then decreases is that if the performance equilibrium point is too low, when the ambient temperature is high, the heat pump is in a partial load state, and the performance cannot be better utilized. If the performance equilibrium point is too high, when the ambient temperature is low, it can only rely on electric heating for heating, and cannot give full play to the advantages of the heat pump.

In addition, we can also see that the HSPF of the heat pump is greatly affected by the ambient temperature, and the HSPF of the typical cities in the three climate zones has obvious stratification. Region with hot summer and cold winter has great advantages in using heat pumps. The HSPF at the optimal performance equilibrium point in severe cold region is only 1.92, while that in region with hot summer and cold winters can reach 2.9. Therefore, improving the performance of heat pump at low temperature is one of the key research directions in the future.

3.2. Optimal performance equilibrium point for different types of buildings

Select different types of buildings in Beijing: residential buildings, office buildings, commercial buildings. The type of heat pump is LATASHP. The building energy saving rate is 65%. Different types of buildings mainly affect the indoor heating load. There are few indoor heat sources in residential buildings, and their winter heating load is mainly affected by outdoor temperature, while office buildings and commercial buildings have more indoor heat sources, and their winter heating load is affected in many ways. Fig.3 shows the heating load of different types of buildings.

![Fig. 2. Performance equilibrium point of typical cities in different regions](image)

![Fig. 3. Heating load of different types of buildings](image)
Due to the work and rest of the staff, residential buildings are heated almost all day, while office buildings and commercial buildings need heating only half the time. Therefore, it can be seen from the picture that the heat load point of residential buildings is more than that of the other two buildings. However, the air exchange times of residential buildings are small and the thermal insulation performance is good, so the heating load per square meter of residential buildings is lower than that of office buildings and commercial buildings. Fig. 4 shows how the HSPF of different building types varies with the performance balance point. The best performance balance point of office building and commercial building is -6°C, and that of residential building is -8°C. Because the load of office building and commercial building changes slowly in the low temperature section, and the influence of partial load is limited, so the optimal equilibrium point of office building and commercial building is higher than that of residential building. Similarly, the change of heating load of different types of buildings can be seen from the changes of HSPF. When the equilibrium point changes from -9°C to -6°C, the HSPF change of office buildings and commercial buildings is not obvious, while that of residential buildings has obvious inflection point, indicating that the linear relationship between heat load and temperature of residential buildings is stronger.

![Fig. 4. The change of HSPF of different building types with the performance equilibrium point](image)

3.3. Optimal performance equilibrium point for different levels of energy saving

Select residential buildings with different levels of energy conservation in Beijing: 30%, 50%, 65%, 75% and near zero energy consumption; the type of heat pump is LATASHP. For heating season, buildings with different energy saving levels mean that their indoor heat load is affected by ambient temperature.

![Fig. 5. The change of HSPF of different levels of energy saving with the performance equilibrium point](image)

The higher energy saving grade has better performance of enclosure structure, less affected by ambient temperature, and less linear. However, after the actual calculation, it is found that the temperature of the
optimal performance equilibrium point is the same, which is -8°C. Based on the analysis of the load characteristics and other parameters in the calculation formula, it is found that this is because the linear degree is not reduced obviously, and the indoor heating load decreases proportionally with different energy saving levels, so it has little effect on the selection of the optimal equilibrium point temperature.

3.4. The optimal performance equilibrium point for different types of heat pumps

With the development of heat pump technology, the coefficient of performance of heat pump applied at low temperature is gradually increasing, and the applicable minimum temperature is also expanding. As the main difference between LATASHP and CASHP lies in the outdoor environment, this section analyzes the severe cold region city of Harbin and the cold region city of Beijing, and selects residential buildings with 75% energy-saving rate. Fig.6 shows the heating load of residential buildings in two cities.

![Fig. 6. Heating load of residential buildings in two cities](image)

The lowest operating temperature of the CASHP used in this paper is -12°C, and that of the LATASHP is -27°C. The ambient temperature in Harbin is lower than -10°C most of the time in winter, and the heating load of the building is significantly higher than that in Beijing. Therefore, in terms of ambient and heating load, for Beijing, the difference between LATASHP and CASHP should be small, and for Harbin, LATASHP should be significantly better than CASHP. Fig.7 shows the curve of HSPF of different types of heat pumps in two cities with the temperature of the performance equilibrium point. The HSPF of heat pump in Beijing is significantly higher than that in Harbin, and the outdoor temperature is an important factor restricting the performance of air source heat pump. For Beijing, the HSPF of CASHP and LATASHP has the same trend with equilibrium temperature, which is consistent with our above analysis. For Harbin, the change curve is completely different, because the lowest operating temperature of CASHP is -12°C, when the performance equilibrium point is lower than -12°C, the selection of air source heat pump is too large and can’t be used at low temperature. On the contrary, it further increases the time of partial load of the unit, so the optimal performance equilibrium point of CASHP must be above -12°C, and it’s -11°C. The working range of the LATASHP is relatively large, because its COP is always above 1, so as long as the air source heat pump is used, it must have an advantage over electric heating. Considering that the unit still has a long time of partial load operation, the optimal performance equilibrium point is -22°C. In addition, the HSPF of LATASHP is about 50% higher than that of CASHP.
4. Conclusions

Through the optimization of the performance equilibrium point of the air source heat pump, the optimal equilibrium point temperature of typical cities in different climatic regions is determined. After analyzing the calculation results, the following conclusions are drawn:

(1) The HSPF of heat pump is greatly affected by ambient temperature, the HSPF of typical cities in different climatic regions have obvious stratification, the temperature of the optimal performance equilibrium point in hot summer and cold winter region is higher than that in cold region, and the optimal performance equilibrium point temperature in cold region is higher than that in severe cold region.

(2) Due to the slow change of load, the optimal performance equilibrium point of public buildings is higher than that of residential buildings in the same region.

(3) The optimal equilibrium points of different energy saving levels are close, but the corresponding seasonal coefficient of performance is different. The higher the energy saving grade, the better the performance.

(4) The optimal equilibrium point of the LATASHP is lower than that of the CASHP in the cold region, and the cold region is the focus of the next step of clean heating, so it is necessary to continue to develop a higher performance LATASHP.

(5) There are many parameters in the temperature optimization formula of the optimal performance equilibrium point, and the sensitivity analysis should be carried out later.

Development of a new GAX-based absorption heat pump for Domestic Hot Water production

Hai Trieu Phan*, Fabio Aste and Hélène Demasles
Université Grenoble Alpes, CEA, Liten, Campus INES, 73375 Le Bourget du Lac, France

Abstract

This paper presents the numerical and experimental results of an ammonia-water absorption heat pump based on a novel Generator Absorber heat eXchanger (GAX) architecture. A prototype at lab scale of 25 kW is developed in a perspective of performance, compactness and use of market-available components in order to address wide industrial applications. This machine is driven by a hot source at temperature above 100°C to produce hot water (> 60°C) from a lower temperature heat of about 30°C. The overall performance of the prototype under different operating conditions is characterized by measurements with high-quality temperature, pressure and mass flow rate sensors. The impacts of the external conditions are investigated while varying the evaporator temperature in the range of 25-50°C and the generator temperature in the range of 110-170°C. The experimental results show attractive performances with a maximum thermal Coefficient Of Performance (COP) of 1.72 and a maximum electrical COP of about 140. Preliminary techno-economic assessment has shown the interest of this technology.

Keywords: absorption cycle, heat pump, GAX;

1. Introduction

In France, the residential and industrial sectors account for 23Mtoe of electric consumption, while the natural gas consumption attests on 24Mtoe (IEA database). In general, these two sectors are responsible of the 43.2% of the French total final consumption, and a great part of this share is converted into heat. In the residential sector, the 78% of the consumption is dedicated to space heating and cooling through systems that are fed for 58% with fossil fuels (https://www.ceren.fr/). Industry is as well dependent on fossil fuels (61% of the total consumption) for heat generation, with even a small share of the electricity consumption (18%, i.e. 21 TWh in 2013) used for thermal production. During the processes, about the 25-60% of the heat is lost to the environment, for a total amount of 8.56 Mtoe of waste heat (https://www.ademe.fr/). However, this rejected heat is available at different temperature levels: almost a third is available at >100°C and can be re-used on site or for feeding heating networks; the second third, between 40°C and 100°C, can be enhanced in temperature by heat pumps; the remaining third is rejected at a temperature < 40°C and is hardly exploitable. The challenge is saving the medium-and-low-temperature heat from being wasted, increasing the overall process performance and reducing the Greenhouse Gas (GHG) emissions. In this context, one of the most adapted solutions is represented by the absorption heat pumps, which use natural fluids and allow upgrading low-temperature sources to a higher temperature level using heat as fueling. In addition, such systems can also be configured in reverse mode to produce cooling, addressing both industrial and residential needs.

To operate, absorption machines need a heat driving source that can be indifferently gas, renewable heat (solar, geothermal, biomass) or waste heat, with an increased economical and environmental interest in the two last cases. Concerning heating, absorption heat pumps can effectively contribute to lower the global energy

* Corresponding author. Tel.: +33 4 79 79 23 72
E-mail address: haitrieu.phan@cea.fr.
consumption for both residential and industrial sectors, thus reducing the GHG emissions in accordance with the European Energy-Climate Framework 2030 and the international goals for limiting the global warming.

As absorption cycles require two fluids for operating, refrigerant and solvent, many possibilities of coupling exist in the literature according to Sun J. et al. (2012) [1]. The most diffused are ammonia-water and water-lithium bromide due to their interesting thermo-physical properties. This last couple has historically been chosen for air conditioning, and in the last decades, it found application even in some heat pumps [2-4]. Despite its good efficiency, especially in multi-stage systems, water-lithium bromide has two important drawbacks: a limited operating field, by both crystallization risk and water freezing temperature, and an important cost of lithium bromide. Ammonia-water couple avoids these problems, being suitable to operate in large temperature fields and having a lower cost, as ammonia is a common product. For the pursuit of the work, ammonia-water will be the chosen fluid couple.

Amongst the different ammonia-water absorption cycles, the Generator-Absorber heat eXchanger (GAX) cycle is the most interesting due to its flexibility and increased performance compared to the single stage cycle. This cycle can effectively be operated as a chiller, down to -40°C, or as a heat pump, even above 70°C with high efficiency. Despite that, few GAX heat pumps exist on the market and most of them based on expensive and bulky heat exchangers in the form of distillation columns. According to the literature, Aprile M. et al. (2016) [2] tested an industrial gas-driven, GAX heat pump that produces 20 kW of hot water at 60°C or 45°C (evaporator temperature TE,in=10°C) with Coefficient of Performances (COP) of 1.6 and 1.73 respectively. Dai E. et al. (2018) [3] tested an industrial 55 kW absorption heat pump that can produce 55°C hot water with an optimal COP of 1.63 at TE,in=20°C and generator temperature TG,in=200°C. The other heat pump present in the literature is a prototype made by Wang J. et al. (2019) [4], where the main heat exchangers consist in tailored-made shell-and-tube exchangers, thus not compact. The best performance obtained is COP = 1.51 with TE,in=15°C and TG,in=193°C. According to these works, the development of GAX heat pumps is particularly interesting for high-temperature waste heat recovery and, due to the COPs above 1.5, even the case of fuelling with fossil sources (gas, biomass, etc.) becomes environmentally and economically attractive.

In this paper, a novel GAX architecture is presented, together with the related numerical model. The prototype is designed, fabricated and tested according to this architecture using only commercially available components, such as plate-type heat exchangers in order to improve the compactness, the amount of charge (ammonia) as well as the minimize the constraint related to high pressure. During the experimental investigations in the laboratory test rig, a particular attention has been given to the operating conditions, which have been varied to test the response of the system in different situations. The experimental results are then discussed to analyse the impact of the main parameters, such as the generator temperature, the evaporator temperature and the solution flow rate. Preliminary techno-economic analysis is carried out to evaluate the interest of this technology.

2. Cycle description

As introduced before, ammonia/water is chosen for the study due to its favourable properties. In addition, this fluid couple is particularly interesting from an industrial point of view, being ammonia a well-known element used in plenty of domains, thus largely available and cheap. In this sense, the components of the GAX heat pump that is further proposed are chosen amongst commercial parts, as plate heat exchangers and pressurized tanks, to demonstrate the viability of such absorption systems.

Detailing the architecture, the GAX heat pump cycle shown in Fig. 1 features a novel architecture where the vapour generation process is discretized via different components, three heat exchangers (GAX2, generator and rectifier) and three pressurized tanks (N21, N22 and N3). This approach is quite the opposite of the concept of distillation column which has a more complex design in order to integrate in one component the vapour generation and separation from the two-phase flow.

2.1. Working principle

As the cycle works in heat pump mode, the absorber and the condenser are connected in series to maximize the hot water output temperature. Preliminary simulations show that the performance is better if the absorber is entered first. The useful effect consists in the heat delivered for production of hot water (yellow line), while the high-temperature heat entering the generator acts as the driving power (red line). The heat flux entering the evaporator can be from ambient or a waste free heat source at low temperature (20°C-35°C)
For a convenient description, the heat pump cycle is divided into three sub-cycles according to the different flows of refrigerant, rich and poor solutions.

2.1.1. Refrigerant sub-cycle
Rich solution two-phase flows coming from the GAX2 and the generator enter the two separation tanks N21 and N22 respectively: there, the vapour separates by gravity from the liquid solution. Due to the difference in the saturation pressures, the liquid is richer in water and the vapour is richer in ammonia, but it is generally not pure. Therefore, the vapour is sent to the rectifier to be enriched in ammonia. The purification occurs through the refrigerant cooling, which causes a partial condensation of the fluid: the water-rich condensate is recirculated to the poor solution line. In parallel, the purified refrigerant is firstly condensed, then subcooled in the precooler before throttling, and finally vaporized in the evaporator. After that, the vapour refrigerant flows through the low-pressure side of the precooler and reaches the GAX1, where the absorption reaction with the poor solution begins.

2.1.2. Rich solution sub-cycle
The rich solution is obtained as the product of the absorption reaction, which begins in the GAX1 and ends in the absorber. There, the ammonia-water mixture presents the highest richness in ammonia and its thermodynamic state is subcooled liquid, which allows protecting the pump. This last component increases the pressure of the rich solution that is subsequently delivered to the GAX1 (12) to be heated. In this first heating phase, desorption might already occur. The desorption process continues in the rectifier and in the GAX2, as the rich solution recovers the available internal heat of the other fluid lines. Being diphasic after the GAX2, a
first phase separation is performed in the N21 tank to avoid sending vapour at the generator inlet. Here, the remaining rich solution is heated to the highest temperature to continue desorption process. The two-phase fluid undergoes a second and final phase separation in the N22 tank, resulting in the poor solution and some additional refrigerant vapour at the outlets.

2.1.3. Poor solution sub-cycle

After phase separation in the N22 tank, the poor solution features the lowest richness in ammonia in the cycle as well as its highest temperature. A first heat recovery occurs towards the rich solution in the GAX2. Then, the poor solution is mixed with the condensate, increasing ammonia richness and decreasing the temperature. The resulting solution is throttled before entering the GAX 1 (25). There, the ammonia vapour coming from the refrigerant sub-cycle (37) is absorbed by the poor solution and, as the absorption reaction is exothermic, heat generation occurs. The internal recovery is realized by the rich solution (13). The complete absorption in GAX1 is limited by the temperature level of the rich solution used for the cooling. Thus, the reaction is continued in the absorber where further absorption is done by cooling with a colder external source.

2.1.4. GAX effect

The GAX cycle is particularly interesting when a large temperature overlap between the generator and absorber occurs: in this case, absorption excess heat is partially available at a temperature that allows the rich solution desorption in GAX1. In GAX2 and rectifier, the desorption continues thanks to the internal heat recovery from the poor solution. Taking advantage of this temperature overlap decreases the input heat in the absorber and generator, improving the global performance and reducing the absorber and generator components size.

2.2. Comparison with literature architectures

The main difference between the proposed architecture and the existing ones consists in the vapour generation system and the absorption system. An easy remark can be made about the rich solution circuit, which shows a different path: instead flowing first through the rectifier and then through the GAX, in the proposed version it encounters first the GAX1, then the rectifier, and finally the GAX2. This variation results from the pinch analysis of the system fluid lines and optimizes the internal heat recovery.

A more technical aspect concerns the heat exchangers technology. In the literature, the technologies used for the components where absorption takes place (GAX1 and absorber) vary according to the authors: two separated falling film heat exchangers tubes in tubes type [2] and [4] or shell-and-tubes exchangers, which allows piling the two units to form a single component [3]. However, all authors choose the same technology for the desorption block: Generator, GAX2 and rectifier are shell-and-tubes exchangers, which allows piling the three units where the ammonia vapour flows in counter-current respect to the solution, being cooled and rectified all along as in a distillation tower. Therefore, the refrigerant vapour is already purified when exiting the generation column and the condensate resulting from rectification is directly recirculated in the underlying sections. Since the vapour generation and separation occur simultaneously, the generation block is sized taking into account the two process. The novel architecture proposed in this work avoids dealing with this point: as the heat and mass transfers and the phase separation occur separately, each component is optimally sized to its function.

Another aspect to be considered is the system manufacturing. Generally, these distillation-column-like elements consist in a cylindrical vessel where the different sections are heated or cooled by coil exchangers. Such assembly requires a complex manufacturing and, due to the low heat transfer coefficient of coil exchangers, it presents a considerable volume that cannot be split without losing all the advantages of a coupled vapour generation and separation. Differently, the proposed architecture involves many smaller units that can be distributed in the space, thus allowing a more rational positioning inside the system and an easy maintenance.
3. Modelling for prototype sizing

To determine the most efficient solution for the novel GAX ammonia-water cycle, many architectures have been modelled and then implemented in the software EES (Engineer Equation Solver, http://www.chemchart.com/) to be numerically studied. EES internally provides NH3/H2O mixture thermodynamic properties, which are calculated through the correlations proposed by Ibrahim O.M. and Klein S.A. (1993). By specifying the heat and mass efficiencies of the components and integrating the hypothesis listed in Table 1, the model returns the thermodynamic conditions of the state points of the cycle and the global performances.

<table>
<thead>

</tr>
</tbody>
</table>

The model is established considering each component as a control volume, thus is 0D: the internal dynamics are excluded from the study, as the behaviour of the component is considered as a whole and included in the relative efficiency. Even if simple, this approach is reliable for the scope, as it has been largely demonstrated in previous works [5].

For each control volume, mass and energy conservation equations have been defined:

- **Total mass conservation** → \( \sum m_{in} - \sum m_{out} = 0 \) (1)

- **Refrigerant mass conservation** → \( \sum m_{in} x_{in} - \sum m_{out} x_{out} = 0 \) (2)

- **Energy conservation** → \( \sum m_{in} h_{in} - \sum m_{out} h_{out} + \sum Q - \sum W = 0 \) (3)

In the last equation, Q and W are the heat and work fluxes exiting the system boundary. Signs respect the traditional convention.

The evaporator temperature glide is defined as \( T_{36} - T_{35} \).

Finally, the Coefficient Of Performance (COP) of a generic heat pump is defined as the ratio between the heat rejected to the external cooling fluid at the condenser and the energy input in the compressor. In the case of absorption cycles, a heat rejection occurs also in the absorber, as the absorption reaction is exothermic. This heat being recuperated by the external cooling fluid, it becomes a part of the useful effect. The energy input changes too: in fact, besides the electric energy consumption, an additional and more consistent high-temperature heat consumption is necessary to power the system. Generally, it is good practice to distinguish the type of COP between electrical (ECOP) and thermal (COP) for the continuation, as heat consumption largely prevails on the electric. In particular, doing techno-economic analysis one of the two parameters is often negligible while the other drives the decision.

- **ECOP** = \( \frac{\text{useful heat power}}{\text{electric power}} = \frac{Q_A + Q_C}{W_{el,pump}} \) (4)

- **COP** = \( \frac{\text{useful heat power}}{\text{heat power input}} = \frac{Q_A + Q_C}{Q_G} \) (5)
According to simulations, the best performance considering both COP and ECOP is obtained for the architecture given in Fig. 1. This model has also been used to size all the components of the prototype.

4. Experimental setup

4.1. Prototype

The sizing conditions are reported in Table 2. The generator inlet temperature is set at 170°C, corresponding to the optimal numerical COP. The target of the machine is to produce 25 kW of hot water (> 60°C) from a lower-temperature heat source (∼ 30°C).

Using these values as model inputs, the characteristic parameters of the components have been defined. Then, each element has been identified on the market, purchased and assembled. To respect the technological readiness asset, only industrial brazed/welded plates heat exchangers are implemented, as those last components are standardized and produced in series. Instead, the piping and separation tanks, even if they are well known industrial elements, must be designed and singularly manufactured to fit the operating conditions. In addition, as the ammonia/water mixture is very corrosive, a special care is taken by selecting only resistant components, mostly made in stainless steel. Considering the material costs of the assembly without instrumentation, the pressurized tanks (36%) and the piping (25%) represent a great share, while the plate heat exchangers affect for a littler amount (13%). A picture of the prototype is shown in Fig. 2.

Three stainless steel tanks are used to separate refrigerant vapour and liquid solution at the outputs of generator, GAX2 and rectifier. Two other tanks are provided as fluid storages: one to store the poor solution before pumping, in order to avoid pump cavitation during the start-up phase; the other one to store the refrigerant after the condenser. These two last tanks allow the heat pump to be operated over a wide temperature range. However, the system is filled with relatively low quantities of water and ammonia, 1.4 kg of water and 2.4 kg of ammonia. Finally, the GAX1 heat exchanger features an original, double distributor system for the poor solution and refrigerant inlet, allowing liquid and gas flows to be uniformly distributed into each channel.

Fig. 2: Front view of the GAX prototype.
4.2. Characterization

Experimental tests were performed at the INES (French National Institute for Solar Energy) facility in a test rig that allowed providing adjustable temperatures and powers for the external fluids. The fluid chosen for all external circuits is pressurized water. The heat pump operating field during the tests is reported in Table 3.

Table 3: GAX heat pump operating range during experimental test. Data refers to external-side fluid for Evaporator, Absorber, Condenser and Generator and to the internal-side fluid (rich solution) for the Pump. In the case of the Pump, both upstream and downstream pressures are indicated.

4.3. Measurement apparatus

The prototype is instrumented with high-precision sensors in order to measure the parameters needed for a thorough comprehension of its functioning. Temperature sensors are positioned on the heat exchangers inlet/outlet. Pressure sensors are positioned on the high- and low-pressure solution and refrigerant circuits. Coriolis flowmeters are employed to measure mass flow, density and temperature of the internal fluids. Liquid level sensors are placed inside the pressurized tanks to measure the amount of the stocked liquid, thus describing the fluid distribution in the prototype. In addition, the level sensor in the storage tank upstream the pump has a protection function, as it shuts off the pump when the stocked liquid level is too low.

Type and uncertainty of the instrumentation are described in Table 4.

4.4. Data processing

Despite the number of sensors deployed across the system, many parameters cannot be directly measured and need to be calculated afterwards. In particular, it is the case of the flow rates in the poor solution and condensate lines, and the heat fluxes in the heat exchangers. The firsts are determined through total mass and refrigerant mass balances; the lasts require energy balances in addition. The heat flux can be properly calculated only on absorber, generator, condenser and evaporator where the measures are accurately done on external fluid. As an example, the absorber heat flux is defined:

\[ Q_A = \dot{m}_A c_p, w (T_{A, out} - T_{A, in}) \]
Where \(C_{P,w}\) is the specific heat of water and \(M\) is the heat carrier fluid flow. However, on internal heat exchangers where there are absorption or desorption reactions, the heat flux cannot be calculated as it is impossible to know the enthalpy of the fluid precisely.

### 4.5. NH3 concentration

Determining the ammonia concentration of the solution is an essential point to qualify the functioning of the system. Therefore, ammonia fractions are calculated from measured density, temperature and pressure through reverse correlations based on Ibrahim O.M. and Klein S.A. (1993) [6-7]. The maximum error is about \(\pm 2.5\%\).

### 5. Experimental results

#### 5.1. Startup

For starting the prototype, we first ran the external circuits (cf. Fig. 1) at the target flow rates and inlet temperatures. Then we initiated the starts of the solution pump together with the openings of the expansion valves (EXP1 and EXP2) in order to regulate the flow rates and the pressure levels. As shown in Fig. 3, the machine took about 400s before reaching the stabilized conditions. This time mainly depends on the thermal inertia as well as the generation rate of the refrigerant vapor in order to reach the required high pressure level.

![Graph](image)

Fig. 3: Evolutions of different parameters during the startup of the prototype.

#### 5.2. Stabilized performance

As the experimental campaign was carried through the conditions reported in Table 3, the impact of different parameters on the system performance has been evaluated. In particular, the study concerns the influences of the solution flowrate, the generator temperature and the evaporator temperature. Some preliminary observations can be presented with reference to Fig. 4. The target temperature for the hot water production \((T_{\text{out}}=60^\circ\text{C})\) is reached for most points, despite the wide field of working conditions. Moreover, the hot water outlet temperature seems being stable at different system heat duty (from \(-50\%\) to \(+30\%\) nominal power), meaning that off-design operation is feasible.
Nevertheless, the COP strongly depends on the operating conditions, which reflect onto the absorber and condenser heat duties, with a sharp decrease below the nominal value (25 kW). Besides, in Fig. 5 the ECOP has an almost linear tendency with reference to the increase of the useful heat production. The highest heating power, 33kW, the best COP of 1.72 and the best ECOP of 170, are reached at 150°C, 30°C and 49.4°C respectively as generator, absorber and evaporator inlet temperatures.

5.2.1. Rich solution flow variation

The impact of rich solution flow rate \( \dot{m}_{12} \) is studied at the nominal temperatures of \( T_{a,in}=29.4°C \), \( T_{g,in}=169.8°C \) and \( T_{e,in}=34.5°C \). Fig. 6(a) shows that an increase in the rich solution flow rate leads to an increase in powers output of all heat exchangers, except for the evaporator. Despite the augmentation in the refrigerant vapour flow \( \dot{m}_{32} \), its exchanged heat does not follow the same trend. The evaporator appears to be limited by its size, since a decrease of the temperature glide is observed, as shown in Fig. 6(b), even when a control target is set at 5K. In addition, we observed that the increase of the exchanged power in the absorber is smoother than in the generator (Fig. 6(a)). A possible explanation is that the mass transfer by absorption process in GAX1 and in the absorber deteriorates with an increase of liquid fraction at the outlet of the evaporator due to lower temperature glide. Indeed, a numerical calculation shows that at measured ammonia concentration of 96\%, 80\% of the refrigerant exits as vapour with a 5K glide at the evaporator outlet, while only 45\% exits with a 1K glide.
5.2.2. Generator temperature variation

The inlet temperature of the hot fluid at the generator is a relevant parameter because a flexibility in this sense would allow an easier management of the energy source and an increased working period. For a given solution flowrate, absorber temperature and evaporator temperature, Fig. 7(a) shows a COP increase with the generator temperature. This is in line with the observations about ammonia concentration in the solution. Indeed, increasing the temperature lead to increases in the capacities of absorption and desorption represented by $DX_{abs} = X_{12} - X_{24}$ and $DX_{des} = X_{12} - X_{22}$. In the order of magnitude, the heat production in the absorber and condenser is linked to $DX_{abs}$ while the heat consumption in the generator is linked to $DX_{des}$. Therefore, the ratio between $DX_{abs}$ and $DX_{des}$ would represent the performance. As shown in Fig. 7(b), its tendency with the generator temperature is in agreement with that of the COP.

![Fig. 6: Rich solution flow variation impact on different parameters with $T_{g,in}=169.8°C$, $T_{a,in}=29.4°C$, $T_{e,in}=34.5°C$.](image)

![Fig. 7: Generator temperature variation impact on different parameters with $T_{a,in}=29.4°C$, $T_{e,in}=34.6°C$, MSR=106 kg/h.](image)

![Fig. 8: Evaporator temperature variation impact on different parameters with $T_{e,in}=29.4°C$, $T_{e,in}=169.8°C$, MSR=106 kg/h.](image)
5.2.3. Evaporator temperature variation

The inlet evaporator temperature is representative of the low-temperature source that feeds the cycle. However, it is not necessary the ambient that would provide the input heat: for example, low-temperature waste heat could be used for this task, with positive effects on the cycle performances.

According to the expectations, increasing $T_{\text{in}}$ leads to a better COP, as illustrated in Fig. 8(a). In particular, if the refrigerant evaporation can occur at higher temperatures, then higher pressures are allowed in the low-pressure side of the system. Operating at higher pressure is advantageous for the absorption reaction, as the equilibrium ammonia fraction of the rich solution increases with the pressure. As a result, the vapour generation flow rate ($\dot{m}_{32}$) increases with the evaporator temperature (while the poor solution mass flow rate $\dot{m}_{24}$ decreases due to a fixed pump flow rate), as shown in Fig. 8(b), leading to higher COP.

6. Conclusions

This paper presents a new architecture GAX NH3-H2O absorption heat pump designed with plate heat exchangers in order to offer a compact machine easy-to-manufacture. An innovative architecture has been proposed with the particularity of using an internal heat exchanger (GAX1) at two level of pressure: in one side, absorption occurs at low pressure and the heat produced is transferred to other side where the desorption at high pressure can be initiated. The desorption process is internally carried out by heat recovery in the rectifier and the solution heat exchanger (GAX2). A model has been developed for design and preliminary performance simulations. Based on the numerical results, a prototype has been built with a production target of 25 kW of hot water (> 60°C) from a lower-temperature heat source of around 30°C. Once the values of the regulation parameters are identified, the startup of the machine can be easily operated with a necessary time of about 400s for reaching stabilization. At nominal conditions, the machine produces a thermal coefficient of performance (COP) of 1.52 and an electrical coefficient of performance (ECOP) of 130. In favourable conditions, the maximum COP and power output are 1.72 and 32 kW, respectively. The tests show the capacity of the machine to operate in a wide range, especially in term of the inlet temperature of the heat driving source from 110°C to 170°C, which is interesting to address different applications with a flexibility in term of heat source temperature.

Abstract

Industry accounts for almost a quarter of the energy use world-wide and energy-related carbon dioxide (CO\textsubscript{2}) emissions. Industry has several pathways to step-change GHG reductions including electrification of process heat, which is responsible for 50\% of on-site energy use. Industrial heat pumps (IHPs) can beneficially electrify much of the process heat needed for low to moderate temperature applications, helping to make dramatic cuts in industrial GHG emissions. Our research shows that moderate IHP deployment in industrial groups with high process heating demands (e.g., pulp and paper, chemicals, and food manufacturing) can save up to 30\% of the source energy or 221.6 petajoules/year (equivalent energy use/year of 1.5 million U.S. homes). In parallel, IHPs can reduce CO\textsubscript{2} emissions up to 18.2 million metric tons /year (equivalent emissions from 4 million passenger cars or 1.3\% of U.S. industrial CO\textsubscript{2} emissions). Expanded adoption of IHPs across all industrial sectors would save even more energy and CO\textsubscript{2} emissions.

1. Introduction

The industrial sector, which accounts for almost a quarter of the world’s greenhouse gases (GHGs) and energy use (including feedstocks) must be decarbonized in order to transition the economy towards a low-carbon future. One crosscutting industrial decarbonization pathway that has been under-explored is the electrification of process heat, the generation and use of which in U.S. industry accounts for 51\% of on-site energy use at 7992.7 petajoules (PJ) (or 7,576 trillion Btu/year) (EIA 2014). The potential for electrification to transform the GHG footprint of process heat is significant, as electricity currently accounts for only 5\% of this heat, while carbon intensive fossil fuels combine for the rest (Whitlock et al., 2020).

Industrial heat pumps (IHPs) are a key technology for industrial decarbonization through electrification (Whitlock et al., 2020). Using electricity generated from low-carbon sources, they can provide adequate supply temperatures of process heat to replace reliance on fossil fuels in industrial processes. IHPs were being commercialized in the late 90s (IEA 1995), but the availability of inexpensive natural gas in the U.S. cut into economic favorability, and adoption stalled. The urgency of the climate crisis and advancements in IHP technology (some IHP types can now reach 160°C (320°F), more than double the supply temperature of earlier models), make them a logical decarbonization pathway. In addition to electrifying process heat, IHPs can also reduce industry’s carbon footprint by improving efficiency (by avoiding complex, unbalanced and inefficient steam operating systems) and reusing or recovering wasted low temperature heat.

Although there are multiple studies examining IHP potential, there is a significant gap in the analysis of actual process heating and cooling streams at the unit operations level. Our research aims to bridge this gap by

\textsuperscript{*} Corresponding author. E-mail address: paul.scheihing@50001strategies.com
examining the IHP market and demonstrations in varied industrial settings and geographical regions; matching capability fit with industrial needs via thermal energy analysis; determining the potential to reduce energy and GHGs; and finding enablers (including federal policy) needed to accelerate overall adoption.

2. Industry Processes and Heat Pumps

2.1. Process heat and thermal ranges of interest for IHPs

Figure 1 shows the temperature ranges of process heat demand in various industrial subsectors. Process heat is used in numerous applications that are common across these industry groups including fluid heating, distillation, evaporation, drying and melting. The temperature range of current IHP capabilities is between 60 and 160°C.

![Figure 1. Process heat demand at various temperature (°C) levels in select industries. Adapted from Adapted from “Manufacturing Thermal Energy Use in 2014,” by C. McMillan, 2019, National Renewable Energy Laboratory](image)

2.2. Industrial heat pumps

IHPs move heat up from a lower temperature heat source to a higher temperature heat sink. IHPs are similar in concept to residential/commercial heat pumps, however, they are more complicated, larger in capacity, engineered to integrate with industrial processes and expected to run continuously all-year round (high reliability). Figure 2 is a generic diagram of an IHP lifting waste heat at $T_{\text{source}}$ and delivering heat to the process heat load at $T_{\text{sink}}$.

![Figure 2. Generic IHP diagram illustrating IHP lift temperature, $T_{\text{source}}$ and $T_{\text{sink}}$. Source: this work](image)
Our research examined six types of IHPs (more detail on their applications, data sources, and data treatment is provided below) (Rightor et al., 2022a). IHPs can be open cycle (where the heat pump working fluid is the process stream itself, such as, waste steam being compressed and returned to process) and closed cycle (where the heat pump has a heat exchanger on the heat source and sink sides to separate the heat pump working fluid from the processes). A classification of IHPs is provided in Figure 3.

![Diagram of Industrial Heat Pumps (IHPs)](image)

**Fig. 3. Six different IHP types considered in this study (EPRI & RCG Hagler Bailly Inc., 1994). Adapted from “Industrial Heat Pump Report,” by EPRI & RCG Hagler Bailly Inc., 1994.**

The most common type of IHP is a mechanical vapor compression (MVC) heat pump which is a closed cycle system with an evaporator and condenser heat exchanger. Mechanical vapor re-compression (MVR) heat pumps are also applied in industry. MVRs directly compress the process fluid or steam without heat exchange on the heat sink or source side (semi-open cycle) or have no heat exchange (open cycle) on either side of the heat pump’s compressor. Note: see appendix A of reference (Rightor et al., 2022a) for explanation of IHP types that were analyzed.

Prior studies show that moderate deployment of IHPs in manufacturing could avoid emissions of 12-25 million tons/year of CO₂ and save 2-5% of the total U.S. industrial process heat demand 180-370 PJ (or 170-350 trillion Btus/year) within 15 years (EPRI & RCG Hagler Bailly Inc., 1994). Advances in refrigerants (McLinden et al., 2014) and other working fluids to operate at higher delivery temperatures have broadened the range of IHP applications, such as in drying and recovery of waste heat, which can account for 12-25% of industrial energy use (Lauermann et al., 2019). The market for IHPs is well-developed in Europe and Japan (Arpagaus et al., 2018), where there are strong policy incentives and economics. A recent study of the IHP potential in Europe indicates that 80% of the IHPs in industry would be less than 5 MW in thermal load capacity (Marina et al., 2021). Recent IHP demonstrations include those at 1 – 2 MW (Borealis, 2021).

2.3. Pinch analyses

Pinch analyses were used to find the optimum location for IHPs in the thermal flows of industrial processes (Rightor et al., 2022a). Pinch analysis is a method for minimizing energy consumption by optimizing energy supply and process heat recovery systems (Natural Resources Canada, 2003). It identifies the best hot streams which are being cooled (heat source) and cold streams which need to be heated (heat sink) for the heat pump to operate between heat source and sink. The Pinch analysis optimizes the heat transfer process between the hot and cold streams to minimize the amount of external process heating and cooling needed. This leads to defining a “pinch point” on the temperature scale in the whole process where heat transfer cannot occur anymore between the hot and cold streams since the temperature driving force required is not available. The ideally placed and integrated IHP takes heat from a heat source below the pinch point and upgrades or “lifts” the heat to a desired heat sink above the pinch point. An energy balance must be maintained between the heat source, heat sink, and the work done by the IHP. Optimal matching of the heat source temperature and the amount of heat required is the key to successful IHP implementation. If done efficiently, heat exchangers can be minimized, particularly above the pinch point.
Figure 4 shows an example of two pinch analysis simulations for a typical potato drying process. The x-axis shows the heat load (kW), and the y-axis shows the corresponding temperature levels for those heat loads. The blue lines represent the cold stream that needs to be heated and the red lines represent the hot stream that is being cooled. The overlap between the red and blue lines is the area of possible heat exchange. The difference between the cold stream heat load and the hot stream heat load, noted by the arrow in the upper right, represents the process heat demand which must be supplied by external sources (steam, direct firing) and is designated as \( Q_{\text{hot}} \). The main goal of applying an IHP is to cost-effectively reduce \( Q_{\text{hot}} \) to the minimum possible amount. Figure 4 (left) shows the baseline case. Note the process heat demand of 3,725 kW and the pinch temperature at about 52°C. Figure 4 (right) shows the same process but with the application of an IHP used in an optimized configuration. Note that the process heat demand has been reduced to 2,314 kW and the pinch temperature has also moved up to about 70°C.

### 3. IHP analysis

#### 3.1. Industrial groups and unit operations analyzed.

The industrial groups and unit operations analyzed in this work are shown in Table 1 (Rightor et al., 2022a).

<table>

</tbody>
</table>

#### 3.2. Industrial heat pump analysis approach.

All industrial process models used actual industrial heating and cooling stream data (ie., mass flow rate, specific heat and temperature increase or decrease for each stream) that was provided by Chalmers University from previous research (Franck et al., 2020). To assess the energy savings potential, we estimated both the “Economic” and “Technical” IHP potential. The Economic potential simply used one hot and one cold stream for the heat pump’s heat source and sink. The IHP lift was limited to less than 40°C, which is within the capability of a single-staged compression IHP. The Technical potential case is more aggressive by using multiple heat sources and sinks at varying temperatures. Multiple staging of heat pumping (2 stages) were possible for the Technical case and the hot and cold streams were not limited to constant temperatures (Rightor et al., 2022a). Figure 5 illustrates the differences between the Economic and Technical IHP potential.
Energy savings across any sector were calculated based on the assumption that all U.S. production was impacted by heat pumping. Table 2 shows the overall approach to analyzing the energy savings and carbon reduction for the sectors shown in Table 1. The analysis progresses left to right: sector process analysis to pinch and heat pump analysis to sector energy savings and carbon emission analysis.

<table>
<thead>
<tr>
<th>Sector Process Analysis</th>

<tr>
<td>Sector - # U.S. facilities with similar production</td>
<td>Pinch analysis of heating and cooling streams to identify streams (source/sink) for heat pumping</td>
<td>Calculate site and source energy savings based on natural gas saved and heat pump driver energy requirement for all 6 IHP types</td>
</tr>
<tr>
<td>Sector total process heat demand (GJ/year)</td>
<td>Calculate heat pump energy savings for 6 different IHP types</td>
<td>Calculate overall sector carbon emission reductions based on natural gas saved and heat pump driver energy type requirement for all 6 IHP types</td>
</tr>
<tr>
<td>Sector total carbon emissions (MMTCe/year)</td>
<td>Determine heat pump driver energy requirement for 6 IHP types – GJ and energy type (electricity, heat)</td>
<td></td>
</tr>
<tr>
<td>Process heat unit operation hot utility targetable by IHP (GJ/ton)</td>
<td>Calculate heat pump energy savings on unit operation (site and source)</td>
<td></td>
</tr>
</tbody>
</table>

The Pinch analysis model determined the amount of thermal energy recoverable by heat pumping relative to the overall process heat supplied. This represented the amount of thermal energy savings that was possible with the application of the heat pump. The actual percentage energy savings varied by heat pump type (Table 3 below shows results for MVC heat pump only) because different heat pump types could capture different amounts of waste heat (source) relative to the heat delivered (sink). Table 3 shows this as natural gas savings (%). Additionally, the different heat pumps have different COPs for the given lift temperature, and this results in different amounts of heat pump driver energy required. Table 3 below shows this as electricity increase (%). Therefore, unit operation natural gas savings for each heat pump type was found by multiplying tons of production for sector by production energy per ton and then by natural gas savings (%) per ton. Similarly, unit operation electricity increase for each heat pump type was found by multiplying tons of production for sector by production energy per ton and then by electricity increase (%) per ton.

Energy savings across any sector were calculated based on the assumption that all U.S. facilities making the product were impacted by heat pumping. This can be considered an upper estimate at 100% market penetration. While this may be a high estimate it should be noted that dual heating and cooling IHP opportunities were not yet included and the benefits of downsizing the process heat load from current steam systems (e.g., oversized boilers, steam losses) were not accounted for.

3.3. IHP summary across all industrial groups and unit operations studies

Results for IHP application across all industrial groups and unit operations studied are summarized in Table 3 (Rightor et al., 2022b) for the MVC IHP case. The simple payback was based on natural gas prices of
$6.86/ billion joules (or $6.5/MMBtu) and electricity price of 6 cents/kWh.

Table 3. Summary of results across all unit operations for the MVC IHP. Source: this work.

</tbody>
</table>

Across all industrial groups and unit operations the total source energy savings are shown in Fig. 6. This plot shows that the total source energy savings is significantly higher for the Technical potential cases as expected given the more extensive application of IHPs assumed. Although lower energy savings are shown for the heat activated (HA) IHP types, it’s expected that greater use of waste heat in the future will be enabled by heat-activated heat pumps since they can lift heat over higher temperatures without the penalty of high electricity operational costs. The MVR-Semi Open and MVR-Open IHPs each show higher energy savings improvement over the MVC heat pump, reflecting the fact that not requiring one (Semi-Open) or two (Open) heat exchangers to capture waste heat vapors yields higher heat pump COPs (e.g., high pump lift temperatures are lower than for the MVC type). The elimination of heat exchange translates into overall source energy savings.

Fig. 6. Summary of source energy savings for all nine unit operations combined. Source this work.

While the IHPs save natural gas, electricity is required to run the compressors for the MVC, MVR Semi Open and MVR Open heat pumps. The heat-activated heat pumps (HA-Type 1 and HA-Type 2) do require less electricity than the MVC, MVR Semi Open and MVR Open heat pumps, but their COPs are lower and thus the thermal energy (natural gas) savings are lower.

3.4. Magnitude of energy and GHG reductions

Figure 7 shows the magnitude of the energy changes for natural gas and electricity usage for all nine unit operations analyzed. The increased electric load is shown to the right of the y-axis, and the natural gas reduction is shown to the left. Looking at the MVC, MVR-Semi, and MVR-Open types, the natural gas savings are similar, but the electricity demand decreases in this order. For the MVC (closed cycle), electricity is used
to compress refrigerant vapors, and there are heat exchangers at both the source and sink so the heat pump lift will be higher requiring additional electrical energy. The MVR Semi Open eliminates one heat exchanger and the MVR Open two heat exchangers, so the lift is lower resulting in lower electricity needs. The HA types require much lower amounts of electricity since they pump liquids and do not compress vapors but their lower heating COP vs. vapor compression heat pumps yield lower net energy savings.

![Graph](image1)

**Fig. 7.** Energy changes across all nine unit operations, Economic case, PJ/year. Source: this work.

Figure 8 shows the changes from a carbon perspective, where it’s evident that the increase in carbon emissions from electricity (right, green) is significantly less than carbon emissions reduction from the decrease in natural gas use (red, left), indicating an overall net decrease in CO₂e emissions. As the electric grid incorporates more low-carbon energy and the emissions factors decrease, the carbon emissions footprint for electricity will also decrease, and the difference between the electricity and natural gas bars will become larger for the MVC types (as the electricity to run the compressors will have a lower carbon intensity).

![Graph](image2)

**Fig. 8.** Changes in CO₂e across all nine unit operations, Economic case, in millions of metric tons CO₂e/year. Source: this work.

### 3.5. Scale of impact

There can be multiple unit operations for each process considered in this work, so it can be challenging to understand the scale of impact. For example, the ethylene debutanizer and the process water stripper reboiler were examined for IHP potential, but these operations are a small portion of those in ethylene production and only the unit operations above ambient were considered in this work (e.g., no analysis was performed in the cold section). An estimate was made then for the application of IHPs not only in the nine unit operations analyzed but also an extrapolation across a broader application base in the three industrial groups examined. Table 4 summarizes the results for the nine unit operations analyzed in the 3 industrial groups, as well as the Industrial group-wide adoption extrapolation for natural gas, source energy savings, electricity demand increase and carbon reduction —near and long-term (when more low-carbon generation capacity decreases emissions factors for the electric grid).
Table 4. Energy savings and carbon reduction for IHP applications. Source: (Rightor et al., 2022a)

4. IHP Deployment and Market Transformation

4.1. IHP Demonstrations

The next phase of our research includes IHP demonstrations where we are partnering with several utilities and a state research energy agency. Demonstrations aim to remove the technical risk, demonstrate IHP energy performance and economics in a variety of sectors and common industry processes. Evaluation factors in choosing at least 3-5 IHP demonstrations that will enable accelerate U.S. IHP deployment, include the following:

- Significant energy saving and GHG emission reduction potential in the currently available temperature range and IHP lift temperature required (e.g., <120°C heat sink range and <40°C lift) and thus favorable economics (e.g., < three-year payback)
- Widespread replicability potential within a sector or sectors due to common unit operation or process across the sector which minimizes technical risk.
- High replicability with a standard IHP design that minimizes significant site-specific engineering (e.g., fuel ethanol, alcoholic beverage, wet corn milling, lumber drying)
- High value product where non-energy benefits (better temperature control, lower maintenance costs, improved yield) are significant in addition to the energy saving benefits (e.g., applications in pharmaceutical, food & beverage.)

We are working with our regional utility and state energy agency partners and their customers to identify other good IHP candidates. Industrial sectors to pinpoint as good candidates for IHP application include the nine unit operations from our research (Rightor et al. 2022a), 13 industrial sectors and subsectors identified from another recent IHP study (Zuberi et al., 2022), and those highlighted by our regional partners with input from their industrial customers. Those high potential sectors include beer brewing, wet corn milling, high fructose corn syrup, lumber drying, paper drying, ethanol, ethylene, automotive processes, and metal manufacturing processes, among many others.
4.2. Regionality

The payback estimates above (Table 2) demonstrate that for the MVC and MVR IHPs with natural gas at $6.86/ billion joules (BJ) (or $6.5/MMBtu) and electricity at 6 cents/ kWh, the paybacks range from 2 to 4 years, which is considered economical for U.S. industry. This is a ratio of approximately 2.7 with electricity/natural gas price. Figure 9 shows the many U.S. states where the ratio of electricity/natural gas is near that number (note data used was 2021 industrial rates). There could be early IHP adoption opportunities in those states.

Fig. 9. Illustration of electricity/ gas price ratio by state. Source: this work.

4.3. IHP market barriers

The barriers to IHP adoption must be identified and considered to form an effective market transformation strategy for IHP deployment that is scaleable throughout U.S. industry. IHPs are currently a niche product today in the U.S. market due to a variety of market constraints. The major constraints that a market transformation initiative will need to address are:

- **Limited product availability in North America:** A recent survey of IHP suppliers found that 24 of them were headquartered and manufactured in Europe and another 3 based in Japan (Arpagaus, 2022; IEA, 2022). Although, there are a few U.S.-produced products that center on industrial applications (mainly wood products and process heat as a service). IHPs are large products that can be expensive to ship so in order for a large IHP market to grow in the U.S., more products will need to be produced in North America. Additionally, European, Japanese and non-U.S. domestic IHP suppliers will need to modify their designs to account for U.S. code differences (heat exchangers, electrical service rating, etc.). IHP equipment manufacturers need to see sufficient market demand to justify both marketing of their products and/or investment to scale up North American production.

- **Limited knowledge by industrial decision-makers and engineers:** Most industrial decision makers are not familiar with IHPs and even many engineering firms have limited knowledge. Experienced engineers can optimize systems in ways that reduce system size and costs while providing important operating benefits, but most engineers presently lack this awareness, expertise, and experience. Many industrial applications cannot simply implement a one-size-fits-all solution so may require tailored system designs.

- **Economic challenges:** The economics of IHPs not only depend on the relative cost of electricity and natural gas, but also on the electric rate structures (e.g., demand and interconnection charges). Site specific timing and considerations are important. Strategies are needed to focus on the applications with the best economics, provide the tools to help manage project costs, and realize the greatest non-energy benefits for the process changes.

- **Service and maintenance:** Personnel to service and help maintain equipment are in limited supply and are often not local to the plants, risking extended production outages. More staff need to be trained and service infrastructure scaled up in parallel with expanding installations to support these projects in the field.
- **Electrical service capacity increase limitations:** U.S. industry is experiencing limitations on how much and/or how fast they can expand the amount of electric supply they can accommodate in their facilities due to long lead times by electrical equipment suppliers to increase electrical capacity. IHPs will require a substantial change in electricity capacity in facilities and could be limited by electrical service available.

- **Equipment certification:** IHPs made abroad haven’t been through Underwriters Laboratory (UL) listing. Also, building code challenges exist for using some low-global warming potential, or regulations on using refrigerants that are potentially flammable.

4.4. **Strategies to initiate market transformation.**

The following strategic near-term actions could help to propel the manufacture and implementation of IHPs in the U.S.:

- **Support manufacturers to scale-up domestic availability of equipment:** Activities to expand domestic product offerings and bring manufacturing to the U.S., such as, government financial incentives to grow manufacturing for IHP technologies and components.

- **Coordinate with utilities, regulators, large customers, and federal agencies to foster a market for substantial growth in IHP sales:** Collaboration amongst the key IHP stakeholders to support technology demonstrations and education of large customers is critical. For example, U.S. Department of Energy announced the Industrial Heat Shot initiative in September 2022 (DOE Industrial Heat Shot, 2022) to drastically reduce emissions from the energy-intensive process heating applications. Industrial heat pumps can play an important role, as was identified in the recent DOE Industrial Decarbonization Roadmap (DOE, 2022).

- **IHP demonstrations, information and tools:** Support the identification, design, installation and validation of performance on IHPs in varied industrial applications with case studies documenting the cost-benefits of each demonstration.

- **Create awareness, knowledge, and workforce:** A communication campaign needs to be developed and deployed to raise the awareness of IHP technologies and benefits among utilities, engineering firms, service personnel and large customers. Training of engineering firms and service personnel needs to be delivered to build IHP related skills.

- **Work with utilities and regulators to develop rate structures in support of IHP:** Rate structures that incentivize IHP installation and yet fairly recovers the utility’s fixed costs.

- **Tax incentives and low interest loans:** Federal tax credits for industrial end users to purchase IHPs and low interest loans for IHP equipment manufacturers to establish and/or expand IHP manufacturing capacity would further help to grow the U.S. IHP market.

5. **Summary**

IHPs can significantly improve the energy efficiency of process heating and cooling applications and reduce CO₂ emissions across the industrial sector. The sectors with applications that are most applicable for IHP implementations are pulp and paper, food and beverages manufacturing, and the chemicals industry, where there are significant proportions of process heating needs at low-moderate temperatures (60 to 200°C). Barriers must be overcome including economics, technical risk, integration, and development of local service capabilities. Enabling policies and programs by government and utilities would accelerate IHP adoption. IHPs can be a key technology in aiding beneficial electrification, with CO₂ reduction benefits increasing as the electric grid becomes less carbon intensive. Key learnings from our research include:

- **IHPs were typically able to save 10 to 30% of the energy used for process heat generation.**

- **The vapor compression type IHPs natural gas savings were typically 2.7 to 3.7X the increases in electricity use.** Similarly, the CO₂ reductions from natural gas savings were 3.5-4.7 X the CO₂ associated with electricity use. Simple paybacks for the compression type IHPs were near or under 3 years at a natural gas price of $6.86 /BJ when electricity/natural gas price ratio was 3 or less.

- **Although the energy savings potential for heat activated type IHPs was lower than vapor compression heat pumps:** for the applications studied, as the technology advances these type of IHPs can potentially have greater impact due to their flexibility and ability to lift heat higher without the penalty of higher electricity consumption and cost as with vapor compression systems.

- **Across all unit operations, the IHP analyses showed the potential to reduce process heat energy 309 - 422 PJs/year (42-57% of the process heat energy in the industrial groups).** The potential for CO₂
reductions was 25 - 29 million metric tons CO$_2$e/year. With lower emissions factors for grid produced electricity by 2050, the reductions potential would be 34 - 43 MMT CO$_2$e/year.

A variety of market transformation initiatives could be deployed to build the U.S. market for IHPs, including:

- Support manufacturers to scale-up domestic availability of equipment
- Coordinating with utilities, regulators, large customers, and federal agencies to foster a market for substantial growth in IHP sales.
- Supporting IHP demonstrations with validation and verification of the cost/benefits as well as developing more up-to-date process data and IHP analysis tools
- Creating awareness, knowledge, and workforce with comprehensive training at all levels.
- Working with utilities and regulators to develop rate structures in support of IHP.
- Creating tax incentives and low interest loans

Acknowledgements

The authors would like to thank Southern Company, New York State Energy Research and Development Authority, Tennessee Valley Authority, and Bonneville Power Administration, for their support of this research. We appreciate the advice given by Neal Elliott of ACEEE in shaping this paper. We would also like to thank Per Ake Franck (Chalmers University) for sharing process information on industrial processes and Ian Kemp (consultant, U.K) for guidance on use of the IChemE pinch analysis software. We are grateful to Cordin Arpagaus (Eastern Switzerland University of Applied Sciences) for sharing information on IHP technology, economics, and emerging capabilities, Jarrod Leak (Australian Alliance for Energy Productivity) for sharing a database of IHP case studies, and Benjamin Zühlsdorf (Danish Technological Institute) for sharing advances from the Annex 58 partnership on high temperature IHP capabilities.

Industrial High Temperature Heat Pumps – Ongoing Research in the USA

Ammi Amarnath* , Baskar Vairamohan

* Electric Power Research Institute, 3420 Hillview Avenue, Palo Alto, CA 94304, USA

Abstract

According to the U.S. Department of Energy, it is estimated that approximately 35% of industrial energy input for process heating is lost as waste heat in the form of exhaust gases, cooling water, and heat loss from product heating. The waste heat inventory in the industrial sector in the United States is estimated to be on the order of 1500–3000 trillion Btu per year [1.58 – 3.17 EJ]. The development and testing of a novel heat pump funded by the California Energy Commission in the United States is presented in this paper. This work effort is aimed at developing an industrial heat pump that can capture low-grade industrial waste heat (around 70 – 80°C) and transform it into high-temperature useful heat, specifically in the form of steam. The paper also discusses the use of a low Global Warming Potential (GWP) refrigerant (R1233zd(E)) that can provide a temperature lift of at least 40°C, thereby producing steam, with coefficient of performance (COP) greater than 3.4. Industries such as food processing, chemicals, paper and textile industries can make use of this steam.

1. Introduction to Industrial Decarbonization

Addressing climate crisis is in the limelight globally and almost every country in the world is on a path to decarbonize the buildings, transportation and industry. It is imperative that economy-wide decarbonization is the way to achieve carbon goals and meet the targets set forth in the 2015 Paris agreement and the electric power industry is leading the charge. Since 2005, the US reduced its carbon footprint by one gigaton, primarily by switching to cleaner fuels, expanding renewables and driving efficiencies. To get to the next gigaton, we need solutions to integrate and manage more low carbon energy generation: from distributed to utility scale solutions covering wind, solar, hydro and nuclear; to systems that help us optimize their output. According to a recent EPRI analysis, the annual U.S. emissions can be reduced by at least an additional 3 gigaton (Gt) from 2030–2050 (refer to Figure 1), consistent with an 80% drop since 2005, through strategic R&D focused on post-2030 deployment of innovations for using clean electricity to capture a growing share of final energy markets. As efficient electrification accelerates, technologies for indirectly electrifying challenging end uses will emerge for deep decarbonization of all major energy sectors.

At the same time, electrification of the end use is a primary option for reducing direct emissions outside the electric sector, particularly in transportation but also in buildings and industry. Combining clean electric power and electrification can help bring about cost-effective decarbonization throughout the economy, although reaching economy-wide net-zero targets will likely require additional breakthrough technologies.
Industrial-scale energy systems integration technologies, such as waste heat recovery and distributed energy generation, can reduce the manufacturing sector’s reliance on the electric grid and increase industrial efficiency. Low-temperature waste heat streams account for the majority of the industrial waste heat inventory. The waste heat inventory in the industrial sector in the United States was analyzed and is estimated to be on the order of 1500–3000 trillion Btu [1.58–3.16 EJ] annually. According to US Department of Energy, process heating account for nearly 70% of the total process energy, accounting for approximately 7500 TBtu [7.91 EJ]. Of this total process heating energy (see Figure 2), only about 5% is direct electricity use and the remaining 95% is contributed by fossil-fuel and steam. Thus, industrial process heating has a very high potential for decarbonization as steam production and fossil-fuel fired processes contribute heavily to the global carbon emissions.

Recovering waste heat, though difficult to achieve, could offer a decarbonization solution to the industrial sector. By utilizing wasted heat energy and putting it back to the process reduces the fuel intake which in turn reduces the emissions. Additionally, using heat pump technology – an electric solution – for waste heat recovery reduces the steam and fossil-fuel dependence which effectively lowers the industrial emissions as well.

Waste heat recovery is often utilized in two different ways, (i) generated waste heat from an industrial facility can be captured and re-used by redirecting waste streams for use in other thermal processes, or (ii) the waste heat stream can be converted to electricity.

In this paper, an innovative heat pump technology that is currently in development which can capture the low-grade industrial waste heat (around 70 - 80°C) and transform it into high-temperature useful heat, specifically in the form of steam will be discussed. Unfortunately, heat pumps that are currently available commercially cannot take advantage of high-temperature industrial processes, as currently available heat pumps have an upper-temperature range limit around 94°C.

Currently, the heat pumps that can produce steam are mostly in developmental stages across the world. Low-temperature waste heat streams available abundantly in industries. Typical waste heat sources are at temperatures in the 70-80°C range. The sources of the waste heat in industry typically are chillers, cooling processes, return steam condensate. Most of the industry need for steam is in the range of 115 to 125°C and industries such as food processing, dairy, paper and chemical can make use of this steam. This will provide an immediate high impact heat pump solution to the industries in not only California but also around the world once successfully developed, tested, and verified in the laboratory.

2. Market Characteristics

The most dominant existing technology for steam production is gas-fired boilers. Such boilers have significant carbon footprint – the GHG emission factor for gas boilers is about 235.6 g CO₂ equivalent per thermal kWh of heat produced. Some boilers have electric resistance heaters (costly electricity, with COP~1)
that add to carbon emission based on the electric power generation mix. The cost of the electric resistance boilers is in the range of $30-$50/kW of heating capacity produced.

The challenge is to bring down the cost of heat pump to be closer to boiler costs. The current projected costs (in literature) are about an order of magnitude higher. This project is exploring the use of existing components with innovative design, in order to be cost effective, as compared to boilers. Details on the bill of materials for low-cost heat pumps are being developed in the project described in Section 5 of this Paper.

Another aspect of this project is to widely transfer knowledge gained. EPRI, through its utility membership consortia, is well qualified to do that. Targeted technology transfer activities are planned to be conducted during the latter part of 2023.

3. Other Emerging Heat Pump Technologies and Pilots Around the World

There are several organizations around the world involved in developing high temperature heat pumps some attempts to develop HTHPs. Several heat pumps in the category discussed in this paper from Japan, Norway, France etc. are still in R&D stage and are nearing commercialization status. Some information about the status of technology is given in Table 1 below through the literature survey. This is just a snapshot of example organizations that are developing high temperature heat pumps. Heat pump research is a hot research area and several other organizations in various countries developing breakthrough heat pump technologies as well as refrigerants.

In Japan, Fuji Electric has developed an early commercial heat pump prototype capable of producing steam from waste heat just recently. This heat pump is a smaller capacity (30 kW) exhaust heat recovery type steam generating heat pump system that can produce 120°C saturated steam by means of efficiently recovering hot wastewater of less than 100°C. Details as to the knowledge of refrigerants and other specifications are not available.

EPRI is a member of United States team that participates in three important international Heat Pump working groups, the IEA Annex 58, Annex 59 and Annex 60. More details about the three working groups are summarized below.

4.1. IEA Annex 58: High Temperature Heat Pump Technologies

This Annex gives an overview of available and close-to-market technologies regarding high-temperature heat pumps. The need for further RD&D developments will be outlined. In order to maximize the impact of high-temperature heat pumps, this Annex also looks at process integration by development of concepts for heat pump-based process heat supply and the implementation of these concepts.
4.2. IEA Annex 59: Heat Pumps for Drying

The Annex aims to structure and describe the numerous possibilities and advantages of heat pump integration in dryers. Drying processes are widely used in industry and commerce (food industry, paper industry, chemical industry, ceramics industry, laundries etc.) as well as in household applications (white goods, tumble dryers, dishwashers) in various forms and contribute significantly to energy consumption. (10-25% of industrial energy consumption is used for drying processes)\textsuperscript{iv}.

4.3. IEA Annex 60: Retrofitting Heat Pump Systems in Large Non-domestic Buildings

The Annex focus on providing straightforward, high-level guidance for building owners and other decision-makers. Retrofitting heat pumps for larger non-domestic buildings is challenging as it contain a variety of complex heating, ventilation and cooling (HVAC) systems. These present different challenges and opportunities. In practice the retrofitting of heat pumps will often be part of more general refurbishment of a building. The scale and extent of anticipated refurbishment will be an important factor in determining which options for heat pump systems are technically or economically feasible. This annex aims to provide evidence of the practical feasibility and satisfactory operation of a range of installed retrofit systems in large non-domestic buildings in a number of countries, together with insights into the thinking that led to the choice of system\textsuperscript{v}.

5. EPRI Project on High Temperature Heat Pump for Industrial Decarbonization

This section outlines the general operational characteristics of heat pumps, current heat pump research project funded by the California Energy Commission (CEC), and the details of a prototype high temperature industrial waste heat recovery heat pump that is currently being developed under this funding.

5.1. Heat Pump Operation

This section provides a brief overview of the heat pump operating principles as applicable to heat recovery and using it within a process in a manufacturing facility. A heat pump consists of a closed loop containing a refrigerant that is either in the liquid or gaseous phase or both. The refrigerant or the working fluid passes through four main components (see Figure 3), i.e.:

- An evaporator where the refrigerant absorbs heat from the waste heat by evaporating.
- A compressor which increases the enthalpy and pressure of the refrigerant (and therefore its condensation temperature),
- A condenser in which the refrigerant transfers its latent heat to the industrial source by condensing,
- A pressure release valve that adjusts the evaporator supply and transfers the refrigerant from high to low pressure.

Energy is recovered by the successive changes in the states of the refrigerant.

![Figure 3 Schematics of a heat pump cycle](image)

5.2. EPRI’s CEC Project on Development of Industrial Heat Pump

EPRI has been funded by the CEC to lead this effort to develop an industry wide acceptable decarbonization solution. This high temperature heat pump (HTHP) technology once developed has the potential to meet the industrial steam need of industries such as food processing, chemical, paper and textile industries. Lack of commercial availability of high temperature heat pump technology to convert industrial waste heat to useful heat in the form of low-pressure steam was the motivation behind this project. In this project funded by the CEC\textsuperscript{vi}, EPRI is working with a research company called the Creative Thermal Solutions, Inc. (CTS) in the US to develop a high temperature industrial waste heat recovery heat pump that can produce steam. The project
uses an innovative design of building this prototype from commercially available components such as compressors, variable frequency drives, heat exchangers etc. The project requirements are that the developed technology should have a COP of 3.4 or better and provide a temperature lift of at least 40°C. The table, Table 2, below shows the project success criteria that need to be met at the end of the project. This is an ongoing project that was started in 2020 with a planned completion of 2023.

The project innovation lies in two main areas: first, the near-zero GWP and ODP refrigerant that has the characteristics to operate in a sub-critical mode with an ability to exist in two-phases can help to extract low grade waste heat to transform to high temperature useful steam; second, the control system as well as the heat pump design that could deliver the temperature lift of 40°C or more at a coefficient of performance (COP) of at least 3.4. The advantages of this heat pump design are two-fold – first, it will provide an immediate high impact heat pump based decarbonization solution to the industries in California and second, the heat pump will reclaim the waste heat from the industry and utilize it by returning it back to the industrial processes and reduces fossil-fuel consumption and therefore reduces overall emissions associated with the combustion.

5.2.1. Refrigerants

One of the requirements of this project is to create a vapor compression system that will be able to operate between temperatures 70°C and 135°C. A low GWP refrigerant such as R245fa, R1233zd(E) or R1336mzz(Z) will be utilized as the working fluid. These three refrigerants were selected based on literature studies conducted during the project design and specification stages [1][2][3] & [4]. In addition to creating a higher efficiency and lower emission technology the project team is also committed to choosing a refrigerant that has close to zero GWP and ozone depletion potential (ODP) with additional characteristics of lower toxicity (A1) and no flame propagation (A1) as shown in Figure 4vii. The system will operate with one of low GWP refrigerants (working fluids) such as R1234zd(E) or R1336mzz(Z). To take it one notch further, the project team is using R1233zd(E) as a working fluid in the prototype because a) it is a non-flammable fluid, b) it has a GWP of 1 and Ozone Depletion Potential (ODP) of 0, and c) it is a non-toxic fluid. The tests conducted with the breadboard system with the three refrigerants have also shown that the R1233zd(E) has better performance compared to the other two refrigerants.

The following charts (see Figure 5) shows various refrigerants used in various high temperature heat pump research around the world [4] [5] & [6]. Table 3 shows the characteristics of three emerging refrigerants that have been considered for this project – R245fa (as baseline), R1336mzz(Z) and R1233zd(E). The latter two refrigerants are considered promising for industrial applications.

</tbody>
</table>

The preliminary simulation results from the refrigerant testing shows that the required COP could be met. In summary, when generating 120°C steam from 80°C heat source, both R1233zd(E) and R1336mzz(Z) show a higher COP than R245fa. R1233zd(E) benefits from its larger specific heat of vaporization at 125°C, while R1336mzz(Z) benefits from its smaller specific compression work and they both have significantly lower GWP than R245fa which was used as a baseline. The characteristics of the three refrigerants are shown in Table 4.

5.2.2. Heat Pump Design

This section presents the simplified, single-stage heat pump design approach taken for this project that meets the performance specifications set forth in the project. The simplified schematic design is presented in Figure 6. below. In the following drawing the refrigerant lines are shown in black while water lines are shown in blue.
Compressor $C_p$ discharges refrigerant to a superheater $Sup$. The superheater serves to superheat the steam generated in the condenser $C_d$. After the superheater, the refrigerant flows to the condenser $C_d$ to be condensed. In that process, water on the other side is evaporated. The mixture of steam and water droplets goes to the separator $Sep$ that sends saturated vapor to the superheater to be additionally heated and effectively prepare for transportation to the user. The condensed refrigerant flows to the high-pressure receiver $Rec$. Liquid after the receiver will be subcooled in the subcooler $Sub$, heating in that process water that will be later evaporated in the condenser. Recuperative “internal heat exchanger” $IHX$ improves the performance of the system, taking care of the dry-out in the evaporator, and increases the reliability of the compressor by reducing the chance of sending liquid to the compressor. Expansion valve $EXV$ controls the flow of the refrigerant through the evaporator $Evap$, which will generate refrigerant vapor to be sent to the suction of the compressor. In this way, we have closed the refrigerant flow loop and explained the flow of water to be evaporated and turned into the superheated steam. The schematics also shows the pipe dimensions in the diagram.

After considering various heat exchanger options, the brazed plate type was chosen because it was by far the most compact and cost-effective option available. Acknowledged potential issues of scaling are to be handled with softened water where possible and periodic chemical cleaning that is conventional and commercially available. Table 5 shows the actual components and the make and model numbers of the parts used in the heat pump design.

</table>
The heat pump has controls to start and stop the compressor and one water pump. The heat pump is connected to a three-phase 480 V nominal power source at 60 Hz. A variable frequency drive (VFD) has been installed to vary the compressor speed. A 0-20 mA analog control signal must be connected to the drive to control the compressor speed. The speed of the compressor is controlled by adjusting the frequency of the VFD. Full rated compressor speed is achieved when the VFD frequency is set to 60Hz (line frequency of the AC power supply). The frequency of the drive directly correlates to the compressor speed, for example, 60Hz of VFD frequency is 100% of rated compressor speed, while 30Hz of VFD frequency is equal to 50% of the rated compressor speed. Subsequently over speeding of the compressor can be achieved by increasing the frequency to beyond 60 Hz, for example, 90Hz corresponds to 150% of the compressor rated speed.

5.2.3. Heat Pump Control System

The key features of the heat pump control system over the existing state-of-the-art technologies that are commercially available today are as follows:

- A new control strategy specifically for new refrigerants in the HTHP applications. Normal control of the expansion valve is based on the superheat exiting the evaporator. Isentropic line (that compressor follows in an idealized way) would enter into the two-phase zone, causing the liquid in the compression volume. To avoid that, the project team is using a novel control based on superheat at the compressor discharge stage.
- Modified compressor. New refrigerants bring several other new challenges. Their specific volume of vapor is significantly higher than in conventional refrigerants so a compressor with a much higher ratio of displacement vs. motor power will be used. Compressor with economized suction or compound type are preferential to maintain simplicity. That is another uniqueness of this approach. The compressor used in the design are commercially available.
- Modified heat exchangers (IHX). Another consequence of specific thermophysical properties (vapor volume) is a need for a special IHXs that will have different channels on the water and refrigerant side. The team would be using a Brazed Plate Heat Exchangers for heat transfer. A Brazed Plate Heat Exchanger (BPHE) offers the highest level of thermal efficiency and durability in a compact, low-cost unit.

5.2.4. Configuration of Laboratory Heat Pump System

The heat pump system and the components of the system are depicted in the figure (Figure 7) below.

![Figure 7 Schematic of a heat recovery heat pump currently being developed in California, USA funded by California Energy Commission (CEC)](image)

Some of the key features of the heat pump design are summarized below:

- Simple single-stage vapor-compression cycle design
- Closed loop refrigerant and closed loop steam system design
- Hermetic sealed compressor to prevent refrigerant leakage
- Emerson (Copeland) scroll compressor is selected and is expected to be a robust and efficient option. The same compressor was used to test all the 3 refrigerants.
- Water conserving design that incorporates a closed loop steam system which returns the steam condensate back to the water reservoir.
The prototype system that is currently being tested at CTS’s facility in Harmony, California is completely instrumented with multiple flow sensors, thermal sensors, steam flow sensors and electrical power meters to monitor and log the data for a thorough and detailed analysis. Multiple iterations have been conducted in the preliminary laboratory testing to ensure the sensitivity of the system load (capacity), input and output temperatures as well as other parameters. The photos in Figure 8 shows the actual prototype system built for this project.

![Figure 8 Photos of the Actual HTHP Prototype System](image)

The chart shown in Figure 9 below compares the compressor speed test results for R245fa (green), R1233zd(E) (blue), and R1336mzz(Z) (orange). The data shows that R1233zd(E) achieves the highest overall COP of 4.54 with a VFD set point of 40Hz (2/3rd rated compressor speed). The x-axis represents the heating capacity (Qh) of the heat pump and the y-axis represents the COP of the heat pump. The curves plotted for each refrigerant represents the COP of the system at various load conditions, which is represented by the frequency set point in the VFD (in Hz).

In the following chart, it can be seen that for the same heating capacity of Qh (= 18.3kW), the COP of R1233zd(E) is 4.8% higher than the COP of R1336mzz(Z). As Qh increases, the percent difference also increases, with the COP of R1233zd(E) being an estimated 13.8% higher at Qh (= 22.4kW). However, the most important comparison is between the three maximum COPs for each refrigerant, as the project’s primary goal is to maximize COP. The maximum COP of R1233zd(E) is 2.2% higher than the maximum COP of R1336mzz(Z), and 10% higher than 245fa’s maximum. Both R245fa and R1336mzz(Z) are within about 10% of the suggested 30kW capacity. Refrigerant R1233zd(E) shows better performance than R1336mzz(Z) in drop-in replacement mode. R1233zd(E) benefits from its larger specific vaporization heat, while R1336mzz(Z) benefits from its smaller specific compression work. R1233zd(E) leads to the highest COP of 4.5, which is 2.2% higher than R1336mzz(Z)’s maximum COP of 4.4, and about 10% higher than R245fa’s maximum COP of 4.1.

![Figure 9 Comparison of COP for a given Qh between R245fa, R1233zd(E) and R1336mzz(Z)](image)

The compressor efficiency of all refrigerants in the VFD set point of 40-70 Hz range are nearly identical, hovering in the 0.65 to 0.7 range. For a given VFD set point of 60 Hz (100% rated compressor speed), the total heating capacity of R1233zd(E) is about 0.89 times R245fa capacity and about 1.35 times of R1336mzz(Z).
capacity. Based on these results as well as other characteristics analyzed per earlier discussion, R1233zd(E) has been chosen as the refrigerant of choice, based on its high capacity, high COP, and lower risk for air to leak into the system.

The heating capacity $Q_h$ is obtained from three heat exchangers (subcooler, condenser, and superheater) where the refrigerant heats the water source, evaporates it, and then superheats the steam flow. The heat energy supplied to the water is given by Eq.1:

$$ Q_h = m_{subw} \times [h_{supso}(T_{supso}, P_{supso}) - h_{subwi}(T_{subwi}, P_{subwi})] $$  

Eq.1

Enthalpy $h_{subwi}$ is found with the temperature $T_{subwi}$ and $P_{subwi}$. Pressure measurement here is not needed because the water is subcooled, and the pressure will not change substantially due to temperature.

Efficiency or Coefficient of Performance (COP) is computed with the Eq.2 given below.

$$ COP = \frac{Q_h}{W_{cp}} $$  

Eq.2

where $W_{cp}$ is the power drawn by the compressor which is measured by a Watt Transducer.

The testing of this system for more than six months has provided consistent, repeatable, and stable results that meet the project goals set forth at the beginning of this project. Table 6, Figures 10 and Figures 11 show the test results from 6 months of heat pump testing. Some of the salient findings from the laboratory tests are given below:

- The COP shows results above the target values of 3.4
- The heating capacity of 25 kW is achieved at compressor speeds around VFD set point of 80 Hz (=1.3 times rated compressor speed)
- Repeatability: The prototype system runs reliably and has shown that repeated test conditions produce similar results
- System has been optimized to achieve an average COP of 3.6 at an average heating capacity of 25 kW ($Q_h$) and COP of 4.0 is easily achieved at an average heating capacity of 20 kW ($Q_h$).

Table 6 Test results from 6 months of Heat Pump Testing at CTS Laboratory

Figure 10 Heating capacity (left) and coefficient of performance (right) of the prototype heat pump system at rated compressor speed (VFD set point = 60 Hz)
6. Summary

This paper provides an overview of an innovative, high temperature, industrial heat recovery heat pump that is currently developed by EPRI under the auspices of the California Energy Commission. This is an ongoing project that has a planned completion timeline of 2023. Results from the prototype laboratory testing show that with the newer and emerging refrigerants, efficient compressors, and innovative control designs, a higher COP heat pump that can effectively recover waste heat from the industrial processes is achievable. The industrial waste heat recovery heat pumps offer multiple benefits to the industrial customers, firstly it produces useful heat in the form of steam; secondly it lowers the fossil fuel energy use by reusing the otherwise wasted heat energy and thereby reduces emissions due to combustion; and finally, by using clean energy electricity it additionally lowers the emissions and helps in industrial decarbonization. The project will also look into market characteristics and develop pricing of the heat pumps, determine the incentives that electric utilities as well as other governmental agencies can provide to help increase the market adoption. In summary, even though there is no one “silver bullet” solution to decarbonize the world, heat pumps offer a great pathway for industries to achieve their carbon reduction targets. Governments around the world should fund more research to develop high performance refrigerants and innovations in heat pump technology designs that could potentially combat the climate crisis more effectively and efficiently.

Acknowledgements

The authors would like to first thank the CEC for funding the project described in this paper, and the CEC’s Contract Agreement Manager, Rajesh Kapoor, for providing guidance. The authors would also like to acknowledge the team at CTS who have contributed to the development of the prototype high temperature industrial waste heat recovery heat pump system as a sub-contractor to EPRI under the CEC contract.

Design of non-flammable mixed-refrigerants Joule-Thomson refrigerator below -100°C

Taejin Park*, Junhyuk Bae*, Sangkwon Jeong

*Korea Advanced Institute of Science and Technology, 291, Daehak-ro, Yuseong-gu, Daejeon 34141, Republic of Korea

Abstract

Refrigeration below -100°C (170 K) is often demanded in various industrial applications such as biomedicine, food stocks, and semi-conductor processing. It is difficult to pump heat from 170 K to room temperature by a single pure refrigerant in Joule-Thomson (JT) refrigerator due to the insufficient thermodynamic properties. Mixed-refrigerants (MR) possess some attractive merit as an alternative for that temperature range. We select the non-flammable refrigerants to avoid the operation safety issues such as flammability and explosiveness of hydrocarbon refrigerants. This paper validates a possibility for obtaining 170 K by using a non-flammable mixture refrigerant and determines its maximum COP. A two-stage cascade cycle is selected for design simulation in order to achieve a high efficiency. In the main cycle, R14, R23, and R218 are used after we consider the characteristics of the iso-thermal enthalpy difference. In addition, R410A, which is broadly used in commercial refrigerators, is utilized in the precooling cycle. The optimal design and the operating condition are evaluated with several parameters in the main and the precooling cycles, such as the suction and discharge pressures of the compressors, the mass flow rate, the precooling temperature, and the MR compositions. The simulation assumes the ideal conditions to analyze the performance of the cycle. Consequently, the maximum COP is calculated at 0.78 when the mole composition of the ternary refrigerants (R14:R23:R218) is 0.7:0.1:0.2.

1. Introduction

With the 4th industrial revolution, the need for treating the amount and time of data is explosively increasing. As this tendency is accelerated, the demand of higher density semi-conductor is inevitable. In the previous semi-conductor manufacturing process such as an etching process, the required temperature of manufacturing chamber ranged from -20°C to -30°C. Recently, as a new method for fabricating the advanced high-density semi-conductor, cryogenic-etching process where the lowest temperature is below -100°C (170 K) is emerging as a novel technology for efficient production and precise manufacturing of the semi-conductor [1]. To obtain the low temperature below 170 K, the Joule-Thomson (JT) refrigeration could be utilized because of the several advantages such as high reliability due to no moving parts, low capital cost, simple structure, and adjustability of the cooling capacity. On the other hand, JT refrigerator has also several disadvantages such as clogging problem in the lowest temperature parts, large pressure ratio, which results in low efficiency. The substitution of a pure refrigerant with a mixed-refrigerant (MR) as the working fluid can be a solution to these problems in the JT refrigeration cycle. Recently, the global environmental issue is to cope with the global warming and the destruction of ozone layer. Many researches have focused on the investigation of the MR-JT refrigerator using flammable refrigerants, which could reduce the emission of the CO2 and increase the efficiency [2]. However, it has critical disadvantages such as the flammability and explosiveness when the system size grows. In the manufacturing process of semi-conductor, it is essential to facilitate a cleanroom which is designed to maintain extremely low levels of pollutant. When the flammable refrigerants are utilized as the working fluid of the...
refrigerator, it has a critical fire hazard, which is the single greatest risk among the courtroom accidents. The damage from a fire can generate tremendous loss of the cost and time-consumption within several minutes. Due to these peculiar issues in the manufacturing process of semi-conductor, the concern of the safety is an essential factor. Therefore, in specific industrial applications, which need highest safety concerns like semi-conductor process, it is justifiable to construct a refrigeration system by using non-flammable refrigerants even though they have relatively high GWP.

Over the past years, numerous investigations of the MR-JT refrigerator are concentrated on the flammable refrigerators as the working fluids due to their advantages such as high efficiency and lower global warming potential. On the other hand, few researches have addressed the non-flammable refrigerants in the past years. The cycle efficiency is affected by not only the composition of the MR but also the configuration of the cycle. The investigation by using non-flammable refrigerants for below 170 K needs more attention for various inevitable applications. Zhili Sun et al. (2019) explore the alternatives of refrigerant substitution in three cascade refrigeration system (TCRS) [2]. In the Zhili paper, the maximum COP is about 0.59 when the lowest temperature is about 170 K by using flammable refrigerants. In 2017, Cheonkyu Lee et al. presented a high-performance mixed-refrigerants JT refrigerator cycle by using non-flammable refrigerants for obtaining about 100 K [3]. The applied refrigerants for main and precooling cycle consist of Ar (Argon), R14, R23, and R218 in the main cycle and R410A in precooling cycle, respectively. In this research, the optimum operating condition is discussed and presented. In the research by Jisung Lee et al. (2011), three-stage cascade cycle was proposed for cooling HTS cables at the refrigeration temperature of about 70 K [4]. For reaching the temperature about 70 K, the non-flammable mixture of neon-nitrogen was selected as the working fluid of the main cycle. However, the flammable mixture of nitrogen, methane, ethane, and propane have been used as the components of MR to improve the cycle’s efficiency. Since then, Jisung Lee et al. (2017) conducted the experimental investigation for validating the results of the previous numerical simulation [5].

The objective of this paper is to design a high efficiency MR-JT refrigerator for 170 K by using non-flammable refrigerants. The concepts of phase-liquid diagram and iso-thermal enthalpy difference are exploited to select the appropriate working fluid. Also, the comparison between the single-stage mixed-refrigerant and the cascade mixed-refrigerant cycle is performed in order to examine what configuration of cycle has a higher efficiency [6, 7].

2. Methodology

2.1. Selection of proper refrigerants and optimal compositions of MR

Cryogenic refrigerators were to be operated over wide temperature ranges from below 1 K to higher than 100 K usually up to 120 K. The traditional target temperature is below 170 K, which specifically dictates heat pumping from 170 K to 300 K. To cope with this wide temperature range (nearly 130 K), the mixed-refrigerants are preferred. One of the methods for selecting proper mixed-refrigerants as the working fluid is to utilize the liquid-phase diagram, which indicates the available range of liquid-phase between triple point and critical point. Fig. 1. shows the liquid-phase diagram for several refrigerants with various temperature. Whenever the refrigerator is operating below 170 K, it is imperative to avoid any freezing problem of the working fluid.

According to Fig.1, Tetra-fluoro-methane (R14,CF₄), Tri-fluoro-methane (R23,CF₃), and Octa-fluoropropane (R218,CF₃) can be selected as the non-flammable refrigerants. The total number of the divided cases per 0.1 mole with respect to their molar compositions of the ternary mixed-refrigerant is about 36 cases. Before we conduct the simulations for all cases, it is useful to sift out several cases for the analysis by considering their iso-thermal enthalpy differences. The iso-thermal enthalpy differences of the selected refrigerants (R14, R23, and R218) are presented in Fig. 2 both for the pure and the mixture refrigerants. The precooling refrigerant in the case of cascade configuration, is chosen as R410A which is one of the frequently used refrigerants in commercial refrigerators. R410A is the well-known near-zeotropic mixture of difluoromethane (R32,CH₂F₂) and pentafluoroethane (R125,CHF₂CF₃).

From Fig. 2, it is possible to determine proper compositions of the mixture and estimate its ideal cooling capacity. To lift heat from 170 K to the ambient temperature (300 K), each of the ternary refrigerants of R14, R23, and R218 plays its role at the lowest, middle, and highest temperature ranges, respectively. It is important to recognize that the minimum iso-thermal enthalpy difference for the whole temperature range actually determines the cooling capacity of the cycle and its COP. This fact justifies the use of precooling cycle in a cascade configuration to narrow down the required temperature range, for example from 170 K to 240 K.
instead of 170 K to 300 K. Since the iso-thermal enthalpy difference of R14 is relatively smaller than the others, the composition ratio of R14 should be larger than that of the other refrigerants for approaching below 170 K. The candidates of the mixture for the analysis is summarized in Table. 1.

2.2. Cycle description

2.2.1. Single-stage mixed-refrigerant cycle (SMR)

SMR cycle, which is referred to as Linde-Hampson cycle and illustrated in Fig.3., comprises a compression unit, which includes compressor and after-cooler, a heat exchanger, an expansion valve, and an evaporator. By using two-stage compression system, the compression work and the compression ratio can be reduced effectively. Also, the operational soundness of the compressor is improved.

Fig. 3. Schematic of single-stage mixed-refrigerant cycle (SMR)

2.2.2. Cascade mixed-refrigerant cycle

Cascade cycle mainly consists of two cycles; the main (red-line) and precooling cycle (blue-line) in Fig.4. The configuration of the main cycle is derived from the basic Linde-Hampson cycle by adding the precooling cycle for the reduction of irreversibility inside H.X.2. In the previous research of C. Lee et al. and J. Lee et al., the two-stage cascade cycle used was proposed to enhance the cooling capacity [3, 4]. For the simplicity and ideal analysis, the minimum temperature approach in all heat exchangers is set to 3 K except for the low temperature side of H.X.1 between the temperature of Main6 and Main11. Generally, after the heat exchanger (H.X.1), the magnitude of the temperature difference inside the H.X.1 increases along the high-pressure stream. The increasing temperature difference inside the heat exchanger causes the area of heat exchange to be extended or the irreversibility in the heat exchanger to be increased. By deploying the precooling cycle inside the main cycle, these problems can be mitigated.

Fig. 4. Schematic of cascade mixed-refrigerant cycle (Cascade-MR cycle)

2.3. Simulation conditions and constraints

SMR and Cascade-MR are analyzed and compared to investigate the effect of precooling-cycle on the efficiency of the MR-JT refrigerator. For analyzing both refrigeration cycles, a commercial simulator, ASPEN HYSYS V8.0 is utilized. In this paper, EOS is chosen Peng-Robinson equation in order to calculate the mixed refrigerant properties and the cycle efficiency. This EOS, which is presented below, has been commonly used for evaluating mixture properties in many previous researches [3-5]. \( P, R, T, v, a \) and \( b \) are pressure, universal gas constant, temperature, specific volume, fluid specific constants. \( P_c, T_c \) and \( w \) are critical pressure, critical temperature and acentric factor.
For simplifying the cycle analysis, we apply the following conditions and assumptions into the refrigeration cycle.

2.3.1. Compression part
- Two stage compression in the main and precooling cycle is implemented to reduce the compression work.
- It is assumed that the compression occurs with the isentropic efficiency of 80%.
- Each compressor in the main and precooling cycle has the same compression ratio.

2.3.2. Heat exchanger parts including after-coolers
- It is assumed that the pressure drops in both hot and cold streams are negligible except for the Joule-Thomson valve.
- Minimum temperature approach is 3 K inside heat exchangers.
- The type of heat exchangers is counter-flow.

2.3.3. Expansion part
- The expansion process is an isenthalpic process.

2.3.4. Simulation constraints
In general, the maximum pressure (discharge pressure) of MR-JT refrigerator is set to 3500 kPa for efficient operation. The minimum limitation of the suction pressure is nearly 100 kPa (1atm) due to the operational safety issue. The summary of the simulation constraints is presented in Table 2.

Table 2. Summary of the simulation constraints

The mass flow rate of the main cycle is set as 1kg/s for the simplicity of the analysis. On the other hand, that of the precooling cycle is determined automatically in order to satisfy the minimum temperature approach 3 K in H.X.2. The discharge pressure of the precooling cycle is 1750 kPa, which means the subcooled or compressed state of R410A at ambient temperature (300 K).

3. Results

3.1. SMR cycle
Fig. 5. describes the variation of COP and the temperature of after-JT valve with the suction pressure of the SMR cycle for two cases of ternary MR compositions of R14, R23, and R218 (0.7:0.1:0.2 and 0.75:0.1:0.15). The longitudinal scales of the upper and the lower graphs are fitted equally for the convenience. Both (a) and (b) in Fig. 5. have the similar tendency. As the suction pressure increases from the 100 kPa, the cycle efficiency and the temperature of after-JT valve also increase gradually. The available suction pressure to achieve the target temperature of 170 K are up to 300 kPa and 330 kPa as indicated in Fig.5. (a) and (b), respectively. The COP of the case (a) is larger than that of the case (b) with more molar composition of R218.
Fig. 5. COP and after-JT temperature with respect to the molar compositions in SMR cycle

(a) R14:R23:R218 = 0.7:0.1:0.2  
(b) R14:R23:R218 = 0.75:0.1:0.15

Fig. 6. COP and after-JT temperature with respect to precooling temperature in cascade cycle

(a) Precooling temperature 230 K  
(b) Precooling temperature 240 K
3.2. Cascade cycle

Fig. 6. (a) and (b) illustrate the variation of the achievable COP and the lowest temperature with the suction pressure and the discharge pressure in accordance with the precooling temperature in the cascade cycle. The overall tendency for the COP and the temperature of after-JT valve is similar with the SMR cycle’s results as mentioned in the previous section. In the cascade cycle, the efficiency is primarily influenced by three main parameters, that are the suction, the discharge pressure, and the precooling temperature of Main7 which is the precooled temperature through H.X.2. From Fig. 6, it is evident that the lower precooling temperature leads to the higher efficiency of the cycle. Although the precooling temperature is controlled by the suction pressure in the precooling cycle, the temperature is limited by the suction pressure in the precooling cycle which isn’t allowed below 100 kPa for the stable operation.

For more precise analyses in cascade cycles with different molar compositions, we considered several cases of 0.05 mole variations as presented in Table 3. Also, in order to find the optimal operating conditions, the constraint range of discharge pressure in the main cycle extends from 2400 kPa to 3200 kPa with the variation of 200 kPa.

Table 3. Subdivided cases for several molar compositions

<table>
<thead>

<td>0.75</td>
<td>0.15</td>
<td>0.1</td>
</tr>
</tbody>
</table>

The sub-divided four cases are simulated and the results are plotted in Fig. 7. As a result, the maximum COP is obtained as 0.785 in the case of (1-1) with the compositions of R14, R23, and R218 (0.7:0.1:0.2). In that case, the suction and the discharge pressures are about 200 kPa and 2600 kPa for 170 K, respectively. The mass flow rate of the precooling cycle is estimated at 0.476 kg/s. Another case also has similar tendencies and the estimated maximum COP for 170 K is about 0.78. Table 4 summarizes the simulation results in terms of the suction and the discharge pressures with the parameters of the precooling cycle.

Furthermore, the second law efficiencies of the sub-divided four cases in Table 3 are calculated to compare their realistic efficiencies with other cycles. The Carnot COP and the second law efficiencies are calculated by eq.(4) and eq.(5), respectively, with the Carnot COP of 1.31. $T_e$ and $\text{COP}_{\text{Carnot}}$ stand for the evaporator temperature and the Carnot COP, respectively.

$$\text{COP} = \frac{T_e}{300-T_e}$$

$$\eta_{II} = \frac{\text{COP}}{\text{COP}_{\text{Carnot}}}$$

The calculated results are depicted in Fig.8.

From the previous section, we deduce that the higher efficiency can be achieved when the precooling temperature decreases. In this numerical analysis, the suction pressure in the precooling cycle with R410A is primarily determined by the precooling temperature, 230 K.

Fig. 7. COP and after-JT temperature for four molar compositions
4. Discussion

Both SMR and cascade cycles with non-flammable refrigerants are analyzed by using commercial software ASPEN HYSYS V8.0. Both results of SMR and cascade cycles represent a similar tendency that the COP and the temperature of after-JT increase in accordance with the increase of the suction pressure. The reason for these characteristics is related to the pressure ratio between the suction (lower) and the discharge (higher) pressures. In condition with the same discharge pressure and the precooling temperature, as the suction pressure increases, the pressure ratio is reduced. As a result, the compression work is reduced by the decreased pressure ratio. By the definition of COP, a ratio of compression work and cooling capacity, the COP increases gradually to some extent. For example, the consumption of work and the cooling capacity in the case of (1-1) is illustrated in Fig. 9.
As the suction pressure increases, the temperature of after-JT also increases. It can be explained by the Joule-Thomson effect, where the difference between the lower and the higher pressures is a major factor in determining the temperature drop. In addition, as shown in the Fig. 10, the precooling stage in the cascade cycle can decrease the temperature difference of hot and cold streams at the low temperature side of the heat exchanger. Therefore, the cascade cycle can result in higher efficiency with less entropy generation associated with the finite-temperature heat exchange in the counterflow heat exchangers.

This study has taken several ideal assumptions such as zero-pressure drop except for the expansion valve, higher compressor efficiency of 80%, and the minimum temperature difference of 3 K. For the realistic results, the effect of minimum temperature in the heat exchangers and the pressure drop in the cycle on COP should be considered as a future work. Furthermore, the predicted results should be validated by experiments.

Fig. 10 Temperature distribution in the heat exchanger for SMR cycle (left) and cascade cycle (right)

5. Conclusion

The purpose of this paper is to show the possibility of efficient MR-JT refrigerator for 170 K by using non-flammable refrigerants only. At first, R14, R23, and R218 are sifted out and selected as the working fluids for the simulation. To achieve the target temperature, 170 K, the molar ratio of R14 should be larger than those of the other refrigerants. In this paper, the mixture composition is R14:R23:R218 = 0.7:0.1:0.2 for maximum COP. The analyzed configuration of the cycles is two-types; SMR and cascade-MR cycle. The comparison between the SMR and the cascade cycle clearly reveals that the efficiency of the low-temperature MR cycle is greatly enhanced by the implementation of precooling cycle. Deploying the precooling cycle in the appropriate location in the main cycle effectively reduces the generation of irreversibility in the recuperative heat exchanger of the refrigeration cycle.

Industrial high temperature heat pump for steam and hot water production

Tim Hamacher

SPH Sustainable Process Heat GmbH, Zur Kaule 1, 51491 Overath, Germany

Abstract

In industrial processes, heat is often required in the form of saturated steam. Due to their thermodynamic process, compression heat pumps are ideal for converting waste heat back into high quality saturated steam. The advantage over steam compressors is the ability to perform the phase change efficiently. An industrial high temperature heat pump capable of generating saturated steam up to approx. 6 bar absolute (approx. 160°C) or hot water at approx. 165°C is presented in this paper. For this purpose, a self-developed high-performance piston compressor is used, which was specially designed for high temperature applications with HFO refrigerants, such as R1336mzz-Z or R1233zd. The article presents two industrial applications in which large amounts of CO₂ are saved or avoided by using innovative high temperature heat pumps. One is 2 bar absolute steam production from cooling water heat of combined heat and power systems, used in the gelatine production. The other is the production of 130°C hot water for a drying process in the recycling industry. The paper shows that steam production in the industry with high temperature heat pumps is possible.

Keywords: high temperature heat pump, steam, HFO, R1233zd;

1. Introduction

Global warming, climate change and the dependence on fossil fuels are defining challenges in the coming years and decades. In order to achieve the goals set by the EU for 2030 [1], a variety of measures are necessary. In addition to the expansion of renewable energies, it is essential to increase energy efficiency and thus reduce primary energy consumption.

About 21% of the total CO₂ emissions in Europe are due to industry [2]. Today, process heat in the range above 100°C is mainly generated with the help of fossil fuels, such as natural gas or fuel oil. A large part of the process heat in the range up to 200°C is used in the form of saturated steam. Saturated steam has the advantage of a large energy content when using the phase change and at the same time low transport costs from the point of generation to the consumer.

In recent years, the use of heat pumps as an alternative to fossil fuel heat generators has become increasingly popular for heating residential buildings. Here, mainly electrically driven compression heat pumps are used, which use environmental heat (outside air, geothermal heat) as a heat source to generate the required useful heat. When used with renewable electricity, quasi CO₂-free heat generation is thus possible.

This article shows the possibility of providing process steam or hot water from unused industrial waste heat with the help of compression heat pumps. The ThermBooster system can generate temperatures up to 165°C, or saturated steam pressures up to 6 bar absolute. The system is based on a piston compressor specially developed for use in industrial high temperature heat pumps. HFOs such as R1233zd are used as refrigerants.

Two industrial applications are shown. On shows the use of the system to produce 2 bar absolute saturated steam for use in the gelatine production. The other shows an innovative heat concept in the production of an innovative thermoplastic compound material, where the high temperature heat pump delivers 130°C hot water for a drying process.
2. ThermBooster pilot system and process

2.1. Compressor

The core of the high temperature heat pump is a specially developed 4-cylinder piston compressor with a displacement of approx. 540 m³/h at 1500 RPM. The compressor is designed for up to 35 bar on the high-pressure side and 18 bar on the low-pressure side. Hot gas temperatures of 250°C and suction gas temperatures of 200°C are possible without any problems. The compressor is optimized by a patented valve system for HFO refrigerants of the latest generation (e.g. R1233zd, R1336mzz-Z) and achieves high isentropic and volumetric efficiencies. The valve system is characterized by an optimized arrangement and the use of the available area, thus reducing the pressure drop in the valve system to a minimum while maintaining a low clearance volume. First measurements on the testbed have shown isentropic efficiencies \( \eta_{is} \) with R1233zd(E) as working fluid, in the range of 85%-95% for pressure ratios between 2.5 and 3.5. These values are calculated by measuring the pressure and temperature at compressor inlet and outlet and comparing the enthalpy difference according to formula 1. The volumetric efficiencies showed to be between 92% and 95%.

\[
\eta_{is} = \frac{h_{Out,ideal} - h_{in}}{h_{Out,measured} - h_{in}}
\]  

To achieve long lifetimes and service intervals with these high temperatures, the heat pump is equipped with an oil conditioning system which always keeps the oil in a temperature range which is as low as possible, but still high enough to prevent too much refrigerant solving into the oil. The cylinder surface of the compressor together with its piston and piston rings is optimized for very low oil transport into the refrigerant circuit. It is also equipped with an oil separator in the crankcase ventilation system to reduce oil transport into the refrigeration circuit to nearly zero. Up to now, no detailed measurement was done but currently no oil transport could be observed. Depending on the refrigerant used, different type of oils will be used. For R1233zd(E) POE (Polyolester) or CE (Complexester) oils are used.

2.2. System layout

The system is designed as a compression heat pump with internal heat exchanger. Figure 1 shows the schematic structure of the system while Figure 2 shows the realised design as a CAD model.

Fig. 1: principle P&ID of the heat pump
Highly efficient plate heat exchangers are used as evaporators and as internal heat exchangers. The condenser in the refrigeration circuit, which is also the steam generator in the heat sink circuit, is implemented as a Plate & Shell heat exchanger. Plate & Shell heat exchangers offer for this application a good combination of efficiency of heat transfer from refrigerant to water and the required robustness for use in industrial steam systems. Evaporation is controlled by electronic expansion valves. To further increase efficiency, an additional subcooler has been integrated. With this subcooler, thermal energy as hot water can be extracted in parallel to the steam generation by subcooling the working fluid to lower temperatures to use it, for example, for feed water preheating or to feed it into another heating circuit.

For optimal oil conditioning, the oil sump of the compressor is equipped with a water jacket, which serves to preheat the oil and expel the dissolved refrigerant from the oil, as well as for oil cooling in high temperature operation. The required water is heated or cooled to the required temperatures by a conditioning unit integrated on the frame of the heat pump.

![Fig. 2: CAD model of the ThermBooster](image-url)
2.3. Thermodynamical cycle

The system operates as a compression heat pump with internal heat exchanger. Figure 3 shows the cycle in the log pH diagram for R1233zd(E).

Here, the process is as follows:
1) Evaporation with low superheat.
2) Superheating in the internal heat exchanger
3) Compression in piston compressor
4) Desuperheating and condensation
5) Subcooling in water-cooled subcooler
6) Subcooling in internal heat exchanger
7) Expansion in expansion valve and evaporator

![Fig. 3: log PH diagram of the thermodynamical cycle](image)

3. Applications in industry

In the following, several project examples in industry are presented. The examples come from the food and recycling sector and show the wide range of possible applications of such systems for the generation of process heat with heat pumps. In addition to the integration, the effects on CO2 emissions are shown with the help of model calculations.

3.1. Gelatine production

Gelatine is mainly obtained from animal components, such as hides and bones of cattle and pigs. For this purpose, after thorough cleaning, the animal products must be pre-treated with the aid of acids so that the gelatine can then be extracted. The extraction is then carried out in several stages using hot water, with the water temperature being increased at each stage. The gelatine solution obtained, which now contains 2-5% gelatine, is then purified of solids before being concentrated to about 20-40%. This is usually done by vacuum evaporator. After leaving the concentration, the gelatine is thermally sterilized. Depending on the desired product (powder or sheet gelatine), various thermal drying processes are now used.

It can be clearly seen that thermal energy is required for most of the different process steps. Most of the thermal energy is required for the drying processes, where also the highest temperatures are needed.
3.1.1. Boundaries/ pre installation status

Currently, heat is generated by a gas-fired steam generator and several cogeneration units, which are used to supply electricity to the plant. There are two heat rails at the plant. A hot water rail at about 85°C and a steam rail at 2 bar absolute, corresponding to 120°C. The hot water rail is mainly fed by the cooling water heat from the CHP units and is used to provide process heat and heat for heating the buildings. The steam line is used exclusively to provide process heat. Since the demand for floor heating varies greatly from season to season and the demand for hot water is also relatively low, there is unused heat at this temperature level, most of which is now discharged to the environment via dry coolers. Figure 4 schematically shows the current situation in heat generation.

3.1.2. Integration

In the future, the heat pump will replace the dry coolers and ensure that 100% of the heat generated is used on the 80°C hot water rail for production and space heating and not longer wasted into the environment. For this purpose, the heat pump is integrated into the circuit parallel to the existing consumers and thus uses the 80°C heat rail as a heat source.

The heat pump used corresponds to the system presented in chapter 2, only without using the subcooler. Figure 5 shows the planned integration. The heat pump has to cool down the heat source to 70°C in order to use all available energy of the cooling water, because this 70°C is needed to be able to cool the CHP units.

Table 2 shows the integration conditions and the resulting performance data of the heat pump. All results are currently mostly based on simulations in combination with first results from the testbed. The heat pump will be installed beginning of 2023. The heat pump evaporates at about 67°C and condenses at about 125°C, giving an internal temperature lift of 58K. The theoretical Carnot efficiency related to evaporation and condensation temperature results from formula 2 to 6.9, this means that we reach here with the achieved COP of 4.4 a Carnot quality of 64% related to evaporation and condensation temperature. This is one used definition of the Carnot quality, another possibility is to calculate it related to the hottest and coldest process temperatures which are here the steam temperature of 120.2 °C and the heat source outlet temperature of 70°C. Using these temperatures, the Carnot quality reduces to 56%.

\[
COP_{\text{Carnot}} = \frac{T_{\text{Cond}}}{T_{\text{Cond}} - T_{\text{Evap}}}
\]

3.1.3. Environmental impact

Since the plant uses the heat supply about 8000 h per year, about 6500 t of steam will be produced by the heat pump in the future with an electrical consumption of about 944 MWh yearly. This corresponds approximately to 4.1 GWh of thermal energy as steam. Assuming an efficiency of 85% in relation to the fuel input for a standard gas-fired steam boiler, approx. 4.8 GWh of natural gas will be saved. If a CO2 emission factor of 0.201 t/MWh_gas [2] is taken as the basis for calculation, approx. 960 t CO2 are avoided here. The exact CO2 emission factor of the electricity used is not known. Different approaches can be used here.

1. CO2 emission factor of CHP electricity (42% electrical efficiency) = 0.479 t/MWh_el.
2. CO2 emission factor when changing the energy source to electricity = 0.366 t/MWh_el [3].
3. use of own electricity from the existing and planned PV systems + purchase of electricity from renewable sources = 0 t/MWh_el.

Thus, depending on the approach, the CO2 savings result in values between 508 t and 960 t savings per year.
3.2. Recycling industry

Recycling of used materials and raw materials is becoming increasingly important. More and more new processes for recycling waste are being developed and implemented on an industrial scale. In the following process, conventional household waste is converted into a high-quality thermoplastic composite material. For this purpose, household waste, previously considered non-recyclable, is taken and split into its basic components of lignin, cellulose, fibers and sugar in a complex process and then reassembled into a new matrix, the thermoplastic composite material. This is to be used in various applications in the future, e.g., for vehicle interiors.

One process step in the production is the drying of the material. Temperatures of around 130°C are required for this.

3.2.1. Boundaries

This project involves the construction of the first industrial application for the production of the new thermoplastic composite material. It was decided that the use of fossil fuel was not an alternative, so a comprehensive heat utilization concept was developed from the outset to bundle various waste heat streams and use them as a source for a high temperature heat pump. The concept includes various cooling and heating circuits at different temperature levels, all of which are interconnected.

3.2.2. Integration

The high temperature heat pump is the last link in a series of heat pumps providing thermal energy at different temperature levels. The schematic in Figure 6 shows only a very rough concept focusing on the different heat pumps. In addition to these heat pumps, there are several other thermal exchangers such as process heat exchangers or dry coolers for winter relief (delivering cooling water from cold outside temperatures instead of using the chiller) or even buffer storage. The circuit with the lowest temperature operates at 8°C and is used to cool various process steps. This temperature is generated by a chiller, which condensing heat is used in a water circuit at about 35°C. This level is used for cooling or heat recovery from warm material and exhaust air streams as well as for preheating material streams. It then serves as a source for a medium temperature heat pump that raises the temperature level to about 75°C-80°C. This level in turn serves as a source for various process steps, as well as a source for the high temperature heat pump. This then provides 130°C hot water for the drying processes. Approximately 1.5 MW of heating power is required for drying. Two heat pump systems, each with two independent refrigeration circuits, are used here, each with a thermal output of approx. 1 MW, so that only three of the installed refrigeration circuits are in operation at any one time and one circuit serves as redundancy or can cover power peaks in certain situations.
3.2.3. High temperature heat pump system

Since this application does not use steam as a heat transfer medium, but hot water, the setup differs from the pilot system shown in chapter 2. Figure 7 shows the circuit diagram for the systems used.

In the CAD model in Figure 8, you can see the compact design with the two compressors on the outside, condensers and subcoolers placed in between. At the other end are the evaporators connected in series and the internal heat exchangers. The design data applicable to this application can be found in Table 4. Because of the series-connected evaporators, the two refrigeration circuits operate at different evaporating pressure levels. In the first circuit, the evaporating temperature is about 67°C and in the second about 62°C. The condensing temperature, in turn, is very similar in both circuits at about 129°C. To make optimum use of the large spread in the heat sink, a subcooler was placed downstream of the condenser in each case to be able to subcool the refrigerant further and extract thermal energy. Due to the different evaporation temperatures of the two circuits, they don’t have an identical power output. To be able to reach 130°C in each circuit a distribution valve is integrated between in the heat source water circuits. An additional distribution valve in each subpart of the water circuit helps to speed up the warm-up process if the complete water circuit is cold. In this case
only a small part of the flow goes through the subcooler and condenser to reach higher refrigerant temperatures in the condenser. This helps in the warm up process due to higher temperatures in liquid part of the internal heat exchangers which then lead to higher superheat before the compressor and the possibility to go to higher evaporation temperatures earlier. In the case of water as a heat sink, the Lorenz COP (2) is often used instead of the Carnot COP to assess the efficiency of the system. Here, no individual temperatures of the process are used as reference, but the entropic mean temperatures are used.

\[ \text{COP}_{\text{Lorenz}} = \frac{\dot{q}_H}{T_H - T_L} \]  

The entropic mean temperatures are defined as follows.

\[ T_H = \frac{\Delta T_H}{\ln \left( \frac{T_H}{T_H,0} \right)} \quad \quad T_C = \frac{\Delta T_C}{\ln \left( \frac{T_C}{T_C,0} \right)} \]  

With \( T_H \) the temperatures on the heat sink side and \( T_C \) the temperatures on the heat source side.

In this application, the Lorenz COP is 9.6. With a designed and simulated COP of 4.4 for the high temperature lift from 75°C to 130°C, this means a Lorenz quality of approx. 46%. The system will be installed in the first half of 2023.

3.2.4. Environmental impact

With a planned annual service life of approx. 8000h, about 10.8 GWh of thermal process energy will be produced in the future. This corresponds to approx. 1.25 Mm³ of natural gas, which will not be required through the use of the heat pump. As the user consequently follows the principle of sustainability, only CO₂ neutral produced electricity is used in this project, so that approx. 2400 t CO₂ per year are avoided compared to a natural gas fired process heat production.

4. Summary

This paper shows the commercial availability of a high temperature heat pump system to produce steam and hot pressurized water in industrial applications. With current HFO fluids temperatures up to 165°C are possible. The system is based on a newly developed piston compressor, optimized for the use in high temperature heat pumps. The system is built as a standard compression cycle heat pump with internal heat exchanger.

The first application which will be delivered into the galantine production and produces steam at 2 bar abs (120°C) with using cooling water from CHP units at a level of 85°C/70°C. For this application a COP of 4.4 has been simulated. The second application is production of 130°C hot water for a drying process in the recycling industry. Here the heat source is given by the waste heat from chiller systems which are combined between 8°C up to 130°C. Here the last step of this cascade, the high temperature heat pump, reaches a COP of 4.4.

Application of multipurpose heat pumps in museums: a case study

Eva Schito*, Paolo Conti, Daniele Testi

Department of Energy, Systems, Territory and Construction Engineering (DESTEC), University of Pisa, Largo Lucio Lazzarino 1, 56122 Pisa, Italy

Abstract

The present work deals with the achievable benefits of using multipurpose heat pumps in museums, where heating and cooling are simultaneously required to ensure proper indoor conditions for artworks preservation. Air-handling units are usually installed to control temperature and relative humidity through both hot and cold coils that are usually fed by dedicated heat generators (e.g., heat pumps, boilers, and chillers). Using a multipurpose heat pump can reduce electrical input, as the same device can concurrently provide both heating and cooling power with a single energy input and recovering energy between the cold and the hot coils. In this perspective, the present work presents a representative real case study for Mediterranean climate. The building thermal load and the HVAC performances have been simulated in TRNSYS 17 and MATLAB with an hourly time step. The multipurpose heat pump provides an energy saving equal to 25% in cooling season compared to the use of a separate heat pump and a chiller. Indeed, the heating load is almost entirely met through the recovery of the condenser heat without significant additional energy input.

Keywords: Multi-purpose heat pump; energy savings; building dynamic simulation; heat recovery.

1. Introduction

1.1. Context

Energy reduction in the building sector is crucial to achieve the objectives set by the United Nations and European Union for the reduction of greenhouse gas emissions [1-2]. Currently, buildings in the European Union are responsible for about 40% of the total energy consumption for the services of heating and cooling [3].

In the last decades, the use of heat pumps (HP) for heating purposes has increased, thanks to their performance especially in the case of low supply temperatures and mild climates. Modern HPs also provide cooling service if a reversing valve is present resulting in an advantageous device that can be used in both winter and summer.

The market share of HP has been notably increasing in recent years: in 2020 the sold heat pumps in EU Countries were more than 1.5 million, about 50% more than the sold units in 2016 [4]. Air-to-water units account for ~13% of the total air-source market with 1.5 M units sold in the 2015–2019 period and a total installed capacity of ~24 GW at the end of 2019. HPs are also strategic devices for increasing the renewable share in nearly Zero Energy Buildings (nZEB), integrated hybrid systems, smart microgrids, and energy communities thanks to the energy shifts between heat to electricity: better exploitation and storage of renewable production (e.g., photovoltaic modules) is thus possible, also through advanced and optimally controlled demand response and power-to-heat strategies. Therefore, HP installation in new or existing buildings is often supported by national governments through several forms of incentives.

An additional possible application of HP technology for energy efficiency purposes is the use of the so-called multipurpose heat pumps (MP-HP), which are chillers where a total recovery of the heat at the condenser is possible. This type of generator, also called total recovery chiller, can be particularly useful in buildings where heating and cooling are simultaneously required. MP-HPs can be seen as both co-generators able to provide two different energy services by using a single energy input, or as a recovery solution as the removed “cold energy” is not dissipated into the environment, but it is re-injected at a higher temperature.

1.2. Literature review

The analysis of the state of the art on MP-HPs has shown a limited application of this technology on scientific research, even if the found results has hinted that this generator allows significant energy savings compared to traditional systems. The literature analysis results fragmented, also because this technology is presented with a variety of different names (such as multipurpose heat pump, multi-heat pump, total recovery chiller, multifunctional heat pump), making the literature research difficult.

Most of the papers on this topic present experimental tests on MP-HP. Agrawal et al. [5] present the results of experimental test on a CO2 transcritical MP-HP for simultaneously production of heating and cooling services. Kang et al [6] carry out measurements on a MP-HP directly exchanging with indoor air, evaluating COP when varying compressor speed ratio. Liu et al [7] present the performance of a prototype MP-HP for both heating and domestic hot water services. At evaporator, this prototype can use external air, gray water, or both these sources with an either parallel or series configuration. The results show that the optimal performance is reached with the parallel configuration at evaporator, using both sources. Other works are aimed at enhancing the MP-HP performances with different methods. As an example, Boahen et al [8] tested a cascade MP-HP for the simultaneous delivering of heating, cooling and domestic hot water at different level of temperatures. In their series of papers, Byrne et al. [9-11] present the results of an in-house designed heat pump for multipurpose services. First, the performance was measured in steady-state conditions, using R407C as refrigerant [9]. In their second paper [10], the dynamic behavior of the heat pump was analyzed, focusing on the performance during transition among operational modes (e.g., from only cooling delivering to both cooling and heating delivering) and on the possibility of partially recovering heating to be used for defrosting. Finally [11], two refrigerants are compared (i.e., R407C and R290) to evaluate best energetic and exergetic performances. Cho et al [12] designed and tested a MP-HP, seeking the optimal refrigerant charge to enhance the total efficiency of the system, in different load and operation conditions. Chiu et al [13] show the results of a monitoring campaign on an air conditioning system where the heat recovery at the condenser is used for domestic hot water purposes.

A small amount of research papers focuses instead on the simulation of MP-HP performances when applied to case studies. Diaby et al. [14] compare two possible applications of a CO2 transcritical MP-HPs in a hotel: in the first case, the heat pump is used for heating, cooling and domestic hot water services; in the second one, the heat pump is used for simultaneous cooling and desalinization purposes. The latter application shows better performances due to the more suitable process temperatures. In [15], the authors expose the outputs of the application of MP-HPs in three climates and three different buildings: a low-energy residential building, a retail store and a small office building. The results hint that applying MP-HP in low-energy residential building allows higher energy savings, as this type of building has often simultaneous heating and cooling load, depending on the solar gains. Shen et al. [16] simulated the performance of MP-HPs in ten different US cities, using a restaurant as case study, for simultaneous production of either heating and domestic hot water, or cooling and domestic hot water. The comparison of electrical energy needs with this technology and a classical solution with heat pump/chiller and electric heater shows savings ranging between 47% and 64%.

1.3. Aim and presentation of the research

The present research aims at evaluating the achievable energy savings when a MP-HP is used as the thermal generator in an environment where heating and cooling services are simultaneously required. The MP-HP performance is compared to a classical configuration where two different generators are used, namely an electric heat pump and an electric chiller. After a presentation of the energy models of the generators (Section 2), we show a case study consisting of a museum room in Italy where temperature and relative humidity should be carefully controlled to avoid artwork degradation (Section 3). To maintain the indoor setpoint values, an air handling unit (AHU) is used, thus requiring both heating and cooling services, especially in the cooling period where the dehumidification demand is high. Two different configurations are compared: the so-called “separate configuration” with two separate hot and cold generators: e.g., the heat pump and the chiller, and an
MP-HP configuration where a unique multipurpose heat pump is used (see Fig. 1 and 2, respectively). The Results Section (Section 4) presents the comparison of the total electrical energy consumption of the two configurations, demonstrating the effectiveness of the multipurpose heat pump.

Fig. 1. The separate configuration, with a chiller and a heat pump, working separately for the AHU cooling and heating coil.

Fig. 2. MP-HP configuration where the generator provides both hot and cold water for the AHU cooling and heating coil.

2. The model

2.1. Multipurpose heat pump (MP-HP)

The considered MP-HP unit is a market-available device and the energy model is based on the manufacturer datasheets [17]. Depending on the dynamic load profile, external air temperature, and humidity, the AHU can only require heating power at the reheat coil ($Q_{H,r}$), cooling power at the cooling coil ($Q_{C,r}$), or both services.
at the same time ($\dot{Q}_{HP}$ and $\dot{Q}_{CR}$). According to the manufacturer’s data [17], the considered multipurpose heat pump can work in three different operational modes (see also Fig. 3):

1. as a classical chiller, only providing cold water to the AHU cooling coil and using an outdoor-air heat exchanger as a condenser (Mode 1). In this case, the absorbed electrical energy at the compressor is evaluated as a function of the supply temperatures to the cooling coil ($T_{c,s}$) and partial load conditions (CR):

$$\frac{\dot{Q}_{CR}}{\dot{E}_{el}} = \text{EER}_{C,MP-HP}(T_{C,CR})$$

(1)

2. as a classical heat pump, only providing hot water to the AHU reheat coil and using an outdoor-air heat exchanger as an evaporator (Mode 2) In this case, the absorbed electrical energy at the compressor is evaluated as a function of the supply temperatures to the reheat coil ($T_{H,s}$) and partial load conditions (CR):

$$\frac{\dot{Q}_{HP}}{\dot{E}_{el}} = \text{COP}_{H,MP-HP}(T_{H,CR})$$

(2)

3. as a multipurpose heat pump: providing both cold and hot water to the AHU. In other words, the MP-HP operates as a chiller with a total recovery of the heat at the condenser (Mode 3). Air heat exchangers do not operate and possible discrepancies between hot/cold generations and thermal loads are managed using ad buffer water storages, according to the following control strategy [17]:

○ The MP-HP tries meeting the cooling load, evaluating the absorbed electrical energy at the compressor as a function of the supply temperatures to the hot and cold coils ($T_{H,s}$ and $T_{C,s}$, respectively) and partial load conditions (CR):

$$\dot{E}_{el} = \frac{\dot{Q}_{CR}}{\text{EER}_{H&C,MP-HP}(T_{H,s}, T_{C,s}, CR)}$$

$$\dot{Q}_{HP} = \dot{Q}_{CR} + \dot{E}_{el}$$

(3a)

(3b)

○ If $\dot{Q}_{HP,MP-HP} \geq \dot{Q}_{HR}$, the multi-purpose heat pump follows the cooling load ($\dot{Q}_{C,MP-HP,e} = \dot{Q}_{CR} + \dot{Q}_{HP,MP-HP,e} = \dot{Q}_{CR} + \dot{Q}_{H,MP-HP}$), storing the possible heating surplus ($\dot{Q}_{H,MP-HP} - \dot{Q}_{HR}$) in the hot thermal buffer. In this case, Eqs. 3a and 3b apply.

○ If $\dot{Q}_{H,MP-HP} < \dot{Q}_{HR}$, the multi-purpose heat pump follows the heating load by increasing its thermal output at the condensing section ($\dot{Q}_{H,MP-HP,e} = \dot{Q}_{HR}$). The corresponding effective cooling production (\dot{Q}_{C,MP-HP,e}) at the evaporator increases to a value higher than the cooling load ($\dot{Q}_{CR}$), thus the cooling surplus ($\dot{Q}_{MP-HP,e} - \dot{Q}_{CR}$) is stored in the cold thermal buffer. In this case, Eqs. 3a and 3b are slightly modified as:

$$\dot{E}_{el} = \frac{\dot{Q}_{C,MP-HP,e}}{\text{EER}_{H&C,MP-HP}(T_{H,s}, T_{C,s}, CR)} = \frac{\dot{Q}_{HR}}{1 + \text{EER}_{H&C,MP-HP}(T_{H,s}, T_{C,s}, CR)}$$

$$\dot{Q}_{H,MP-HP,e} = \dot{Q}_{HR} = \dot{Q}_{C,MP-HP,e} + \dot{E}_{el}$$

(4a)

(4b)

We arbitrarily chose the EER as the reference thermodynamic coefficient of performance of the MP–HP. Analogous formulæ can be deployed by using condenser output and COP definition to model the MP-HP performances. Moreover, for the sake of simplification, the cold and hot thermal buffers are considered as ideal, without thermal losses or energy exchange constraints.

The values of $\text{EER}_{C,MP-HP}(T_{C,CR})$, $\text{COP}_{H,MP-HP}(T_{H,CR})$, and $\text{EER}_{H&C,MP-HP}$ are obtained through the polynomial fitting of the nameplate data provided by the manufacturer [17] (see, for instance, Eqs. 5).

$$TR = \frac{T_{H,s} + 273.15}{T_{C,s} + 273.15}$$

(5a)

$$CR = \frac{\dot{Q}_{CR}}{\dot{Q}_{C,NOM,MP-HP}}$$

(5b)
\[ EER_{H\&C-MP-HP}(T_{H\&C}, T_{C-MP}, CR) = \frac{\alpha_0 + \alpha_1 \times TR + \alpha_2 \times CR + \alpha_3 \times TR^2 + \alpha_4 \times TR \times CR}{T_{C-MP} + 273.15} \times \left( \frac{T_{H-HS} - T_{C-MP}}{T_{H-HS}} \right) \]  

(5c)

In Eqs. 5, the values of temperatures are in °C.

The nameplate data of the multipurpose heat pump working in Mode 1, Mode 2, and Mode 3 are reported in Table 1, Table 2, and Table 3, respectively.

2.2. Separate heat pump and chiller configuration

For the separate configuration, the same regression coefficients obtained by fitting the data in Tables 1 and 2 are used. Using these values, the performances of the two generators in the separate configuration are evaluated as in Mode 1 (“Only cooling”) and Mode 2 (“Only heating”). The performance coefficients are named $COP_{H,SC}$ and $EER_{C,SC}$. Application of the model to a museum showroom
To compare the efficiency of a multipurpose heat pump with the two separate generators, we selected a case study consisting of a room of a museum hosting temporary exhibitions in Pisa, Italy. The simulation period starts on July 1st up to August 31st, with a one-hour timestep. The reference outdoor climate (external temperature, relative humidity, horizontal solar radiation) refers to the TMY provided by the Italian Thermotechnical Committee [18].

The considered room has a floor area of 100 m² and a volume of 500 m³; walls are made of bricks and masonry (U-value of external walls: 1.1 W/(m²K)) and no glazed elements. For the maintenance of indoor conditions, an AHU is used, consisting of a cooling/dehumidifier coil, a reheat coil, a steam vaporizer, and a fan.

The room is kept at precise internal conditions to avoid artwork deterioration:
- The indoor temperature setpoint is equal to 25 °C, with a control dead band of ±1K;
- The indoor relative humidity is equal to 50%, with a control dead band of ±2%.

An hourly profile of visitors has been used as the source of both sensible and latent internal gains; the maximum peak is 100 visitors. The visitors can visit the museum every day from 9:00 a.m. to 7:00 p.m. However, to ensure the maintenance of the indoor air setpoints, the AHU can be activated 24/7.

Other details on the case study and visitors’ presence profile can be found in [19-20]. For the simulation of the AHU, a dynamic model has been used [21]: this model simulates the behavior of the various components (two heating coils, a vaporizer, and a cooling coil) using ε-NTU equations, mass and heat balance. The model evaluates the temperature and humidity ratio exiting the single coils \( T_{\text{air},r} \) and \( x_{\text{air},r} \), at the end of the cooling coil, and \( T_{\text{air},s} \) and \( x_{\text{air},s} \) at the end of heating coil), knowing the external parameters \( T_{\text{ext}} \) and \( x_{\text{ext}} \), ensuring the room energy requirements. The energy balance at the coils allows the evaluation of the supply temperatures \( T_{H,s} \) and \( T_{C,s} \). More information on this model can be found in [21].

The building-HVAC system has been simulated in TRNSYS 17 [22] and MATLAB [23] obtaining the hourly values of the performance coefficients and electrical energy input as presented in Section 2. The two configurations in previous Figs. 1 and 2 are then compared in terms of seasonal energy input.

3. Energy performance results

Through the dynamic simulation of the building-AHU system, hourly values of supply temperatures \( T_{H,s} \) and \( T_{C,s} \) at the cooling and heating coils are calculated. Those temperatures are the required temperatures at the evaporator and condenser of the devices, the same in both “separate” and “combined” configurations as they depend on the same thermal loads and heat transfer performances of the two coils. Through the thermal loads, the supply temperatures and (in case of a single energy load) the external temperature, the performance of the heat pump is evaluated.

On average, the required supply temperature at the heating coil is 39.5 °C, and the one at the cooling coil is 7.7 °C. The average external temperature is 22.5 °C. Table 4 shows the results of the comparison of the two generator configurations of the case study, using the previously presented indicators. Also the value of Total Efficiency Ratio (TER), defined as the ratio between the total provided energy and the total electrical energy input, is shown.

The results show that the simultaneous operation of the MP-HP for both services frequently occurs: more than 90% of the heating load is delivered through this operation mode (Mode 3). In this case, considering the greater relevance of the cooling load, the hot thermal storage is charged. Mode 2 (“Only heating”) is rarely used: it only applies in those timesteps when only the heating load occurs. On the contrary, the MP-HP frequently works in Mode 1 (“Only cooling”) using the hot water buffer to meet the heating load and recover the heat stored in the previous Mode-3 operation.

Fig.4 shows the operation of the MP-HP for a typical day in July. During the night, the cooling load is low, so the MP-HP follows the heating profile. As an example, at “Hour 1” the MP-HP provides the AHU heating requirements, but the cooling output results in an overproduction compared to the actual load and the surplus energy is stored in the cold water storage. At “Hour 2”, the stored energy in the cold water storage is sufficient to cover the AHU cooling load, so the MP-HP works in Mode 2 (“Only heating” mode). During the opening hours of the museum, the high cooling load drives the AHU operations that switch between Mode 1 and Mode 3, depending on the charging/discharging status of the hot water storage. As an example, at “Hour 16”, the heating output at MP-HP is over 14 kW, even if the actual requirement is around 6 kW. The surplus is stored in the hot water buffer and used to meet the heating load at “Hour 17”, where the generator works in Mode 1 (“Only cooling”).

![Fig. 4. Modes of operation of MP-HP in a day of July: energy delivered by the heat pump compared to the energy requirements at AHU. The position of the line representing delivered energy and required energy indicates the surplus of heating/cooling stored in dedicated buffers and later used.](image)

Table 4 shows that the average MP-HP coefficient of performance is lower than in the case of separate configuration, namely, \(SEER_{H&C,MP-HP} < SEER_{C,MP-HP}\). Indeed, the average temperature difference between the supply water temperature (7.7 °C) and the outdoor air temperature (22.5 °C) is lower than the temperature difference between the two supply temperatures in Mode 3 (7.7 °C and 39.5 °C). However, the latter comparison is affected by our choice of using EER as the coefficient of performance for the MP-HP and it does not consider the simultaneous delivery of both heating and cooling loads. The \(TER\) indexes in Table 4 provide a better comparison of the two configurations, accounting for both hot and cold services. As previously mentioned, this indicator is defined as:
\[ T_{ER_{MP-HP}} = \frac{\left( \sum Q_{H,MP-HP,eff} + \sum Q_{C,MP-HP,eff} \right)}{\sum E_{el}} \]  \hspace{1cm} (6a)

\[ T_{ER_{SC}} = \frac{\left( \sum Q_{H,r} + \sum Q_{C,r} \right)}{\sum E_{el}} \]  \hspace{1cm} (6b)

Thus, the comparison of this index in combined and separate configuration hints the better exploitation of electrical energy in the MP-HP use. In this case study, using an MP-HP allows a decrease of electrical energy input equal to 25%. In Fig. 5, the daily electrical energy inputs for the “separate” and “combined” configurations are compared over a typical week (from 1st August to 7th August). For each day, the electrical energy consumptions in the three operational modes are independently visible. The figure shows that the heating load is almost always delivered as a total recovery of heat at the condenser when providing also cooling service. The daily reduction of electrical energy ranges between 20% and 30%.

4. Conclusions

In this paper, we have shown the potential of using a multi-purpose heat pump in a building where heating and cooling loads are simultaneously required. The analysis has compared the energy requirements of a “separate” configuration, using an independent air-source chiller and a heat pump, with a “combined” configuration using a MP-HP to feed the same AHU.

For the analysis, a case study has been identified: a room of a museum in the Mediterranean area where indoor temperature and relative humidity are kept constant using the AHU. Through an hourly dynamic simulation, the electrical energy consumptions required to operate the cooling and reheat coils have been calculated for both “separate” and “combined” configurations. The results show a reduction of electrical energy input of about 25% in the case of a “combined” configuration and MP-HP use. Due to the greater relevance of the cooling load in the presented case study, the MP-HP mainly operates in “Both heating and cooling” mode (Mode 3) and “Cooling only” mode (Mode 1). The system uses the surplus of the heating production in Mode 3 to charge the hot storage and then uses this energy in Mode 1 avoiding the need for another heating generator.

As a matter of fact, together with possible energy savings, the paper has also investigated the importance of the two “energy buffers” in MP-HP systems: indeed, depending on hot and cold load profiles, energy recovery would not be feasible where the two instantaneous load profiles were not properly synchronized. Thus, further development of the research will include the modeling of other MP-HP devices (also using more efficient refrigerants as R744), a more accurate model of the thermal buffers in the MP-HP contexts, including the effects of their optimal sizing and control required to assess the actual potentiality of those systems. In addition, the efficiency of this technology in a whole-year simulation, also in different climates, and various types of buildings and services will also be investigated.

Abstract

Electrically driven high-temperature heat pumps (HTHPs) are becoming a promising and cost-effective technology to replace fossil-fuel driven boilers through residual heat recovery and revalorization. HTHPs are however often designed and optimized in terms of thermodynamic performance, neglecting financial aspects such as the levelized cost of heat (LCOH). In this study, the heat pump design and operating conditions are optimized by minimizing the LCOH. This is done for a wide set of working fluids and boundary conditions. Both subcritical, transcritical and supercritical cycles, as well as (zeotropic) binary mixtures, are considered. Depending on the boundary conditions, both pure fluids as well as (zeotropic) binary mixtures, mostly operating in the subcritical region, are financially attractive. The potential benefits of zeotropic mixtures are twofold: (1) more favorable operating conditions and (2) higher COPs. Transcritical cycles only showed to be attractive for large temperature glides at the heat sink side. The results also shows that the financial and thermodynamic optima differ in many cases. One reason for this is that working fluids with a high COP often induce high compressor inlet volume flow rates, resulting in high compressor costs.

Keywords: High-temperature heat pumps; binary mixtures; pure working fluids; techno-economic

1. Introduction

High-temperature heat pumps (HTHPs) are an emerging technology, allowing for efficient electrification in the industrial heating sector. It is expected that HTHPs will soon be able to supply process heat up to 200 °C [1]. By reaching supply temperatures of 200 °C heat pumps could deliver 37% of the process heat demand in the European industry [2]. Consequently, there is an increasing amount of research on working fluids and cycle configurations for these HTHPs. This research mainly focusses on achieving a maximum COP and therefore minimal electricity use.

However, some working fluids with a high COP may require large compressors, or multiple compression stages, while configurations with a high COP may be more complex and therefore expensive. The discrepancy in thermodynamic and financial optima for some boundary conditions has been shown for organic Rankine cycles [3]. For HTHPs however, less research is performed on financially optimal heat pump cycles and working fluids. Moreover, if a financial analysis is performed it is typically done for just one application. In addition, the amount of working fluids screened and configurations considered is often not complete. This research focusses on the selection of optimal working fluids for HTHPs, by optimizing and analyzing the levelized cost of heat (LCOH) for each working fluid. Both pure working fluids as well as binary (zeotropic) mixtures are considered as candidates. For this purpose, a financial framework is developed and applied to a large set of generic data, rather than to one, or a limited amount of, case studies(s).

2. Methods

In this section, the financial framework is first explained. Afterwards, an overview of the refrigerant candidates is given. Subsequently, the large set of generic boundary conditions, to which the financial framework will be applied, is presented. Finally, the post-processing of the results is explained. In this procedure, working fluids may be eliminated because they violate technical constraints.

2.1. Financial framework

The financial framework is an extension of the thermodynamic simulation and optimization framework developed by Vieren et al. [4,5]. This framework allows for optimizing the COP for pure fluids and binary (zeotropic) mixtures, both in the subcritical, transcritical and supercritical regime. A single-stage heat pump cycle was chosen as reference cycle, with the option for an internal heat exchanger (IHX). Based on the obtained optimal, or sub-optimal working fluids, more advanced cycles can be modelled. The optimization framework maximizes the COP of the heat pump cycle by varying the superheat ($\Delta T_{sh}$), subcooling ($\Delta T_{sc}$), pressure during heat delivery ($p_{high}$) and pressure during heat extraction ($p_{low}$). For operation above the critical point, $\Delta T_{sh}$ and $\Delta T_{sc}$ are defined with respect to the critical point. For the binary mixtures, the molar fraction of the components is also optimized.

Because the LCOH is a function of the COP, the developed thermodynamic framework acts as a well-suited basis. Next to changing the objective function from COP to LCOH, the main adaptions to the existing model are:

- Removal of the constraints on the pinch point temperature difference (PPTD). From a thermodynamic point of view the COP would be maximal for a PPTD of 0 K. This would however require infinitely large heat exchangers. Therefore, a PPTD of 5 K in the heat exchangers was imposed in the thermodynamic model. In this financial analysis however, a low PPTD will be automatically penalized by a strong increase in heat exchanger costs, while the COP increases only marginally.
- Introduction of multiple compression stages. In the financial model, multiple compression stages will be considered if the compression ratio is high. This was not done in the thermodynamic model, because the use of multiple compression stages will not drastically influence the COP. For the financial model however the impact can be much higher. A maximum compression ratio per stage of 6 is selected.

2.1.1. Levelized cost of heat

The LCOH is the average net present cost of the heat production (€/kWhth) over the lifetime of the heat generating system. The LCOH is calculated by use of Eq. 1.

$$LCOH = \frac{C_{\text{CAPEX}} + \sum_{t=1}^{n} \frac{C_{\text{OPEX}}}{(1+i)^t}}{\sum_{t=1}^{n} \frac{Q_t}{(1+i)^t}}$$

(1)

With $C_{\text{CAPEX}}$ the capital expenditure (€), $C_{\text{OPEX}}$ the operational expenditure at year t (€/year), n the heat pump lifetime (year), $i$ the interest rate (%) and $Q_t$ the amount of heat produced at year t (kWhth/year).

2.1.1.1. Capital expenditure

The capital investment cost of the heat pump ($C_{\text{CAPEX}}$) is determined according to the preliminary and study cost estimation method of Turton et al. [6], providing estimates in the accuracy range of -25 % to +40 %. In addition to the equipment purchase costs, the method also accounts direct and indirect project expenses, contingency and fees and auxiliary facilities.

First the purchasing cost of each component ($C^0$) was determined. An overview of each component cost function can be found in Table 1.
Table 1: Overview of the bare module cost ($C^0$) of each component.

The heat exchanger cost is based on the heat transfer area, which is based on heat transfer coefficients (HTCs). These HTCs depend on the working fluid, Reynolds number and Prandtl number. Since a large set of pure working fluids and binary mixtures will be screened, it is not feasible to implement heat transfer correlations. Moreover, high uncertainties are expected for the binary mixtures. Therefore, fixed HTCs, depending on the phase of the working fluid or secondary medium, are chosen in this high-level analysis. An overview of the selected HTCs can be found in Table 2. The HTC for the liquid phase, two-phase and gas phase where determined based on extrapolation of overall HTCs reported in the VDI Heat Atlas [10]. For the supercritical phase the same HTC is chosen as for the liquid phase.

In order to account for inflation the cost functions reported in Table 1, which are derived in the past, are adjusted to the year 2021 by use of the chemical engineering plant cost index (CEPCI) [8]. The indexed purchased equipment cost is used to calculate the bare module cost ($C^0_{BM}$) of each component. This cost also accounts additional direct costs (e.g. labour) and indirect costs (e.g. engineering expenses) for each component. The bare module cost is found by multiplying the purchased equipment cost ($C^0$) with a bare module cost factor ($F_{BM}$):

$$C_{BM} = C^0 \cdot F_{BM}$$  \hspace{1cm} (2)

An overview of the bare module cost factor of each component can be found in Table 3.

Table 3: Bare module factor ($F_{BM}$) for each component, according to Turton et al. [6].

</tr>
</tbody>
</table>

The total module cost ($C_{TM}$), which equals the capital expenditure, is the summation of each bare module costs with an additional 15% and 3% added for contingency costs and fees respectively:

$$C_{TM} = 1.18 \cdot \sum_{i=1}^{n} C_{BM,i} = C_{CAPEX}$$  \hspace{1cm} (3)

2.1.1.2. Operational expenditure

The yearly operational expenditure is determined by the total yearly electricity use and the yearly maintenance cost.
\[ C_{\text{OPEX}} = c_{\text{el}} \cdot \left( \frac{\dot{Q}_{\text{process}}}{\text{COP}} \right) \cdot h_a + f_{\text{maint}} \cdot C_{\text{CAPEX}} \]  

The total yearly electricity use is determined by the specific electricity costs \( c_{\text{el}} \) (€/kWh), the electricity use rate (kW\(_{\text{el}}\)) and the annual operation hours \( h_a \) (h). The electricity use rate is determined by dividing the heat demand rate of the industrial process (\( \dot{Q}_{\text{process}} \)) by the COP. The yearly maintenance cost is calculated as a fraction \( f_{\text{maint}} \) of the capital expenditure.

2.1.2. Financial boundary conditions

For the computation of the LCOH, several external parameters are required that depend, amongst others, on the type of industry and country where the HTHP is to be integrated. In this work financial boundary conditions are chosen that represent a typical energy-intensive industry in Belgium, as shown in Table 4.

<table>

<td>0.0806 €/kWh(_{\text{el}})</td>
<td>[14]</td>
</tr>
</tbody>
</table>

For the specific electricity cost, the bi-annual electricity costs reported by Eurostat for Belgium between 2016-2020 [14] is averaged. This was done for the prices reported in the yearly electricity consumption range of 500 MWh\(_{\text{el}}\) to 2000 MWh\(_{\text{el}}\). According to Eurostat, most of the EU non-household consumers fall in this use range.

2.2. Refrigerant selection

Regarding the pure working fluids, a selection is made based on the REFRPROP10.0 database [15]. The following selection criteria are applied:
- Ozone depletion potential (ODP) of approximately zero.
- Global warming potential (GWP) below 150.
- National Fire Protection Association (NFPA) 704 instability grade of 0.
- Thermally stable up to 200 °C or higher.

Based on the selection of the pure working fluids a pool of binary mixtures is made. From this pool, mixtures where both components have a critical temperature below 160 °C are eliminated, because the goal is to study these mixtures in the subcritical region. All these working fluids are examined for the configuration with and without IHX.

2.3. Operational boundary conditions

First the financial model is applied to two boundary conditions reported in earlier work of Vieren et al. [4], where the COP was optimized by this simulation framework. The temperature levels of the two selected boundary conditions can be found in Table 5.

After these cases are discussed, an estimate of the financial performance for the selected refrigerants is formulated for a wide range of generic boundary conditions. The generic data is classified in four groups.
depending on the nature of the heat source or sink. An overview of the classifications, and the amount of datapoints (i.e. boundary conditions) selected, can be found in Table 6.

Table 6: Overview of the four classifications depending on the nature of the heat source or sink.

Each datapoint has a heat sink outlet temperature between 160-200 °C, whereas the heat source inlet temperature varies between 80-120 °C. Because the degrees of freedom increase when the secondary stream is of sensible nature (addition of a temperature glide next to the absolute temperature level), more datapoints are selected in these scenarios. However, less datapoints are selected compared to the COP optimization [4] due to the increased complexity and therefore computational power.

Important to note is that whilst the COP computation of the developed framework is independent of the capacity of the heat pump system, the LCOH is not because non-linear cost functions are used. In this work a heat pump with a heating capacity of 500 kW is considered.

2.4. Post-processing

After the pool of refrigerants is simulated, the results are post-processed. During post-processing working fluids which require a compressor discharge pressure above 60 bar are discarded. The reason is that few compressors exist for pressures above 60 bar, except for CO2. Moreover, for the binary mixtures a minimum deviation in molar fraction and LCOH from the respective pure fluids is imposed. A minimum deviation of respectively 2 mol % and 2 % is selected so that there is a clear distinction between pure working fluid and binary mixture.

3. Results

3.1. Sensible-sensible boundary condition

An overview of the financially best performing working fluids for the ‘sensible-sensible boundary condition’ can be found in Table 7. This table reports the working fluid, molar fraction of the first component, number of stages, use of an IHX, COP, LCOH and the specific investment cost ($c_{inv}$) of the 5 best performing fluids. The specific investment cost is obtained by dividing the capital expenditure (Eq. 3) by the heating capacity (500 kW).

Based on the reported results it can be observed that the financially most attractive refrigerants are (zeotropic) binary mixtures. These binary refrigerants are made up entirely of natural refrigerants, or more specifically, of hydrocarbons and ammonia. To reveal the potential of these mixtures, the results of the respective pure working fluids with the largest molar fraction are reported in Table 8.
Comparing these tables shows that mixtures are able to increase the COP and decrease the specific investment costs compared to the pure fluids. One of the reasons for the increase in COP can be explained by the non-isothermal phase change of these mixtures. This may result in a better temperature match between refrigerant and secondary medium, decreasing the exergy destruction. As an example, the T,Q-diagram of both methanol/ammonia and pure methanol is given in Figure 1, where it can be observed that methanol/ammonia results in a better temperature match. Moreover, the pressure levels shown in the figure indicate that the addition of ammonia to methanol increases the pressure levels. As the increase in evaporator pressure is relatively more outspoken compared to the condenser pressure, the compression ratio decreases from about 8 to 5.7, resulting in the possibility of using one compression stage. Moreover, mixing the pure fluids may result in a lower volume flow rate at the compressor inlet compared to one of the pure constituents and therefore a lower compressor cost. For the methanol/ammonia mixture for example the volume flow rate at the compressor inlet is 0.083 m³/s whereas for pure methanol a flow rate of 0.130 m³/s at the inlet of the compressor is needed.

Figure 1: T,Q-diagram of methanol/ammonia and methanol for the ‘sensible-sensible boundary condition’.

Table 7 and Table 8 also demonstrates that the financially most attractive heat pump does not necessarily have the highest COP. Benzene for example has a COP of 3.82 which is about 13 % higher than for cyclobutene (3.37). However, the LCOH of a heat pump with benzene is 26 % higher compared to a heat pump with cyclobutene. This is because a heat pump with benzene would have a specific investment cost of 871 €/kWth, compared to 357 €/kWth for cyclobutene. The investment cost of the benzene heat pump is high because of the high pressure ratio resulting in the need for two compression stages, and the high volume flow rate resulting in large compressors. Both the high-pressure ratio and high volume flow rate are caused by the low evaporation pressure, associated to the high normal boiling point (NBP) of benzene (80.1 °C).

3.2. Latent-sensible boundary condition

An overview of the financially best performing working fluids for the ‘latent-sensible boundary condition’ can be found in Table 9, which has the same structure as Table 7.

Table 9 shows that all best performing working fluids are pure fluids. These fluids operate as transcritical cycles. For applications with a large temperature glide at the heat sink side and a small or zero temperature glide at the heat source side, these cycles are able to provide a good temperature match. In fact binary mixtures were able to increase the COP and LCOH, but only in such a minor degree that they were eliminated by the post-processing. Both natural refrigerants (i.e. hydrocarbons) and synthetic refrigerants hydrofluorolo-olefins (HFOs) and hydrochlorofluoro-olefins (HCFOs) are found to be well performing. Again, the working fluid with the highest COP is not necessarily the working fluid showing the best financial aspects. This is shown in Figure 2, where the LCOH of the 100 best performing refrigerants is plotted as a function of the COP, showing no correlation between the two parameters. This is an important result: even though a higher COP inherently lowers the LCOH by reducing electricity consumption, other factors determine the financial optimum. The figure also shows that for the best performing fluids, the optimized LCOH does not show large variations. This is partly due to the large number of working fluids simulated. It should also be noted that due to the uncertainty in LCOH, the working fluid with the lowest simulated LCOH may not have the lowest LCOH in practice. Therefore, the generalized selection matrix will show the best performing refrigerant types (e.g. hydrocarbons or mixtures of HFOs) rather than a single working fluid.

3.3. Selection matrix

Based on a large amount of simulated boundary conditions, explained in Table 6, the results are generalized in the form of a ‘selection matrix’, as shown in Table 10. This selection matrix reports the best performing working fluid(s) for each type of heat source and sink. Since flammability concerns may prevent the installation of the heat pump, and the cost of ATEX related regulations is not considered, a distinction is made between flammable refrigerants and non/mildly-flammable refrigerants. As the feasibility also depends on the absolute temperature levels, it is also indicated for which temperature level (low, medium and high, within the studied temperature ranges) of heat source and/or heat sink the working fluid is recommended. Water for example is only recommended for high source temperatures, because for low source temperatures the evaporation pressure is low, resulting in high suction volume flow rates. Cyclobutene, cis-2-butene or HFOs and HCFOs on the other hand are only recommended for lower heat sink temperatures, as for high heat sink temperatures the compressor discharge pressure becomes too high (> 60 bar), resulting in elimination by the post-processing.

Interestingly, binary mixtures almost always show to be (near-) optimal, also for boundary conditions where the temperature glide of the heat source and sink differ, or there are no temperature glides at all. As an example, the $T,Q$-diagram of acetone/water is shown for a sensible (120-90 °C) latent (160 °C) boundary condition (Figure 3.a) and a latent (120 °C) latent (200 °C) boundary condition (Figure 3.b). From Figure 3.a it can be observed that for the optimized pressures and molar fraction the temperature glide of the acetone/water mixture during condensation is rather small (∼10 °C) compared to the temperature glide during vaporization (∼20 °C), resulting in a decent temperature match. For other molar fractions and pressures, the temperature glide of the mixture during evaporation and condensation may approach zero (i.e. near-azeotropic mixture) as shown in Figure 3.b. In these scenarios binary mixtures do not necessarily increase the COP (although in this case they did), but they may result in better operational parameters and therefore financial aspects. The only scenario where the potential of zeotropic mixtures is limited, is for boundary conditions with large temperature glides as the heat sink (≥ 60 °C) and small to zero temperature glide at the heat source, as has been shown in section 3.2.
The reported (near-) optimal working fluids are, or consist of at least one, highly flammable hydrocarbon. If these highly flammable working fluids are not taken into consideration the options are limited. Generally, HFOs and HCFOs show the best feasibility if the source and sink temperature are low. For higher temperatures (where the pressure of the HFOs and HCFOs becomes too high) water is recommended. In some scenarios, addition of ammonia to the water can have beneficial effects in financial performance.

4. Discussion

A framework is developed that is capable of simulating single- and double-stage heat pump cycles, with and without internal heat exchanger. It is also able to simulate all the refrigerants in REFPROP 10.0 and the binary mixtures of these refrigerants. By assigning costs to the components of the heat pump, the financial performance over the lifetime of each heat pump cycle was estimated and ranked.

A preliminary financial screening is carried out for a wide range of generalized boundary conditions, rather than for a limited number of specific case studies. Generally, there is a common misconception in the literature that the payback period is used instead of LCOH. In such cases, the configurations with the optimum payback tend to be those with the lower investment costs, while they may not have the lowest LCOH, as has been shown in the work of Zühlsdorf et al. [19]. The LCOH is used in this work because it takes into account the period after the investment has been paid back. Moreover, the LCOH is independent of external boundary conditions such as gas prices. It is expected in this work that the calculated LCOH provides a good first estimate of the financial appraisal. The results showed that binary mixtures often have beneficial effects compared to their pure components, either by increasing the COP through improved temperature matching in the heat exchangers, or by improving the operating conditions due to the flexibility in thermophysical properties. Moreover, due to the presence of azeotropic behavior in the vapor-liquid equilibrium, these binary mixtures are also interesting for applications with no temperature glides. For applications where the temperature glides of the binary mixture cannot be matched with the secondary fluids, some authors even propose heat pump cycles with a variable mixture composition regulation, so that a satisfactory temperature match can be achieved in both condenser as evaporator [16], [17]. Nevertheless, the increase in COP for such cycles may not outweigh the additional cost. The only region where binary mixtures operating in the subcritical region are less interesting, is for applications with large temperature glides at the heat sink side. In such scenarios, pure fluids operating in the transcritical regime are the most favorable. In addition, in event of large temperature glides, zeotropic mixtures may experience fractionation and composition shift [18]. Furthermore, the results shows that there is a mismatch between thermodynamic and financial optima. The financially optimal working fluids do not have the highest COP. Furthermore, the best performing working fluid does also not have the lowest investment cost.

For the best performing working fluids reported in this work, the financial performance could be analyzed in more depth by (re)considering the following aspects:
1. The assumption of a fixed heat transfer coefficient. This assumption is particularly favorable for zeotropic mixtures, as these may experience a degradation of heat transfer [18]. Nevertheless, the breakdown of the LCOH showed that the contribution of the heat exchangers with respect to the total LCOH is often small.
2. The cost of the refrigerant, especially synthetic refrigerants shows to be more expensive [20].
3. The influence of material compatibility or pressure on the equipment costs.
4. The off-design behaviour.
5. An isentropic compression efficiency, which depends on the properties of the working fluid [21].
6. Influence of costs related to ATEX compliance.

In addition, there is a clear dependency of the results towards the considered financial boundary conditions reported in Table 4. Arpagaus et al. [22] showed that the electricity costs and operating hours in particular have a large impact on the LCOH, and thus could influence the most optimal heat pump cycle from a financial point of view. A sensitivity of the selection matrix towards these parameters could be included in future work.

5. Conclusion

A financial framework, able to optimize the LCOH of a heat pump is developed. This framework is used to give a preliminary indication of the financial appraisal for a broad range of pure fluids and binary mixtures. The model is applied to a large set of generic data.

The results show that there is a discrepancy between optimum COP and optimum LCOH. Consequently, selection of a refrigerant just based on maximal COP, may lead to a sub-optimal financial solution. Moreover, the selection matrix shows the optimal working fluid strongly depends on the boundary conditions. However, binary mixtures of natural refrigerants (hydrocarbons, ammonia and water) showed to be (near) optimal for a large range of boundary conditions. The potential of these mixtures is twofold: the COP can be improved by temperature matching in event of zeotropic mixtures and mixing working fluids allows for more advantageous operating conditions (e.g., lower compression ratio or lower volume flow rate).

High Efficiency Heat Pump Industrial Drying with Water Vapor-Selective Membranes

Andrew J. Fix, James E. Braun, David M. Warsinger*

Purdue University, School of Mechanical Engineering & Herrick Laboratories, 585 Purdue Mall, West Lafayette, IN 47907

Abstract

Convective drying processes consume a significant amount of energy within the industrial sector. Heat pump-based drying processes are gaining attention as a potential technology for enabling efficient, electricity-driven drying for various applications. In this work, we propose a new heat pump drying system concept that employs water vapor-selective membranes for active control of the air humidity in drying processes, termed the MemDry system. We developed system-level models for the MemDry and representative baseline systems based on the first and second laws of thermodynamics to explore energy trends and limitations of the concept. It was found that energy savings on the order of 30-40% are possible when high temperature, low humidity conditions are required for the drying process. Furthermore, membrane dehumidification could theoretically reduce required drying temperatures by 10-20°C while still saving energy. The unique design of the MemDry system and its use of exhaust air condensation may improve heat pump COPs by as much as 2x. This theoretical work shows that the MemDry concept has significant potential to provide efficient, feasible, and controllable conditions for industrial heat pump drying applications.

Keywords: selective membranes; dehumidification; drying; Carnot; high temperature; thermodynamics; heat pump

1. Introduction and Background

1.1. Convective Drying Technologies

It has been estimated that thermal dehydration technologies account for anywhere between 10-20% of industrial energy consumption in developed countries [1]. Convective drying is one of the most common types of drying technologies, employed in drying food, pharmaceuticals, fabrics, chemicals, and more. Another common application for convective drying is residential clothes dryers, which constitute 3% of residential energy consumption [2]. Currently, industrial drying processes rely heavily on the combustion of fossil fuels [3]. More recently, there has been increased interest in moving away from combustion-based drying technologies, in favor of heat pump drying technologies [4].

Many different configurations and combinations of heat pump drying technologies have been proposed, including air-source [5], ground-source [6], solar assisted [7], chemical heat pumps [8], various forms of energy recovery, and more [4]. However, in their simplest form, the two categories of heat pump dryers are closed and open systems. Open dryers pull in ambient air, heat it up, send it to the drying process, and then simply exhaust the warm and humid air that leaves the drying process. In a closed heat pump dryer, instead of exhausting the warm and humid air leaving the drying process, it is instead passed through the vapor compression cycle’s evaporator to condense water out of the air and is then reheated and recirculated [9].

Open heat pump systems can achieve high efficiency performance if the ambient conditions are very low humidity, but otherwise may be limited by the ambient conditions [3]. On the other hand, closed systems are not as dependent on the ambient conditions but must spend a considerable amount of energy condensing water...
out of the air. Conventional air conditioning technologies experience similar energy penalties when dealing with humidity [10]. Generally, closed heat pump dryers are more common in the literature, but even open systems could benefit from pre-dehumidification technologies. Thus, there is a need to identify innovative solutions to address the energy demands associated with air dehumidification in heat pump drying processes.

1.2. Water Vapor-Selective Membranes for Air Dehumidification

Recently, water vapor-selective membranes have gained interest in air conditioning research [11]. Conventional air conditioning technologies rely on cooling the air below its dew point to induce condensation dehumidification, and condensing water vapor requires a significant amount of energy [12]. Instead of relying on energy-intense phase-change dehumidification, selective membranes can mechanically separate water vapor out of air, which can save energy input depending on the system design [12], [13].

Most membranes used for air dehumidification are referred to as “dense” membranes [14]. For dehumidification membranes, a dense (non-porous) hygroscopic material, usually a polymer, is coated onto a support material. Because this hygroscopic layer is non-porous, air cannot easily penetrate, though the hygroscopic nature of the layer enables water vapor to transport across via the solution-diffusion process [15]. Some high-performance membrane materials for dehumidification include Pebax 1657 combined with graphene oxide [16], polyvinyl alcohol combined with triethylene glycol [17], and cellulose [19].

The two important performance metrics for the membrane materials are the permeance to water vapor and the air selectivity. The water vapor permeance simply describes the membrane’s ability to pass water vapor. The air selectivity describes how well the membrane blocks air transport and is generally taken as the ratio of the water vapor permeance to the air permeance. Optimal membranes achieve both high selectivity and water vapor permeance. Top performing membranes generally achieve water vapor permeance on the order of 1,000-5,000 GPU, and selectivity up to 10,000 [16], [17]. However, the analysis in this work will provide high-level thermodynamic insight into the application of membrane dehumidification in industrial drying applications in a manner that does not rely on knowing or assuming values for these membrane material properties.

1.3. Scope and Novelty

While thermodynamic modeling for vacuum membrane dehumidification has been carried out extensively for air conditioning applications [13], [20]–[22], little-to-no work has been done in the field of industrial heat pump drying. This work, to the best of our knowledge, is the first to propose a hybrid membrane dehumidification and heat pump system configuration for efficient industrial drying applications. This analysis provides an introduction to the concept and explores the potential energy benefits through high-level, thermodynamic models that employ both theoretical and practical assumptions. The results provided in this paper will serve as a basis for further detailed modeling and prototyping efforts and can help establish a new sub-field within the heat pump and membrane research communities.

2. System Descriptions

2.1. Membrane Dehumidifier and Heat Pump Dryer System Description

In this work, we will refer to the system that combines membrane dehumidification and heat pump drying as the “MemDry” system. The left half of Figure 1 depicts the flow schematic of the MemDry system. Starting at State 1, relatively warm, saturated (100% relative humidity) air leaves the drying process and enters the dehumidification membrane module. A water vapor compressor maintains a low water vapor partial pressure on the top (permeate) side of the membrane at State 7 [23]. This difference in water vapor partial pressure draws humidity out of the drying process exhaust air while requiring no heat transfer. Then, the dry air at State 2 is reheated before being sent back to the drying process. The humidity that was removed between State 1 and State 2, is then slightly pressurized by the water vapor compressor to the second membrane module at State 8 and rejected across a membrane to the ambient air at State 4 [24].

The humid air at State 5 then passes through the evaporator of the vapor compression cycle, where heat is absorbed for reheating the process air (States 2 to 3). Condensing water vapor in this exhaust air is beneficial, as a significant portion of the heat transfer will come from the latent heat of vaporization. This means that, under certain conditions, warmer evaporator temperatures can be used, resulting in higher heat pump COPs. Plus, heat pump capacity requirements are lower, meaning smaller heat pump systems can be implemented.
2.2. Baseline Heat Pump Dryer System Description

In the baseline closed heat pump dryer system, shown in Figure 1 (right), State 1 and State 3 are identical to those states in the MemDry system. However, the relatively warm and humid air at State 1 is cooled to a lower temperature to induce condensation dehumidification. In this work, we model both systems such that the absolute humidity at State 2 is equivalent between both systems. But, because the air was cooled to induce condensation dehumidification, a significant amount of reheating must be provided by the condenser. While the condensation will provide a significant source of heat transfer in the baseline system as well, it is not strictly beneficial (as it is in the MemDry system) since it induces significant reheating requirements and lower evaporator temperatures are needed to maintain the desired humidity levels. Additionally, the condenser rate of heat transfer will be higher than the evaporator, so in order to maintain an energy balance within the drying process flow, an auxiliary condenser would be included to reject excess heat to an ambient air stream [2]. Figure 2 provides a sample psychrometric plot of the thermodynamic states in the two drying systems.

Figure 1. System schematics. (left) Membrane dehumidifier and heat pump dryer system schematic, referred to herein as the MemDry system. (right) Baseline, closed heat pump drying process.

Figure 2. Sample psychrometric process plot showing the thermodynamic states within the drying cycle specific to the baseline system (green), MemDry system (pink), and shared isenthalpic drying process (blue). The supply temperature is shown as 75°C as an example.

3. Modeling Methodology

3.1. Modeling Overview

The models developed in this work are system-level, steady-state thermodynamic models based on a first-law analysis. Specific components are not modeled in detail (e.g., membrane area, heat exchanger area, membrane properties are not included in the model). This will become clear as the model is derived in the following sections. The models were developed in Engineering Equation Solver (EES), which is an iterative
solving software with built-in thermodynamic property functions for many fluids, including humid air [25]. Furthermore, some portions of the model were first replicated from prior published drying technology models before extending the framework to the MemDry system to ensure reasonable assumptions for the model. Overall, the intent of these theoretical models is to capture performance trends for the systems with both highly idealized assumptions and more practical assumptions and to assess key benefits and limitations.

### 3.2. Convective Drying Process Model and Validity

The convective drying process is modeled the same way for both systems in this work and is assumed to be a relatively ideal drying process. The supply temperature, \( T_3 \), and supply dew point temperature, \( T_{DP,3} \), are set as inputs for most of the analyses. The supply dew point temperature is used as the metric for setting the dryer inlet humidity condition for convenience, as this will be directly tied to the evaporator temperature in the baseline system shown later. Thus, the inlet conditions, including the inlet humid air enthalpy, \( h_3 \), are known. To determine the dryer outlet conditions, we assume an ideal dryer where the drying occurs adiabatically (constant enthalpy) and the air leaving the drying process reaches 100% relative humidity [2]. These two critical assumptions are given by Equations 1 and 2.

\[
h_1 = h_3 \tag{1}
\]
\[
RH_1 = 100\% \tag{2}
\]

Thus, the inlet and outlet humid air conditions are known. In this work, a specific drying process is not explicitly modeled (conveyor drying, batch drying, etc.) Furthermore, we do not consider any dynamic behavior associated with the type of material being dried, thermal mass, or the change in drying rate as the water content changes in the product material. Similar simplifications have been made in other works and are justified here since the focus is on providing a comparative analysis between two heat pump technologies meeting the same theoretical drying load. Models from prior published work [2] were obtained for comparing inlet and outlet temperature conditions for different scenarios. It was found that the maximum error between our model and the prior model’s temperature calculations was less than 1%, giving confidence that our drying process model was consistent with other works.

### 3.3. Vapor Compression Cycle Model

Both the MemDry and baseline systems incorporate a heat pump for process air heating. Due to the high temperature lift in this application (up to 130°C in some cases), a more complex cycle architecture would be needed to achieve competitive COPs. However, this work focuses more on the comparison of the MemDry system to the baseline system, emphasizing the benefits of membrane dehumidification. So, to simplify the modeling of the vapor compression cycle energy requirements, two sets of results are presented. One set of results looks at the most ideal scenario and applies Carnot COPs to evaluate energy input requirements for the heat pumps. The Carnot cooling COP and heating COP, based on the thermodynamic states in the baseline system, are given by Equations 3 and 4, respectively.

\[
COP_{Carnot,C} = \frac{T_2}{T_3 - T_2} \tag{3}
\]
\[
COP_{Carnot,H} = \frac{T_3}{T_3 - T_2} \tag{4}
\]

Similar equations can be applied to the MemDry system but replacing \( T_2 \) with \( T_6 \). The second set of results that are presented apply a second law efficiency (\( \eta_{II} \)) to estimate real vapor compression cycle COPs for high temperature lift applications. Based on a review of detailed modeling efforts for high-temperature heat pumps employing two stage compression with some form of economization, it was found that the second law efficiency was around 0.40 across a broad range of conditions [26], [27]. The “practical” results in this work apply this second law efficiency to the Carnot COP to estimate “real” COPs, shown in Equation 5.

\[
COP = COP_{Carnot} \times \eta_{II} \tag{5}
\]
Thus, the vapor compression cycle performance can be reasonably captured using the straightforward framework to compare the two systems and assess the benefits of adding membrane dehumidification.

### 3.4. Baseline Heat Pump Dryer System Model

Since the drying process is modeled identically in both systems, the remaining model derivations will focus on the portions of the two systems that remove humidity from the process air and reheat the process air.

#### 3.4.1. Evaporator Energy Balance

The primary purpose of the evaporator in the baseline system is to provide dehumidification to the process air before it is reheated and sent back into the drying process. The temperature of the air at State 2 is used as an input or is varied in some of the following analyses. Since the air at State 1 is 100% relative humidity, State 2 will also be 100% relative humidity. The air-side energy balance on the evaporator in the baseline system is then given by Equation 6.

\[
\dot{Q}_{\text{evap,b}} = \dot{m}_a(h_1 - h_2 - (\omega_1 - \omega_2)h_w)
\]  

(6)

Here, \(\dot{m}_a\) is the mass flowrate of air (on a dry basis) in the drying cycle, \(h\) represents the enthalpy of humid air, \(\omega\) is the air humidity ratio, and \(h_w\) is the enthalpy of liquid water. In a steady state vapor compression cycle, the evaporator heat transfer rate is always less than the condenser heat transfer rate. So, we know that if the latent load is met by the evaporator, we will have sufficient (actually excess) heat available to reheat the process air in the condenser. Thus, the power consumption for the baseline heat pump system is based on the evaporator load, given by Equation 7 [28].

\[
W_b = \frac{\dot{Q}_{\text{evap,b}}}{COP_c}
\]  

(7)

Here, \(COP_c\) is the cooling coefficient of performance and can either be the Carnot COP (\(\eta_{II} = 1\)) or practical COP (\(\eta_{II} = 0.4\)), depending on the result being presented.

#### 3.4.2. Condenser Energy Balance

Based on an energy balance for a vapor compression cycle, we can calculate the heat transfer rate in the condenser (\(\dot{Q}_{\text{cond,b}}\)) according to Equation 8.

\[
\dot{Q}_{\text{cond,b}} = W_b + \dot{Q}_{\text{evap,b}}
\]  

(8)

The actual heat transfer rate required for reheating the process air (\(\dot{Q}_{\text{heat,b}}\)) from State 2 to State 3 is given by Equation 9.

\[
\dot{Q}_{\text{heat,b}} = \dot{m}_a(h_3 - h_2)
\]  

(9)

The enthalpy at State 2 (\(h_2\)) is known based on the set temperature and knowing the relative humidity is 100%, and the enthalpy at State 3 (\(h_3\)) is known based on the set drying temperature (\(T_3\)) and knowing that \(\omega_3 = \omega_2\). As discussed before, excess heat is available on the condenser side of the vapor compression cycle due to the energy balance, therefore, the heat transfer rate in the auxiliary condenser is given by Equation 10.

\[
\dot{Q}_{\text{aux}} = \dot{Q}_{\text{cond,b}} - \dot{Q}_{\text{heat,b}}
\]  

(10)

### 3.5. MemDry System Model

For the MemDry system, the vapor compression cycle is implemented slightly differently, requiring different energy balances, and the membrane dehumidification portion of the system model must be presented.

#### 3.5.1. Membrane Dehumidification Governing Equations

Air leaving the drying process at State 1 enters the membrane module. In order to fairly compare both systems in this analysis, the dew point temperature at State 2 (\(T_{DP,2}\)) is equivalent in both systems for all analyses. This dew point temperature has an associated humidity ratio (\(\omega_2\)) and water vapor partial pressure...
Thus, \( P_{v,2} \) is known/set in the model. The low vacuum vapor pressure \( (P_{v,7}) \) required to meet this dehumidification load is set based on a given pinch point vapor pressure difference \( (\Delta P_{v,pinch}) \). Thus, \( P_{v,7} \) can be calculated according to Equation 11.

\[
P_{v,7} = P_{v,2} - \Delta P_{v,pinch}
\]

Estimating vacuum vapor pressure in this manner is analogous to estimating vapor compression cycle evaporator or condenser temperatures based on assumed pinch point temperature differences. In this work, we use a pinch vapor pressure difference of 0.5 kPa for the practical scenarios, falling in the range analyzed by [21], and 0 kPa for the ideal scenarios, representing a mass exchanger with 100% effectiveness. State 7 and State 8 are both assumed to be pure water vapor, which implies that the membranes are perfectly selective. This assumption has been applied in many modeling works for assessing theoretical thermodynamic energy requirements of the technology [20], [21]. The mass flowrate of water vapor removed in the dehumidification process is given by Equation 12.

\[
\dot{m}_v = \dot{m}_a(\omega_1 - \omega_2)
\]

Next, we assume that when the water vapor is rejected to the exhaust air, the relative humidity is brought to 90% at State 5. With this assumption, a mass balance can determine the exhaust air flowrate \( (\dot{m}_{a,ex}) \) needed to achieve this condition.

\[
R H_5 = 90\% 
\]

\[
\dot{m}_v = \dot{m}_{a,ex}(\omega_5 - \omega_4)
\]

Now, knowing the water vapor partial pressure at State 5, the rejection side water vapor partial pressure, \( P_{v,8} \), can be calculated using the same pinch point vapor pressure difference as before.

\[
P_{v,8} = P_{v,5} + \Delta P_{v,pinch}
\]

3.5.2. Condenser Governing Equations

The membrane dehumidification process is assumed to be isothermal \( (T_2 = T_1) \). Therefore, the condenser energy balance is simply given by Equation 17.

\[
\dot{Q}_{cond,M} = \dot{m}_a(h_3 - h_2)
\]

The power consumption of the water vapor compressor is calculated by assuming an isentropic efficiency, as shown in Equation 16 [22], [28].

\[
W_{WVC} = \dot{m}_v h_{v,7} - h_{v,8s} \eta_{WVC}
\]

Here, \( h_{v,7} \) is the enthalpy of water vapor at a pressure of \( P_{v,7} \) and a temperature of \( T_1 \). \( h_{v,8s} \) is the enthalpy of the water vapor at a pressure of \( P_{v,8} \) under isentropic compression from State 7. \( \eta_{WVC} \) is the compressor isentropic efficiency, taken as 1 for the ideal scenarios and 0.7 for the practical scenarios [22].
3.5.3. Ambient Air Evaporator Governing Equations

As was stated previously, the ambient air evaporator makes use of the condensation to enable higher evaporating temperatures and therefore higher vapor compression cycle COPs. By assuming that $\frac{RH_6}{RH_5}$ is set at 100% (since $\frac{RH_5}{RH_6}$ is set at 90%), $T_6$ is calculated iteratively by three coupled equations (Equations 3, 19, and 20). Essentially, the condenser load ($\dot{Q}_{\text{heat},M}$) is set, the evaporator load depends on the heat pump COP, which depends on $T_6$ (which is dependent on the energy balance in Equation 20). Thus, three unknowns ($\dot{Q}_{\text{evap},M}$, $T_6$, and $COP_c$) are solved iteratively by the EES software.

$$\dot{Q}_{\text{evap},M} = m_{a,ex}(h_5 - h_6 - (\omega_5 - \omega_6)h_w) \quad (19)$$

$$\dot{Q}_{\text{evap},M} = \dot{Q}_{\text{cond},M} - W_{\text{cond},M} \quad (20)$$

Having determined $T_6$, the latent heat ratio on the evaporator can be expressed according to Equation 21.

$$LHR = \frac{m_{a,ex}(\omega_5 - \omega_6)h_f}{\dot{Q}_{evap,M}} \quad (21)$$

Additionally, the framework can be modified to assess the value of $T_6$ if no latent heat was available, which can then be used to estimate the heat pump COP when no latent heat is available, as will be shown later.

3.6. Key Performance Metrics

Several performance metrics will be evaluated in this work. The first is the energy savings. The energy savings metric simply compares baseline system power consumption to the MemDry power consumption. The baseline power consumption is simply equal to the vapor compression cycle power consumption. The MemDry total power consumption is given by Equation 22.

$$W_M = W_{\text{WVC}} + W_{\text{cond},M} \quad (22)$$

In both systems, fan power consumption is not included in the current models. This would be specific to the system design and is therefore outside the scope of this high-level analysis. Instead, we are more concerned in evaluating the fundamental thermodynamic requirements of heating and dehumidification in the two systems. Next, the drying efficiency relates the latent heat removal rate of the drying process divided by the total system power input, represented generally by Equation 23 [2], [29].

$$\eta_d = \frac{m_a(\omega_3 - \omega_1)h_f}{W_{\text{sys}}} \quad (23)$$

Here, $W_{\text{sys}}$ generically represents the total system power consumption for either system (either $W_b$ or $W_M$). The drying time ($t_{\text{dry}}$) represents the time to remove all of the water from a product. The mass of water in the product to be dried ($m_{w,p}$) can be set arbitrarily, and then for a given dry time and drying conditions, the air flowrate ($m_a$) can be calculated iteratively by the model.

$$t_{\text{dry}} = \frac{m_{w,p}}{m_a(\omega_3 - \omega_1)} \quad (24)$$

In the analyses of this work, $m_a$ is set at 0.0646 kg/s and $m_{w,p}$ is set at 2.05 kg based on typical clothes drying applications [2]. Of course, the eventual application for this technology is focused on industrial drying, through these clothes drying conditions provide a test case to study the thermodynamics.

4. Results and Discussion

The following results explore the thermodynamic performance of the MemDry concept and compare it to the baseline heat pump system. As has been alluded to in the prior sections, two sets of results are presented in this section: one for the “ideal” scenario and one for a “practical” scenario. Table 1 summarizes the model inputs for these two scenarios.
4.1. Energy Savings Over Baseline System

First, the energy savings of the MemDry system compared to the baseline heat pump drying system are evaluated. Figure 3 displays the energy savings for the ideal scenario, and Figure 4 displays the energy savings for the practical scenario.

A few interesting trends can be noticed from these plots. First is that energy savings are generally higher for drying applications with high drying temperatures. As drying temperature increases, the dehumidification load increases exponentially, and reheating energy requirements increase linearly. Since membrane dehumidification specifically targets improving the energy input associated with the humidity loads, it is expected that greater energy savings would be achieved when these humidity loads become more significant. Also, as the ambient humidity ratio increases (increasing temperature at constant relative humidity) the energy savings decrease because the water vapor compressor must pressurize the water vapor to a higher pressure in order to reject it, thus requiring more power input.

In Figure 3a and Figure 4a, it appears as though the “ideal” MemDry system (Figure 3) achieves less energy savings than the “practical” MemDry system (Figure 4) in some conditions, however this is only

Table 1. Summary of the model inputs for the ideal and practical scenarios

<table>

</tbody>
</table>
because the ideal MemDry system is compared against an ideal baseline system in Figure 3a (both with 100% Carnot efficiency). When practical operating conditions are imposed in Figure 4, the MemDry system does achieve higher savings relative to the baseline system than it did under the ideal operating scenario in Figure 3a because the membrane dehumidification helps alleviate the practical inefficiencies associated with condensation dehumidification in the baseline system that are less pronounced under ideal conditions.

Additionally, for a given drying temperature, an optimal dryer inlet dew point temperature (for the practical scenario) will exist, shown by Figure 4b. At sufficiently low inlet dew point temperatures, very low vacuum pressures are required to achieve this inlet dew point, and therefore the MemDry system achieves lower energy savings. Furthermore, at high inlet dew point temperatures, vapor compression cycles will have a high COP, and therefore the energy savings of membrane dehumidification become less pronounced.

Lastly, the MemDry is not suitable for low-temperature applications with high dryer inlet dew point temperatures (shown by the negative energy savings in the top left of Figure 3b and Figure 4b). In these scenarios, humidity loads would be relatively small and heat pump COPs would be very high, negating the need for energy efficient membrane dehumidification. However, these conditions are not conducive for convective drying and are therefore not likely to be used in many applications.

4.2. MemDry Evaporator Enhancement from Condensation

Next, the enhancement from air-side condensation in the MemDry evaporator is quantified. To clarify this concept, a certain amount of heat must be absorbed by the evaporator to sufficiently reheat the air in the condenser. Without condensation from State 5 to State 6, the evaporator would need to impose a large temperature change to the exhaust air stream. This in turn would mean that lower evaporator temperatures would be required, lowering the heat pump COP. But, with a substantial amount of the evaporator heat being pulled from the condensation process, less temperature change (sensible cooling) is provided to the exhaust air. Therefore, higher evaporator temperatures and higher COPs can be achieved when latent heat is available. The COP assuming no latent heat is available is denoted as \( \text{COP}_{\text{dry}} \), whereas the COP with available latent heat is denoted \( \text{COP}_{\text{wet}} \) in this section.

![Figure 5. Evaporator latent heat fraction (left axis) and heat pump COP improvement ratio (right axis) as a function of the ambient air temperature for both ideal and practical scenarios. \( T_3 = 100^\circ\text{C} \) and \( T_{DP,3} = 10^\circ\text{C} \). Ambient humidity was constant at 40% RH.](image)

For the conditions analyzed in Figure 5, we showed that the latent heat fraction ranged between 0.5 to 0.8. As the LHR increased and the evaporator temperature increased, the heat pump COP could be nearly doubled. Compounding this improved heat pump COP with the lower heating loads and efficient membrane dehumidification, the MemDry concept has great potential to provide significant savings.

4.3. MemDry System Drying Efficiency

Next, we evaluate the drying efficiency, defined by Equation 23, in Figure 6. The drying efficiency is evaluated as function of the drying temperature and inlet dew point temperature for a set ambient condition. As can be seen in Figure 6, the ideal drying efficiency ranges between 3-10 whereas in the practical scenario, the drying efficiency ranges between 0.8-3. A drying efficiency greater than 1 implies that the specific energy input for drying was less than the enthalpy of vaporization for water. A drying efficiency of 1 should be considered the minimum acceptable efficiency. The range of drying efficiencies below 1 in Figure 6a occur
where the heat pump supply temperature is very high (high heat pump energy input and low heat pump COP) and the inlet dew point temperature is low (requiring significant energy consumption from the water vapor compressor). This represents a rather extreme application/condition, though it is important to recall that, even though the drying efficiency dips below 1, the energy savings would still be positive relative to the baseline system. Some combination of heat pump heating and resistive heating could potentially bring this drying efficiency closer to 1. Additionally, for a constant dryer temperature, higher inlet dew point temperatures yield a higher drying efficiency, but the drying time will also increase since the air cannot remove as much humidity due to the higher inlet air humidity. Drying time is considered in the next section.

4.4. Drying Temperature Reduction

Lastly, we evaluate the impact that the dryer inlet dew point temperature has on the required inlet dryer temperature. The inlet dryer temperature ($T_3$) is plotted as a function of the dryer inlet dew point temperature for a constant drying time in Figure 7. Essentially, as the inlet to the dryer becomes more humid (higher dew point temperature), a higher drying temperature ($T_3$) is required to compensate and maintain a constant drying time.

As can be seen, reducing the dryer inlet dew point temperature could lead to drying temperature reductions on the order of 10-20°C. This is important for the technology because, achieving exceptionally high temperatures for drying with heat pumps can be challenging. However, if the goal is to electrify many drying processes, reducing inlet humidity conditions with membrane dehumidification can enable lower dryer temperatures (attainable with heat pumps) without sacrificing drying time. Plus, compared to the baseline heat pump system providing the same supply and dew point conditions, the MemDry system may provide energy savings on the order of 20-25% for lower inlet dew point temperature conditions.
5. Conclusions

In conclusion, this work has presented a novel system concept, termed the MemDry system, that combines selective membrane dehumidification with a heat pump for industrial drying applications. The theoretical models were used to explore energy savings and efficiency trends, relative to a baseline heat pump drying system modeled under an identical set of assumptions for fair comparison. It was found that, for the conditions analyzed, up to 40\% energy savings could be possible, and negative energy savings are also possible under some extreme conditions. The vapor compression cycle COP can be improved by almost 2x due to the available latent heat in the evaporator for the MemDry, marking a unique advantage to the clever thermal system design. The drying efficiency was found to range between 3-10 under ideal conditions and 0.8-3 under more practical conditions. Furthermore, drying temperatures could be reduced by 10-20℃ while maintaining equivalent drying times and saving up to 25\% of the energy input for drying. Overall, the concept shows great potential to offer significant energy savings and process control for industrial drying applications. Future work will focus on prototype development, detailed model development, and detailed model validation.

Case Study of the Largest Air Source Heat Pumps Central Heating Project in China

Zhao Mishen, Wang Huping, Zhao Hengyi, Xie Sherry, Ni Long

Abstract

This paper summarizes the best practices for Air Source Heat Pump (ASHP) central heating systems in large-scale residential buildings. Central heating of residential buildings in northern China typically depends on coal-burning power plants, which are the main sources of reducing such pollution as well as carbon emissions. The project described in this paper is one biggest ongoing ASHP heating projects in the world. More than 1,200 units of ASHPs were deployed as heating sources in northern China, heating approximately 4 million square meters of living spaces in large residential buildings. Various parameters were monitored and collected over about 120 days during the heating season from 2019 to 2020. Operating costs and carbon dioxide emissions were measured and compared to the corresponding figures for equivalent heating by other systems. It is demonstrated that ASHP systems are well suited for meeting the heating requirements of this region while reducing operating costs and greenhouse gas emissions.

Keywords: air source heat pump, large scale central heating project, carbon reduction.

1. Introduction

The heating project in Zhao County is located in Hebei province, north China, it is a typical cold winter area, and space heating in winter is managed by the government. The heat source that came from two coal-burning power plants caused serious air pollution significantly. In 2019, the local government decided to replace the coal-burning power plants with ASHP to reduce running cost and air pollution. Therefore, 1,200 ASHP units (input power is 60HP for each) are used for a 4.07 million square meters heating area; the terminals in the buildings are radiator and floor heating. The operation data of the 2018-2019 heating season provide favorable support for the heating system renovation. To fit the existing heating pipe network the whole heating project is designed to build 42 distributed air source heat pump stations with the 1200 units ASHP for heat supply. The old heating pipe network consists of two coal-fired power plants (A and B) as shown in Fig. 1(a), and the ASHP heating stations as shown in Fig. 1(b). Fig. 2 illustrates the Beling temple station and the Lichun station with ASHP units.

For large-scale ASHP projects, multiple sets of units placed together will impact the performance of the unit is a big problem. In the Zhao County project, many sites faced this challenge. There are also many other factors that affect the sites of the air source heat pump heat source selection, distributed heat source arrangement for the urban heating project is recommended to minimize the heat loss of the pipe network.

2. Project overview

2.1. The system configuration scheme

The heat load of this project was calculated using the real-time calculation method (secondary stations with monitoring conditions) and the area index method (secondary stations without monitoring conditions). The average heat load during the heating period was calculated to be 137.9 MW. Combining with the heating load and development of the urban area of Zhao County and the fuel characteristics, 1200 ASHP units (120 KW of heat production per unit under heating condition) were selected for this project, and the development end was reserved in the heat source to meet the demand of future heating heat load growth. Low temperature water was adopted as the heating medium, with the supply and return water temperature of 55 °C/45 °C at the end of radiator and 45 °C/35 °C at the end of floor heating. The system configuration scheme of a station is shown in Fig. 3. Considering factors such as system drainage, the make-up water rate of this project was taken as 1%-2%, and the make-up water pump was used for variable frequency continuous pressure fixing.
2.2. The system operation scheme

The system adopts group control automatic management, which can realize to present the site water temperature and operation status of heat pump unit on the computer and cell phone, and also adjust the site parameters and remote switch operation. As shown in Fig. 4, the low-temperature hot water produced by the air source heat pump is transported to the heat users through the pipeline, and the whole heating process is monitored in its entirety.

3.2. The unit performance analysis

Based on the Fig.4 scheme, the monitoring data of the key parameters for corresponding systems such as outside ambient temperature, humidity, total electric energy consumption, transient flow rate of the heating water, and total flow rate of the heating water, the temperature of inlet and outlet water, the pressure of inlet and outlet water, the water pump running status and so on.

The heating capacity of the unit is calculated according to Eq. (1).

\[
Q = \frac{c\rho}{3600}V(t_s - t_h)
\]  

(1)

Where, \(Q\) is the heating capacity of the unit, \(\rho\) is the density of the water, \(V\) is the water flow rate, \(t_s\) and \(t_h\) are the supply and return water temperature, respectively.
The heat dissipation of the cable comes from the heat loss of the current-carrying conductor. The single cable power loss can be calculated according to Eq. (2).

\[ Q' = \frac{I^2 R}{A} \]  

(2)

Where, \( Q' \) is the power loss, \( I \) is the cable current flow, \( A \) is the cable cross-sectional area, and \( R \) is the resistance value per meter of cable.

The coefficient of performance (COP) of the unit is calculated by Eq. (3).

\[ COP = \frac{Q}{W} \]

(3)

Where, COP is the coefficient of performance of the heat pump unit, \( W \) is the power consumption of the heat pump unit.

The key operating parameters of the system and the performance of the unit are shown in Table 2.

Table 2 The key parameters and the COP for a unit in the 5 stations.

3.3. Air source heat pump for low ambient zone space heating

Air source heat pumps for heating in cold areas will face many challenges for efficiency and reliability, vapor injection technology for compressors of ASHP unit is a solution to resolve these issues. According to the winter climate record data of Zhao County, the lowest ambient temperature goes to -15 ℃.

Vapor inject technology brings great benefits for ASHP heating in cold ambient conditions. According to the lab test result by Emerson Climate technology, it shows 21% - 40% heating capacity improvement and 7% - 22% efficiency improvement. (Table 4)

<table>

Vapor injection technology also can improve the reliability of the heat pump unit, it allows the system to be used in a -30°C ambient area and deliver high enough temperature water even for radiators. The envelop of the compressor in Figure 7 shows the improvement.
4. Heating project optimization

The project is large in scale, short in the cycle, complex at the end, and diverse in construction conditions. How to accurately divide district heating in a complex on-site environment, how to solve the cold island effect and ensure that the selected air source heat pump can exert its maximum performance, how to solve the noise problem, how to achieve the pre-designed control effect, etc. are very critical to ensure that the overall project can meet the requirements of high efficiency, stability, and energy saving. According to the actual specific situation, from design to product, the manufacturer New Energy has repeatedly improved, tested, adjusted, and optimized the unit and the installation.

4.1. Equipment performance matching and tuning optimization

- Environmental climate is a key factor affecting the use of air-source heat pumps, which determines the initial investment and operating costs of the project, as well as the performance advantages of ASHP. At the beginning of the project design, the historical climate and environmental characteristics of Zhao County were investigated, and make the analysis of the data as shown in Fig. 6.

- “Cold Island” effect in the large ASHP heating project is a common issue if the air circulation around the ASHP units is not optimized. In order to ensure the good circulation of the air around the units, all the stations have been designed as frame structures with a height of above about 8 meters from the ground, so that the cold air from the units will flow to bottom and other open spaces. Besides, the layout of the units in each station is in line and has a max. 2 or 3 units in the row direction. In this way, the cold island effect in the project is avoided. Refers to Fig. 2.

4.2. Noise reduction

Large scale ASHP heating project could have higher noise for the environment. It is important of sound reduction for this heating project. Sound insulation wall (Fig. 8) is installed on field to reduce the noise impact.

Fig. 8. Noise insulation wall.

4.3. Radiator and floor heating combination

To get same heating performance from the terminals, the water temperature in the radiator will be higher than in floor heating. The hot water temperature leaves the radiator still is high enough for floor heating. But the water quantity for floor heating is bigger than the radiator. Some additional equipment and pipe are needed to balance the water system. Fig. 9 shows the scheme of the combination of the radiator and floor heating.
4.4. System control

Heating load is determined by ambient temperature and residential behavior, it means the heating capacity requirement constantly changes. The management of 1,200 units ASHP with a higher system performance is important for energy saving. With IoT technology, depending on the temperature of outlet water and return water, automatically adjust the ASHPs for a better system efficiency. Fig. 10 shows the scheme of system control and interface.

5. The economic and environmental analysis

5.1. Economic calculation

According to the statistical data from the monitoring system of the whole project, the total electric energy consumption in the heating season of 2019-2020 is 100.37 million kWh in the project. The average electrical energy consumption is 30.88 kWh per square meter. The detail data for economy calculation is as in Table 5.
Table 5 economy calculation for a heating season of 2019-2020.

In the same project, about 220k square meter area lack of electrical power is heated with gas boilers. The average heating cost of the area is 27.27 CNY/ m² for the heating season 2019-2020, more than twice of ASHP heating cost.

5.2. Cost saving

Total actual heating area in 2019-2020 heating season is 3.25 million square meters, according to the data recorded in cloud, comparing with another heating project with gas boiler that located in Zhao County as well, the running cost has more than 50% saving. Table 6 shows the comparison:

5.3. CO₂ emission reduction

Air source heat pump is recognized as a green technology which can collect heat energy in the air to heat indoor space. It can reduce the CO₂ emission by replacing coal boiler. Comparing with gas boiler, the running cost is lower.

Ambient temperature has great impact on the ASHP efficiency, according to the climate bin data of Zhao County and the COP of ASHP under different ambient temperature, the average COP is 2.93 for whole heating season. Fig. 11 shows the detail data of ambient condition of Zhao County and COP of ASHP.

Fig.11. Climate bin data of Zhao County and COP of ASHP.
CO₂ emission comparing with coal boiler is show in Table 7, based on standard coal, ASHP can reduce around 38% CO₂ emission.

<table>
<thead>
<tr>

<td>17584 kJ/kg</td>
</tr>
<tr>
<td>CO₂ emission per kJ</td>
<td>0.095 g/kJ</td>
<td>0.154 g/kJ</td>
</tr>
</tbody>
</table>

The total electrical energy consumption in the heating season of 2019-2020 is 100.37 million kWh. The energy consumed by the water pumps is about 8% of the total one. Therefore, the ASHP unit’s actual consumption of energy is 92.34 million kWh, and the total heating energy produced by the ASHP units is 974002.32 million kJ. The reduction of the CO₂ is 57466.1 tons, and the standard coal reduction is 21522.9 tons.

5.4. Feedback on ASHP heating project

By on site interview, average indoor temperature can reach 20-22 ℃, no air polluted in Zhao County, residential people are satisfied with the heating project. Heat company also saves the cost by replacing coal boiler with ASHPs.

6. Conclusion

This paper presents a large air source heat pump project in Zhao County, which has the advantages of fast fault response, low maintenance cost, and significant energy savings. The main conclusions are as follows.

- The COP of the air source heat pump stations selected was above 2.8. When the outdoor temperature was -15 ~ -10 ℃, the heat pump cop could still reach 2.26.
- The cost of gas boiler heating is more than twice that of air source heat pump heating.
- Based on standard coal, air source heat pump can reduce carbon dioxide emissions by about 38% compared with coal-fired boilers.

Investigation of a Novel Hybrid Heat Pump Concept
Tobias Reum*, David Schmitt, Thorsten Summ, Tobias Schrag
Institute for new Energy Systems (InES), Technische Hochschule Ingolstadt, Germany

Abstract
Hybrid heat pumps can utilize two low-grade ambient heat sources to provide heating energy. However, efficient operation of two heat sources and its effect on heat source dimensioning has not been thoroughly examined. In this research, a hybrid heat pump is developed which can switch between an air heat exchanger and a ground source heat exchanger as the heat source. The hybrid heat pump interconnection also allows parallel operation of both heat sources. Based on an experimental investigation, a black box model is created including a suitable control strategy. An annual simulation for space heating of a domestic building is conducted. The hybrid heat pump provides about 18.9 MWh of heat while extracting only 47.1 % of this heat from the ground source heat exchanger. Parallel operation allows a heating capacity reduction of the ground source heat exchanger to about 80 % compared to a conventional ground source heat pump. The hybrid heat pump therefore allows a smaller design size.

Keywords: hybrid heat pump; dual source heat pump; parallel operation; black box model; annual simulation

1. Introduction
1.1. Background and motivation
Heat pumps are one of the main heat generators for future heating systems. The heat pump market is growing rapidly. In 2021, the heat pump sales in Germany grew by about 28 % [1], even before the current energy crisis in Europe. Heat pumps are expected to become a main heat generator in the domestic sector [2].

Heat pumps provide heat using highly efficient refrigerant cycles, operating as reverse Carnot engines [3]. A small amount of (usually electrical) work is needed to provide a large amount of heat. Heat pumps therefore enable a transition of the heat generation into a fully electrical system. Electricity can be provided by renewable energy sources, e.g. wind power and photovoltaics. The remaining heat is drawn from ambient low-grade reservoirs. This means they are also significantly more efficient than direct electric heaters for domestic purposes. The fraction between the delivered heat capacity \( Q_{heat} \) and the necessary electrical power \( P_{el} \) is called the coefficient of performance (COP):

\[
\text{COP} = \frac{Q_{heat}}{P_{el}}
\] (1)

In practice, the COP usually varies between 2 and 6 depending on the temperature above levels of the ambient reservoir and the temperature needed for the heating system [4, 5]. This requires proper
implementation into the buildings for high efficiencies, for example by adding thermal insulation or large area heating systems like floor heating. Common ambient heat reservoirs serving as the heat source are air, the soil and ground water. While air source heat pumps are relatively cheap and easy to install, the efficiency especially during peak heating load hours in winter is lacking due to low ambient (outside air) temperatures. Using the soil or ground water as the heat source promises higher efficiencies due to higher reservoir temperatures during winter months, but the installation costs for either heat source are usually higher and there are higher geological requirements. Ground water needs careful examination of the underground water flow. Using the soil with vertical boreholes demands geological investigations and often longer time scales due to bureaucratic allowances, while horizontal heat exchangers occupy large areas, which are an issue especially in urban spaces. Each heat source for heat pumps therefore has their own advantages and disadvantages.

1.2. Hybrid heat pumps

Hybrid heat pumps (HHPs) – in literature often also referred to as dual source heat pumps to not confuse these systems with systems combining a heat pump with a gas boiler – combine several ambient heat sources to utilize the aforementioned advantages while minimizing the disadvantages. Commonly, HHPs optimize the usage of the heat sources to increase either the efficiency of the system, to reduce the energy extracted from the secondary (commonly the ground) heat source to limit ground source heat exchanger (GSHX) size or to profit from both benefits.

Allaerts et al. [6] combined two borehole GSHX with an air-based regenerator. The system was designed for an office building, where the cooling load was the dominating requirement. The HHP operated with one of the GSHXs while the other could be regenerated passively (i.e., not using the refrigerant cycle) over the ambient air. Serially, the HHP operated either in heating mode or cooling mode with one of the GSHXs. They researchers still found that a decrease of about 47 % in borehole sizing was possible due to regeneration with this air-based regenerator as compared to a single ground-source heat pump system.

Another project by Cannistraro et al. [7] extended an existing air-to-air heat pump into a HHP for an air-conditioning system. The heat pump could utilize either an air source or a flat-plate GSHX to provide heating and cooling. During cold ambient air conditions, the HHP used the GSHX to provide heating. A mixed operation was possible without stating further details. They found an improved efficiency compared to the original air-to-air heat pump at specific operating conditions. No annual comparison was given.

In a simulation-based study, Dongellini et al. [8] attempted to reduce the sizing for the borehole GSHX of an HHP. This HHP could also switch between the air and the GSHX as the heat source. Based on previous experimental results, a model of the HHP was developed. This model was then used with different borehole GSHX sizes and compared to a pure air source and a conventional ground source heat pump. They found that a significant reduction of the borehole dimensioning to 50 % showed only minor reductions in annual efficiency compared to a conventional ground source heat pump (-11 %), while improving the efficiency compared to the air source heat pump system (+26 %).

1.3. Research gap and scope

HHPs currently focus on utilizing one heat source at a time. However, utilizing both heat sources in parallel operation can provide significant flexibility to the heating system: while it is relatively simple to reduce the energetic load on a GSHX by reducing the heating load during comparatively high ambient temperatures by switching to air source operation (ASO), the peak load still requires a large heat exchanger area. This research aims at investigating the potential on efficiency and GSHX sizing by including parallel operation of both heat sources into a HHP by utilizing two compressors compared to conventional ground source heat pumps (GSHP).

This study focuses on building a model of a HHP which can not only switch between utilization of either heat source, but also allows parallel operation of both heat sources. An air as well as a ground source is used. The HHP was developed and tested experimentally in [9]. This paper aims at (a) developing a model based on this investigation including an operation mode controller for the single heat source operations as well as the parallel operation of both heat sources, and (b) an annual simulation to determine the effect on the annual efficiency, the total energy extracted from the GSHX and the heating capacity the GSHX needs to provide. By this, the energetic advantages of parallel operation are evaluated.
2. Methodology

The overall method of this paper includes the development of a black box model for the HHP including both the single source operations with the air source (ASO) and the ground source (ground source operation; GSO) as well as the parallel operation (PO). The experimental investigation in [9] provides the necessary data. This model is then implemented into an annual simulation with weather data, soil temperatures and a building heating load.

To evaluate the annual efficiency, the seasonal performance factor (SPF) is used with the cumulative energies for the heat $Q_{\text{heat}}$ and the electricity $E_{\text{el}}$ over the whole year:

$$\text{SPF} = \frac{Q_{\text{heat}}}{E_{\text{el}}} = \frac{\sum \dot{Q}_{\text{heat}} \ast dt}{\sum P_{\text{el}} \ast dt} \quad (2)$$

The HHP model needs to yield the heating load $\dot{Q}_{\text{heat}}$ as well as the necessary electrical power $P_{\text{el}}$ for each simulation time step $dt$. These values are also required for the evaluation of the energetic and power load on the GSHX. The extracted energy over a whole year $E_{\text{GSHX}}$ can be calculated by evaluating the GSO and the corresponding difference between the heating capacity $\dot{Q}_{\text{heat,GSO}}$ and the electrical power $P_{\text{el,GSO}}$, also summed up over the simulation time steps $dt$. The energy extracted during PO is included here, since PO is assumed to be a combination of full power GSO and additional ASO.

$$E_{\text{GSHX}} = \sum (\dot{Q}_{\text{heat,GSO}} - P_{\text{el,GSO}}) \ast dt \quad (3)$$

The maximum power load on the GSHX $Q_{\text{GSHX,max}}$ can be evaluated by finding the maximum of the aforementioned difference between the vectorial values of the heating capacity $\dot{Q}_{\text{heat,GSO}}$ and the electrical power $P_{\text{el,GSO}}$ during GSO:

$$\dot{Q}_{\text{GSHX,max}} = \max (\dot{Q}_{\text{heat,GSO}} - P_{\text{el,GSO}}) \quad (4)$$

2.1. Development of the black box model

The model type of the heat pump was chosen to be a black box model to limit the computing time. For each operation mode one performance map was developed based on the measurements in [9]. These measurements described the heating and electrical powers ($\dot{Q}_{\text{heat,GSO}}$ and $P_{\text{el,GSO}}$ respectively) depending on boundary conditions like ambient temperature $T_a$, source inlet temperature $T_{\text{so,GSO}}$ and sink outlet temperature $T_{\text{si}}$ based on [10]. The detailed control of the HHP model described below was then realized within the simulation model.

The heating controller switched between the operation modes depending on the ambient temperature. The inverter frequency $f_{\text{inverter}}$ resulted in a non-linear behavior of the heating and electrical power. This was included into the model. The range allowed for the inverter was $0 - 100 \%$.

Two bivalence points were defined: bivalence point 1 $T_{\text{biv1}}$ is the temperature, when the HHP switches from ASO to GSO and vice versa. Bivalence point 2 $T_{\text{biv2}}$ is the temperature, when the HHP switches from GSO to PO and vice versa. A heating threshold temperature $T_{\text{thr}}$ was implemented, at which the general operation of the HHP switched on and off depending on the moving mean ambient temperature $T_{a,\text{mean}}$ over the last seven days. Figure 1 shows the general structure of the decision tree to determine the operation mode.

![Decision tree](image)

Fig. 1: Decision tree of the HHP model to derive the operation mode. Each check includes a hysteresis.
The GSO model had the inputs of source temperature from the GSHX, the outlet temperature of the heating system and the inverter frequency. The performance map along with the inverter correction factor then determined the output heating capacity and the electrical power.

The ASO model worked similar, except that the input for the source was the ambient temperature.

The PO was the combination of both operation modes. In this work, below the bivalence point $2T_{biv2}$, the GSO continued at maximum inverter frequency. Additionally, the ASO was added to the GSO at maximum inverter frequency: the inverter frequency fed into the PO model then only changed the frequency of the ASO. Both source temperatures for the ground source and the ambient temperature were needed for PO, since both compressors are running in this operation mode.

2.2. Description of the annual simulation

This HHP model was then implemented into an annual simulation. The general scheme of the annual simulation is shown in Figure 2. The input data consisted of a weather data set for Ingolstadt, Germany, in the format of a test reference year [11]. For the GSO, the source temperature was derived from an undisturbed ground temperature model. This ground temperature model was based on approaches for seasonal temperature variations in the ground [12, 13]. A horizontal GSHX was used, buried in a depth of 1.5 m. Additionally, for the heat transfer to the brine cycle, a temperature difference of 3 K was assumed below this undisturbed ground temperature for the source temperature.

The load was described by a simple linear house heating load $Q_{\text{heat, set}}$ dependent on the ambient temperature. The conditions were:

- $Q_{\text{heat, set}}(T_a = 20 \, ^\circ C) = 0 \, kW$, assuming a target room temperature of 20 °C and no internal gains.
- $Q_{\text{heat, set}}(T_a = -20 \, ^\circ C) = 10 \, kW$, assuming maximum load at $-20 \, ^\circ C$.

This led to the following calculation for the necessary heating load of the house dependent on the ambient temperature:

$$Q_{\text{heat, set}} = -0.25 \frac{\text{kW}}{^\circ C} T_a + 5 \, \text{kW} \quad (5)$$

Then PID controller compared the necessary heating load with the delivered heating load delivered by the HHP $Q_{\text{heat}}$. It then changed the frequency accordingly to minimize the error $\Delta Q_{\text{heat}}$. It is important to note, that only one single inverter frequency is varied at a time: for the active compressor during ASO and GSO and during PO, the GSO compressor worked at maximum frequency and only the ASO compressor was controlled by the PID controller signal. The PID controller operated only with a proportional gain $P = 0.5$ and an integral
gain I = 0.1. The derivative gain was found to be not necessary. Also, the PID controller reset with every operation change of the HHP model due to non-linear behavior.

Since the heating system was designed around a buffer storage tank, the sink temperature of the HHP was assumed to be constant $T_{si} = 35 \, ^\circ C$. Only space heating on floor heating temperature levels was considered. Bivalence point 1 was chosen to be $T_{biv1} = 4 \, ^\circ C$ with a hysteresis of $\pm 1 \, K$. Each change of operation mode leads to one compressor start (either the GSO compressor switches off and the ASO compressor switches on or vice versa), which should be limited to avoid damaging the compressor. Bivalence point 2 was set to be $T_{biv2} = -3 \, ^\circ C$. A lower hysteresis of $+1 \, K$ was chosen, because only the change from GSO to PO leads to one compressor start (from PO to GSO only deactivates the ASO compressor). This indicates that repeated switching between GSO and PO is half as harmful to the number of compressor starts compared to a switching between ASO and GSO. The heating threshold temperature was $T_{thr} = 12 \, ^\circ C$ with a hysteresis of $+1 \, K$.

The output data consisted of the current operation mode (ASO, GSO or PO) including the inverter frequency, the weather and soil data and the HHP output data for the heating and electrical power.

3. Annual simulation results

3.1. Analysis of the HHP black box model within the simulation

The main inputs of the simulation are shown in Figure 3(a). While the ambient temperature fluctuated significantly on a short time frame, the moving average ambient temperature showed a much smoother behavior. This led to a clearer distinction of whether heating is necessary or not, which finally resulted in less on-off cycles. This clear separation of no operation in summer time due to dependency of the mean ambient temperature can be observed in Figure 3(b). The inverter frequency was normalized to a relative value of its maximum. During summer time, the relative inverter frequency remained at zero, which here means the heat pump is switched off. Also shown in Figure 3(a) is the source temperature of the GSHX. The large thermal
inertia of the ground leads to smaller amplitudes and a phase shift. It can be seen that especially in the last weeks of the year, the ground source temperature was notably higher than the ambient temperature, leading to a higher source temperature for the refrigeration cycle and therefore more efficient GSO compared to ASO. At the same time, however, in spring it seemed to be more beneficial to let the HHP run in ASO mode due to a cooled GSHX. A flexible bivalence point depending on the ground source temperature should be analyzed, even though the increasing ambient temperatures indicate lower heating loads and therefore less impact on the annual efficiency. More detailed GSHX models are needed to verify this behavior of the slowly changing ground source temperatures which could impact the dependencies used for the bivalence points.

Next, the switching around the bivalence points 1 and 2 was analyzed exemplarily. In Figure 4, the ambient temperature during the last two weeks of the year can be observed. Additionally, the state of the GSO is shown: at 1, the state is ON, so GSO is active. At 0, GSO is off/inactive. Around day 356, the ambient temperature dropped below \( T_{biv2} = -3 ^\circ C \) and GSO was replaced with PO. For this, the GSO operates at maximum inverter frequency and ASO is added to cover the necessary heating load. This remained the case until the ambient temperature rose above the bivalence point including the hysteresis \( T_{biv2} + 1 K = -2 ^\circ C \) about two days later. Then, GSO reactivated instead of PO. GSO remained active until the ambient temperature increased above bivalence point 1 including hysteresis \( T_{biv1} + 1 K = 5 ^\circ C \) on day 362. GSO deactivated and ASO started instead until the ambient temperature decreased below the bivalence point 1 including hysteresis one day later \( T_{biv1} - 1 K = 3 ^\circ C \). The switching was operative and worked according to the rules.

The inverter frequency was controlled as expected. However, during PO the low inverter frequency indicates that PO was not really needed yet and the bivalence point 2 was set too high for these weeks. During GSO – when the state of the GSO is on –, the relative inverter frequency varied to match the heating capacity of the HHP to the necessary heating capacity defined by equation (6). The same was the case during ASO from day 362 to 363. One notable difference was the lower relative inverter frequency during ASO compared to GSO. The reason for this was a higher heating capacity by the ASO compressor than the GSO compressor’s capacity. This led to a lower necessary inverter frequency to cover the load, which in turn led to the non-linear jump in the inverter frequency. The PID controller was reset during the operation mode change and therefore reacted quickly to minimize the heating capacity difference to the necessary heating load.

Non-intuitive was the relative inverter frequency during PO from day 356 to 359. The value during this time was zero, indicating a switched-off air source compressor, since the ground source compressor was supposed to run at full inverter frequency during this operation mode. The explanation is, that the GSO was still able to cover the necessary heating load below maximum inverter frequency. This is an indicator, that the parallel operation was activated at too high temperatures when it was not yet necessary. However, at earlier
stages during the year, this was not the case: since the heating capacity of the GSO depends on the ground source temperature as well, the heating capacity of the GSO is reduced during late winter/early spring as shown in the GSHX source temperature in Figure 3. During times of still high source temperatures during GSO in late autumn/early winter, GSO could therefore provide enough heating capacity on its own and PO was activated with a deactivated air source compressor.

Figure 5 shows the operation modes (here: GSO and PO) during the first week of the year. Here, during PO starting at day 4 the frequency actually varied up to around 20 %, indicating that the GSO cannot cover the full heating load anymore due to a lower source temperature level of the GSHX. In this week PO was therefore necessary. This indicated that a flexible bivalence point 2 is required for proper coverage of the necessary heating load.

![Fig. 5: Example of the relative inverter frequency at certain operation modes (ASO, GSO, PO) during the last two weeks of the year.](image)

### 3.2. Effects of PO on annual efficiency and the GSHX

Still, the HHP showed an annual efficiency calculated using equation (2) of SPF = 4.37 for floor heating operation. The total delivered heating energy was $E_{heat} = 18.9$ MWh and the electrical energy $E_{el} = 4.3$ MWh. The energy extracted from the soil is the sum of the energy extracted during GSO and the GSHX energy extracted during PO. Equation (3) yielded $E_{GSHX} = 8.9$ MWh, which is a fraction equal to about 47.1 % of the delivered heating energy. The remaining energy was taken from the ambient air:

$$E_{air} = E_{heat} - E_{GSHX} - E_{el} = 5.7 \text{ MWh} \tag{7}$$

Using the same periphery (source and load), a conventional GSHP yielded an annual efficiency of SPF\text{GSHP} = 4.27 and extracted heat energy from the GSHX of $E_{GSHX,GSHP} = 14.4$ MWh. The HHP showed improvements on both values: The SPF increased by about 2 %, the energy extracted from the soil to about 62 %. The bivalence points need to be examined further to not only allow flexibility as mentioned before, but also to analyze further reduction in GSHX size.

The heating capacity necessary by the GSHX was evaluated as well. The maximum difference per time step between the heating capacity $\dot{Q}_{heat}$ and the electrical power $P_{el}$ resulted in $\dot{Q}_{GSHX,max} = 4.5$ kW. The comparison with a GSHP led to $\dot{Q}_{GSHX,max,GSHP} = 5.6$ kW. This was a relatively small difference of about 1 kW (or down to almost 80 %), indicating a limited power reduction due to PO of the HHP. This power reduction should be evaluated further: with an increased necessary heating load during PO, this effect should
be more distinct, because further air source power needs to be added to cover the heating load, while the power on the GSHX remains the same.

Lastly, the PID controller was operating properly. The mean error of heating load and necessary heating load over the whole year was $\Delta \dot{Q}_{\text{heat,mean}} = -2.9 \text{ W}$. So even though the PO mode often led to significant heating capacity differences when it was activated at too high ambient temperatures, the mean error heating capacity difference over the whole year was reasonably small.

3.3. Discussion of the results

The decision tree for the operation mode determination worked as intended: depending on the ambient temperature, one operation mode was active to cover the necessary heating load. Appropriate hysterisis’s prevented repeated switching between the operation modes, which in turn would lead to an increase in compressor starts. The SPF = 4.37 was comparable to market available GSHPs and the heat extracted from the soil $E_{\text{GSHX}} = 8.9 \text{ MWh}$ was reduced to about 62 % compared to conventional ground source heat pumps.

This can allow a reduction in size of the GSHX. However, the potential needs to be further evaluated with varying bivalence points as described in chapter 3.1 and also varying sink temperature levels with radiant heaters and/or without buffer storage.

Also, the inverter frequency control was working properly, covering the necessary heating load over the whole year at a small error. Especially during ASO and GSO, the PID controller worked well, while it struggled matching the heating load during PO. However, this was an issue of the bivalence point 2, not the PID controller. Also, in practice most inverters do not allow lower frequencies below about 25 %, which needs to be included in future simulations.

There are several steps which need to be improved in the simulation to enable further more detailed evaluations: first, the model of the PO is a simple combination of the single source operations. Since both operation modes share one condenser heat exchanger (see the interconnection in [9]), this is a simplification. The PO needs to be examined more closely in the laboratory to determine a proper PO model. Also, allowing a variation of the GSO inverter frequency during PO can add another level of flexibility: even at higher ambient temperatures, when GSO is more efficient than ASO but PO is not strictly necessary yet, running both inverters in part-load can reduce the energy extracted from the GSHX without a large influence on the efficiency.

The bivalence points are the second necessity: during the annual simulation, the ASO was often not used to its full extend. It is even possible that the annual efficiency increases by decreasing bivalence point 1. Also, bivalence point 2 needs dependencies to allow a more beneficial PO. Dependencies on the ground source temperature, building or buffer storage temperature or on the year’s month are options for further examinations.

The periphery for the annual simulation is currently still simplified. The load is a linear heating load, which requires not the highest heating capacities possible by the HHP. Domestic hot water is not included yet, which also makes the heating controller more complex. The sources need to be modelled more in detail to show more complex behavior. Especially the GSHX was simplified in this work. Dynamic behavior of heat extraction and regeneration could therefore not yet be simulated.

Further operation modes possible to the interconnection [9] need to be implemented. Some of these requirements, especially active regeneration, need more detailed GSHX models to show their potential.

4. Conclusion

The interconnection of the HHP allows for an increased efficiency compared to conventional GSHPs. The increase in SPF from 4.27 for the GSHP to 4.37 for the HHP is an increase by only about 2 %, which is marginal. The HHP also reduced the extracted energy from the GSHX to about 62 %, PO specifically reduced the maximum heating load to about 80 %. These findings indicate a significant reduction possibility in dimensioning of the GSHX, while the increase in efficiency is marginal.

Further improvements of the simulation need to be applied. Most important are detailed heat source and heat sink models. The HHP model needs to include non-linear inverter frequency influence and limits as well as comprehensive PO modelling. On the controller side, especially the bivalence points – when to switch between ASO, GSO and PO – need to be examined and optimized.

**Abstract**

In the motivation of energy conservation and emission reduction, several provinces in China are promoting and subsidizing heat pump (HP) technology adoption for tobacco baking rooms to replace conventional baking room with heat resources by coal burning and others. HP technology used in tobacco baking room illustrates significant benefits for better baked tobacco leaves quality, more automation by occupying less manpower and more environment friendly with less emissions. Total solution for this application is developed with dedicated designated ZW/ZWD compressor and customized system controller, in order to facilitate OEMs and contractors to better serve end users and quickly grasp the opportunity to enter the market. One field project explains processes of tobacco baking in baking room and how Emerson solutions secure good quality of finished tobacco.

1. Introduction

China is the largest country in the world for its planting area of flue-cured tobacco, and also the largest tobacco consumer [1]. The annual planting area of flue-cured tobacco is about 2.5 million acres, and the annual output of flue-cured tobacco leaves is about 2 million tons, accounting for more than half of the world's total volume of cured tobacco [2]. Also, flue cured tobacco is an important agricultural product among China's crops, the main raw material for cigarette production, and one of the major agricultural products exported by China, making positive contributions to the national and local financial income increase and economic development [3].

At present, the tobacco curing technology in China is still relatively backward, and coal burning intensive curing houses are widely used to bake tobacco [4]. As the main way for baking, the total coal consumption of coal-fired baking is about 3.5 million tons per year. The coal consumption is large, and the cost of baking fuel is high. The flue gas emitted after the combustion of bulk coal carries a large amount of CO2, CO, SO2, NO, H2S and PM2.5 particles, and it is unable to conduct centralized desulfurization, and dust removal, causing serious environmental pollution, which has become a serious environmental problem in the tobacco baking regions [5]. According to statistics, the annual CO2 emissions of flue-cured tobacco leaves in China are close to 8 million tons, about 600 thousand tons of smoke and dust, and 30 to 50 thousand tons of toxic gases. The anthropogenic emission of air pollution particles and carbon dioxide has become a serious environmental problem [6-8]. With the increasing shortage of fossil energy and the continuous promotion of green ecological civilization construction, new and clean energy will become the new direction used in tobacco baking in China.

Since the year of the Fifth Plenary Session of the 18th Central Committee of the Communist Party of China, China announced to take "green development" as one of the five development concepts, and clearly proposed that: to adhere to green development, we must adhere to the basic national policy of saving resources and protecting the environment, adhere to sustainable development, and form a harmonious development between...
human and nature. In recent years, President Xi has repeatedly emphasized that "green water and green mountains are golden and silver mountains", and he pointed out that "we should accelerate the formation of a green development mode, promote win-win economic development and environmental protection, and build a global society where economy and the environment advance together."

At the same time, on September 22, 2020, at the general debate of the 75th United Nations General Assembly, President Xi announced that China's carbon dioxide emissions would strive to reach the peak by 2030, and would get to be carbon neutral by 2060, including greenhouse gas emissions in the whole economy, from carbon dioxide to all greenhouse gases. This has brought huge challenges and market opportunities to China's refrigeration, air-conditioning and heat pump industry, including agricultural drying and baking.

It is said that by the end of 2017, China has built 1.2 million intensive curing rooms, including 1.19 million coal-fired curing ones, 3000 heat pump curing rooms and 6690 other energy types [5]. With the increasing awareness of environmental protection throughout China, the voice against the traditional flue-cured tobacco production mode is becoming stronger and stronger [9]. Coal fired flue-cured tobacco is no longer in line with the development in terms of heating mode and resource utilization efficiency [10]. It is an urgent problem to develop a clean and green tobacco curing room, which also brings huge business opportunities. The upgrading, reconstruction of the old intensive curing rooms and new constructions will add a market of 70 billion yuan. The following is a further description of the relevant policies in China and technical routes of new environment-friendly tobacco curing room combined with air source heat pump technology.

2. Application and promotion of modern baking room technology

This section describes the process and development related to the baking room and tobacco baking. In the past 100 years, the baking room equipment has changed from low to high level and simple to complex. Before the 1950s, China has been using the simple clay baking room, directly making a fire to heat in it. In the 1960s, the baking technology was improved with the popularization and application of dry and wet thermometer in tobacco baking, but the baking process was mainly empirical. Into the 1970s, the baking process adopted the “high temperature and fast baking” operation technology to pursue the goal of yellow, freshness and clean. From the mid-late 1980s to the early 1990s, the 5-stage, 7-stage and 6-stage of low temperature and humidity baking processes were proposed around the country successively based on the study of baking process, but it still stayed at the low level of inspecting tobacco by human experience and burning by personal feeling. In the 1990s, the baking technology and baking room equipment in China had obvious technical progress and innovation. And the 3-stage baking process was proposed, which achieved the similar level of the international general advanced baking [11].

Now, here introduces the 3-stage process in tobacco baking, which is divided as yellow discoloration, color fixing and stem drying stage, and each stage is divided into multiple temperature rising and holding stages, as shown in Figure 1.

![Fig.1. Tobacco Drying Process Curve](image)

**Yellow discoloration stage**: The temperature and humidity in baking room should be gradually increased. And the temperature, humidity and baking time should be adjusted according to the actual situation of tobacco leaf change. The fresh tobacco leaves are tied reasonably and conveyed to the baking room, then start the heat pump unit. Gradually increase the temperature in the baking room to 38°C and keep stable, with a difference of 2~3°C between dry and wet bulb temperatures. When the tobacco leaves reach about 80% yellow, the
temperature in the baking room gradually rises to 42℃ and keeps stable. The difference between dry and wet bulb temperatures changes from 2℃ to 4℃. When the leaves become soft to fall on the shelf and yellow with little cyan, the yellow discoloration stage is completed.

**Color fixing stage:** The temperature in the baking room gradually rises to 54℃ with low to high heating rate. Before the temperature in the baking room reaches 50℃, the wet bulb temperature should be stabilized at 38~39℃. After the temperature in the baking room reaches 50℃, the wet bulb temperature should be stabilized at 39~40℃. The color fixing should be timely in this stage to improve the appearance grade quality and internal quality of tobacco leaves.

**Stem drying stage:** Temperature in the baking room gradually rises to 68℃, and the wet bulb temperature is rapidly adjusted to 41~42℃, to ensure that the whole tobacco leaves are dry and baked through, without wet stems and pieces, and swelled stems phenomenon.

With many years practice, air source heat pump system is proven that it’s well controlled to stabilize the moisture content of tobacco and meet the temperature and humidity requirement of yellow discoloration, color fixing and Stem drying stage. Associated with modern control technology, heat pump system controller has multiple baking curves, which can modify the dry ball temperature, wet ball temperature and baking duration of each stage according to the local tobacco and climate status.

After seeing many and many successful projects from several provinces in China by introducing heat pump baking room technology, in order to further standardize the bidding and procurement behavior of baking room equipment, unify the construction standards and specifications of dense baking rooms, and promote the construction of new type baking rooms, the Office of the State Tobacco Monopoly Administration issued the “Management Measures for Bidding and Procurement of Baking Room Equipment” and “Revised Technical Specifications for Dense Baking Rooms (Trial)” in 2009. According to this policy, the baking room equipment to be bid must be designed and processed in strict accordance with the relevant requirements of the “Revised Technical Specifications for Dense Baking Rooms (Trial)”, and suppliers are encouraged to actively carry out technological innovation and development of new equipment.

Meanwhile, Henan Tobacco Company released "Air Source Heat Pump Dense Baking Rooms" on December 15, 2020, which has been implemented on January 1, 2021. The standard specifies the basic structure, main equipment, and technical parameters of the air source heat pump dense baking rooms, and is also applicable to the new construction, reconstruction, and installation of heat pump baking room. The main components of the heat pump baking room are heating room, tobacco filling room, heat pump unit and controller. Figure 2 shows the standard requirements for the basic structure of the heat pump baking room (heating room, tobacco filling room), and Figure 3 shows the standard requirements for the display content of the main interface of the heat pump baking room controller.

![Fig. 2. Defined Baking Room Size and Structure (For Reference)](image-url)
3. Heat pump system design

The current application of heat pump system for tobacco baking can be roughly categorized as open loop system and closed loop system. Figure 4 shows the open loop system.

The low-temperature and low-pressure liquid refrigerant enters the evaporator to absorb the heat of the ambient air, and the refrigerant evaporates into medium-temperature and low-pressure vapor. The compressor consumes electric energy to make the pressure and temperature of gaseous refrigerant rise. Then the high-temperature and high-pressure gaseous refrigerant enters the condenser to release heat. The process of refrigerant heat release heats the return air on the other side of the condenser, so that the return air rises to a certain temperature. The refrigerant condensed into liquid is throttled by the throttle valve, and then becomes a low-temperature and low-pressure liquid, and then enters the evaporator to absorb heat. In this way, the thermal cycle process from the evaporator side to the condenser side is realized.

The performance of open loop system is greatly affected by ambient temperature. The starting and ending time of tobacco baking in different regions are not the same. When the weather is continuously rainy or the night temperature is lower than 10℃, the energy efficiency of the open loop heat pump is significantly reduced, COP is even less than 2.0, and the heat output may not meet the requirements of baking [12]. And in the late baking period, the moisture content of tobacco leaves is already low. The humidity of outdoor air can no longer meet the requirements of tobacco drying in the baking room, the only way is to reduce the relative humidity by rising the temperature of circulating air, but this will increase the load of the heat pump system. Meanwhile, the baking process requires that the temperature of the baking room should be maintained at 65~68℃ during the stem drying stage, which means the room for reducing the relative humidity by rising temperature is limited, so there are certain disadvantages and limitations for open loop system.

Figure 5 shows a closed loop system, and the enthalpy-humidity chart of hot air cycle in the baking room is shown in Figure 6: Point R is the state of the hot air from the baking room, and it is divided into two parts. One first enters the sensible heat exchanger and is cooled from point R to point C without specific humidity change. Then enters the evaporator and is cooled and dehumidified from point C to point L. After coming out of the evaporator, it enters the sensible heat exchanger to pre-cool the high temperature air, and itself is heated from point L to point H without specific humidity change. Then it is mixed with another part of air along H-R.
to point M, and the mixed air enters the condenser and is heated to point S, and the air at point S is sent into the baking room along the heat-humidity ratio line to complete the hot air cycle.

Different from the open loop system, the cycle medium air of the closed loop system absorbs the moisture in the tobacco leaves in the baking room, and then dries tobacco leaves again after being dehumidified by the evaporator. The whole system basically does not introduce outdoor fresh air. Therefore, in the middle and late period of tobacco baking, the system can effectively reduce the humidity of cycle air to meet the requirements of drying process and reduce the heat load, but the dehumidification efficiency of evaporator will affect the drying efficiency of the whole tobacco baking process [12].

The closed loop system circulates the hot air in the baking room to form a closed loop heating for the baking room. So, the heat provided by it is the compressor power consumption. In the late period of tobacco baking, the heat load of the baking room decreases, but to ensure the dehumidification efficiency of the evaporator, compressor need to run continuously, causing the temperature in the baking room to continuously rise. At this time, part of the fresh air needs to be introduced to meet the requirement of baking process temperature in the baking room. The closed loop system is not affected by the ambient temperature and maximizes the retention of various fragrance substances in tobacco leaves. The heat load in the middle and late period of tobacco baking is lower than that of the open loop system because the closed loop system recycles the latent heat absorbed by the moisture in tobacco leaves when evaporating.

Fig. 5. Closed Loop Heat Pump System

After comparing the difference between open and closed loop heat pump system, these two types are commonly used in field, which really depend on HP OEM technical readiness and ambient temperature. In order to promote heat pump drying technology more efficiently, Emerson Asia provides an integrated and total solution for heat pump drying system from, which provide great convinent for customers to adopt with one-stop shopping. As shown in Figure 7, which offers all key components and then greatly simplifies the application of heat pump in drying system. This total solution includes digital and fixed compressors, programmable controller as system control, X-web monitoring, HMI (human and machine interface), temperature and pressure sensor, and electronic expansion valve for high temperature application.

Fig. 6. Enthalpy-humidity Chart Of Hot Air Cycle

Fig. 7. Emerson Total Solution for Tobacco Baking
Digital and fixed compressors are designed for high evaporating and condensing temperature drying and baking application and have superior reliability, proven in the field. Digital compressor, called ZWD, have capacity modulation with range adjustment from 10% to 100%, which could deliver precise temperature control to have better baking quality of specimen including tobacco leaves. Together with ZWD compressor, modulation controller, called XC35, is also provide to control capacity output for customer to easily adopt digital compressor with minor change to their existing HP system main controller. An optimized system control scheme is built into the system controller, called iPro Lite, to enhance system performance and reliability. It is also embedded the program for tobacco drying processes with lots of flexibilities. The electronic expansion valve (EXV), dedicated design for high temperature, is one body structure design for best sealing and qualified with high reliability. HMI is slim design and has a 7 inches LCD display with high resolution. X-web monitoring can be connected with system controller through RS485 to inspect the operating conditions and real status in baking room, and provides data for remote monitoring system.

ZWD digital scroll compressor features stepless energy regulation in the range of 10-100% to ensure accurate temperature control and reduce dry consumption of goods. To compare the temperature control curves of fixed speed compressor and digital compressor, we carried out the experiments of mushroom drying in fixed drying system and digital drying system respectively. Figure 8 shows the temperature and humidity curves in drying system’s baking room with fixed speed compressor, and Figure. 9 shows that in drying system’s baking room with digital scroll. It can be seen from the figures that the temperature and humidity curve in the digital drying system has a higher coincidence with the control target. In addition, compared with inverter technology, the structure of digital scroll compressor is less complex. A large number of practical applications also prove that digital scroll technology can provide higher reliability and energy efficiency thanks to mechanical modulation technology.
4. Field project summary

As mentioned above, when the traditional coal-burning drying is used, it is necessary to hire an experienced tobacco baking master to operate. In view of the pain points above, Emerson Asia has been doing in-depth researches and developing tobacco baking process, using iPro Lite programmable controller as the main control for air source heat pump system.

Taking the tobacco baking field test in Yuxi, Yunnan Province as an example, the system is an open loop heat pump system. The structure of the baking room is 8000mm×2900mm×4800mm, as shown in Figure 10, the wall material is double-sided color steel polyurethane plate. Its thermal conductivity is 0.023W/(m·K), indoor surface convection heat transfer coefficient is 8.7W/(m²·K), and outdoor surface convection heat transfer coefficient is 23.3W/(m²·K). Indoor temperature and humidity are given by tobacco baking process curve, as shown in Figure 1. The outdoor temperature is selected as the ambient temperature of 18~32°C during the local baking period. Taking the tobacco leaves Yunyan 97 as an example, the weight of fresh tobacco leaves before baking was 3150kg, and the baking duration was determined to be 154h according to relevant literature and tobacco baking practice [13]. According to the existing references and relevant data, the law of water loss in tobacco baking can be obtained. The approximate water loss of tobacco leaves in the baking process is as follows: 27%-35% water loss in yellow discoloration stage, 50%-55% water loss in color fixing stage and 10%-23% water loss in stem drying stage[14]. The wet base moisture content of Yunyan 97 fresh tobacco is 88%, and about 6.5% at the end of baking[15], so the total water loss is 3150×(88%−6.5%)/(1−6.5%) = 2746kg. The water loss rate of each stage obtained from literature[15-16] is shown in Table 1.

Fig.10. Baking Room Appearance

The sensible heat load of the baking room was the highest at the initial temperature rise, followed by the temperature rise of each stage, and the lowest at the temperature holding of each stage. In the early baking period, the moisture content of tobacco leaves is high, the water evaporation is more, the wet load is larger, but the duration is short. In the yellow discoloration temperature holding stage, the baking room needs to maintain a high humidity environment, the humidity load decreased. To the color fixing stage, the temperature of the baking room rises to 54°C, and the baking room needs to maintain a low humidity environment, and the humidity load increases to the maximum. The moisture content of tobacco leaves in stem drying stage decreased significantly, and the moisture evaporation was less, and the humidity load decreased to the lowest. The calculation result shows that the maximum heat load in the color fixing stage is 31.15kW. According to the calculated load of the baking room and the evaporating and condensing temperature of the heat pump operation, two ZW79KBC compressors are equipped for the baking room heat pump unit. Figure 11 shows the heat pump unit, control board and HMI.
Two exhaust fans are added to the baking room for strongly discharging humidity to enlarge the dedumidification capacity. Test data collection is shown in Figure 12 and comparison of tobacco leaves before and after baking is shown in Figure 13. The first stage is the low temperature yellow discoloration, compressor running rate is low as heat load is small. The second stage is color fixing, compressor running rate is high, up to more than 90% as the heat and humidity load is large. The third stage is mesophyll drying, heat load is the main demand and humidity load need is affiliated. And compressor running rate is about 60%. Stage 4 is stem drying, basically heat load. And compressor running rate is consistent with stage 3. This tobacco baking test took 164 hours, and consumed 929.2kWh. The longer baking time is mainly due to the lengthening of yellow discoloration and stem drying. From the perspective of the whole drying process, the trend of the measured temperature and humidity curves in the baking room is highly consistent with the requirement of tobacco baking process shown in Figure 1. The air source heat pump drying technology has incomparable advantages in the accurate control of temperature and humidity.

In order to ensure the quality of tobacco baking, the baking room dry and wet bulb temperature control strategies are different at each stage. In the first stage, yellow discoloration of tobacco needs high humidity condition, so only dry bulb temperature needs to be controlled by adjusting the output of compressor. The exhaust fans are off and exhaust valves are closed since there is no requirement for discharging humidity. In the second stage, baking room dry bulb temperature needs to rise gradually by increasing compressor output. At this time, the exhaust fans are on and the wet bulb temperature can be controlled by adjusting the opening of exhaust valves. For example, if baking room wet bulb temperature > setting value + offset, increase the exhaust valve opening. If baking room wet bulb temperature < setting value, decrease the exhaust valve opening. When baking room wet bulb temperature is between setting value and setting value + offset, keep the exhaust valve opening. When coming to the third stage, baking room dry and wet bulb temperature needs to be kept near the target value by controlling compressor output and exhaust valve opening. For the last stage, it is necessary to hit higher dry bulb temperature and keep wet bulb temperature close to the target in baking room by controlling compressor output and exhaust valve opening.
Compared to the coal-burning baking, the results are shown in Table 2. The power consumption of the heat pump baking room is 929.2 kWh, and the labor cost of baking 1kg dry tobacco is 0.11 yuan. In coal-burning side, the electricity consumption of the coal-fired baking room is 181.8 kWh, the coal consumption is 808kg, and the labor cost of baking 1kg dry tobacco is 0.38 yuan. The electricity price is calculated as 0.53 yuan/kWh (the electricity price for agricultural production in the provincial power grid electricity price standard) and the coal price is calculated as 775 yuan/t. The total operating cost of 1kg dry tobacco in the heat pump baking room is 1.33 yuan, and that in the coal-fired baking room is 2.17 yuan. The baking cost of heat pump baking room is about 61% of that of coal-fired baking room, which saves 39% of the cost of tobacco baking. Moreover, the carbon emission of heat pump baking room is only 32% of that of coal-fired baking room, so the effect of cost saving and emission reduction is significant.

### 5. Summary and prospect

Traditional coal-fired tobacco baking not only has higher cost, but also has some uncertainty in baking quality, even brings serious environmental problems to tobacco regions. Under the influence of environmental policy, clean energy, especially air source heat pump technology has made great progress. Combining with the requirement of tobacco baking process, this paper expounds the important role of heat pump drying technology in energy conservation and environmental protection and improvement of tobacco baking quality and efficiency. Following summaries can be drewed:

1. Even the initial equipment investment of heat pump drying technology is large, but its energy consumption and manual operation cost are quite low, and the long-term comprehensive benefit is attractive.
2. Heat pump drying technology is highly electrified, and the temperature and humidity in the baking room can be accurately controlled, which greatly improves the proportion of top-grade tobacco.
3. Heat pump drying technology can partially recover the waste heat from the baking room and realize a high degree of automation, significantly reduce the tobacco baking cost and improve the economic income of tobacco farmers.
In the future, with the continuous development of heat pump drying technology, the heat pump drying system and its control will be further optimized to make the temperature and humidity control of the whole baking process be more accurate, and the temperature fluctuation tends to be minimized. With more studies and practise on closed loop heat pump drying system, energy utilization efficiency could be further improved. In China, heat pump based tobacco baking room will has prospective future and it will contribute a lot to China national carbon emission targets.

Abstract

R410A is a refrigerant commonly used in air conditioning and heat pump applications that has become the target to be replaced by lower global warming potential (GWP) alternatives. R-454B with a GWP of 466 has been proposed as a lower GWP replacement for R-410A with similar performance and operating characteristics. Long-term refrigerant solutions are required to provide similar to improved efficiency with comparable capacity while having a GWP of less than 300. This threshold has been identified as an industry-wide average in line with global climate commitments.

This paper investigates alternative refrigerant options to replace R-410A including R-454B, as well as DR-4 and R-479A with a GWP of less than 300 and less than 150 respectively. Thermodynamic simulations followed by an investigation using a component system model of a 3-ton unitary heat pump are performed. Varying ambient temperatures in cooling operation as well as standard rating conditions for both heating and cooling operation for each candidate are considered, to compare refrigerant performance and to determine their viability as a replacement option. Drop-in performance and adjusted compressor speeds are used to compensate for the capacity penalty the lower GWP options experience to achieve relative COP and capacity within 5% of R-410A for investigated heating and cooling conditions.

Keywords: R-410A; Low GWP; Air conditioning; Heat pump, R-479A, DR-4

1. Introduction

Global climate change has brought the scientific community together through the research performed within the Intergovernmental Panel for Climate Change (IPCC, [1]). The reports that document the findings of experts confirm mankind’s impact on ever increasing carbon dioxide emissions that drive temperature rise. Refrigerants with high global warming potential (GWP) are estimated to potentially contribute an average global temperature rise of 0.5°C if no action was to be taken with reducing the GWP of fluorinated hydrocarbons in use today in HVACR equipment. Air conditioning and heat pump applications are hereby an important factor for which R410A is one of the leading refrigerants with a GWP of 2088 [2].

Multiple studies have been performed to investigate refrigerant options with a lower GWP to replace R-410A. The reduction of refrigerant GWP requires in many cases a blend design which contains lower GWP hydrofluoroolefin (HFO) refrigerant components that are ofen, ASHRAE Standard 34 flammability Class 2L [3]. For example, R-410A is a blend of R-32 which has a flammability classification of 2L and R-125 (Class 1) is added only to render the blend non-flammable. An industry wide test program that evaluated lower GWP R-410A replacements included R-744 as a nonflammable option along with nine lower flammability options with classification of 2L based on R-1234yf and R-1234ze(E) in combination with R-32 in most cases [4]. The GWP of the investigated 2L candidates offered hereby significant reduction compared to R-410A in a range from a GWP of about 200 to 1500 as described in [5]. Another lower flammability candidate with a GWP of 466 is the binary blend R-454B formulated with 68.9% R32 and 31.1% R-1234yf as presented by Hughes et

\*Corresponding author

\textit{E-mail address:} michael.petersen@tranettechnologies.com
al. [6]. This blend provides similar capacity with slight improvements in efficiency while having higher compressor discharge temperatures compared to R-410A. Considering a weighted average approach of GWP of refrigerants being used today throughout the industry, the GWP will need to be less than 300 to meet the phase-down targets of the Kigali Amendment to the Montreal Protocol as described by Schultz et al. [7]. Schultz describes the potential blend development opportunity by using newly introduced low GWP molecules CF3I, R-1123, R-1132a. Candidate blends were identified to have suitable properties to be considered as R410A replacement candidates. However, the expectable capacity would be 10 to 15% lower compared to R410A. Additional challenges remain in chemical and material compatibility considerations of these new molecules that need to be investigated for a successful implementation in air conditioning and heat pump applications. Recently another low GWP (GWP<1) molecule has been introduced with R-1132(E) as described by Rydkin et al. [8]. This molecule which has a safety classification of B2 by ASHRAE Standard 34 [3] has been formulated in the blend R-479A with 21.5% R32 and 50.5% R1234yf.

For the investigation performed in this study R410A is compared to R-454B and the binary blend option DR-4 as evaluated by Schultz et al. in [9] with a GWP of less than 300 and R-479A with a GWP of less than 150 as summarized in Table 1. All the investigated replacement blend candidates are of lower flammability and provide significant GWP reduction potential. The normal boiling point temperatures as well as the critical properties of the replacement candidates are similar while their temperature glide increases with decreasing GWP.

Figure 1 shows the property diagrams for all four compared blends visualizing their similarity in terms of heat of vaporization for R-410A, DR-4 and R-479A (pressure-enthalpy) as well as compressor discharge temperature (temperature-entropy). R-454B has a wider two-phase dome due to its larger R-32 blend fraction causing higher compressor discharge temperatures at the same time. The larger glide of DR-4 and R-479A compared to R-410A and R-454B becomes noticeable in the condenser and evaporator.

![Figure 1. Pressure- Enthalpy and Temperature- Entropy property comparison of evaluated refrigerants](image-url)
A thermodynamic model was set up using REFPROP 10 [10] refrigerant properties to evaluate the R-410A lower GWP alternatives in terms of expected performance and operating characteristics as outlined in Petersen et al. [11]. Pressure drops are hereby not accounted for in the heat exchangers and connecting lines. AHRI 210/240 A test point [12] conditions were used for the study with an evaporation temperature of 10°C considering 8.3K superheat and an approach of 8.4K based on an indoor air side temperature of 26.7°C. Similarly, the condensing temperature was set at 46.1°C with 8.3K subcooling and an approach temperature difference of 2.8K based on 35°C air temperature entering the outdoor unit. A heat exchanger weighting of 0.7 is applied for the evaporator and the condenser as a weighted average of the dew point and bubble point temperatures. Figure 2 summarizes the relative COP (COP*), relative capacity (CAP*) and relative compressor discharge temperature difference (ΔCDT) compared to R-410A.

The relative COP of the alternative candidates are all within 5% of R-410A making them viable options, whereas the only R-454B provides this margin for relative capacity. The lower GWP alternatives DR-4 and R-479A both have a roughly 20% lower capacity compared to R-410A as well as similar to lower compressor discharge temperatures. Both lower GWP options provide similar performance characteristics whereas R-479A has a GWP below 150 or half of DR-4 with a GWP of less than 300. To better understand the relative performance and operating characteristics of the refrigerants exhibiting pressure drop and utilize their transport properties in the heat exchanger a system model was developed and investigated.

2. System and model description

A unitary packaged rooftop heat pump unit was chosen for the refrigerant system modeling. The unit is rated with a cooling capacity of 3 RT or 10.6kW while operating at 60 Hz. The nameplate R-410A refrigerant charge is 7.7 lbm or 3.5 kg. The unit is driven by a scroll compressor and uses indoor and outdoor heat exchangers with aluminum-fin/copper-tube construction with fixed speed fans. The Modelica platform with TiL suite library [13] has been used to create the heat pump unit system model. The system comprises of a physics based refrigerant independent compressor model which is developed using the R-410A test data. The compressor model parameters can then be used to predict the performance with other refrigerants over the entire operating map. Both the indoor and outdoor coils used have fin and tube heat exchanger configurations. The heat transfer (Shah [14],[15], [16] for two-phase and Dittus-Boelter [17] for Single-phase) and pressure drop (Konakov [18]) correlations from the literature are used both on the refrigerant side and air side (Haaf, [19]), while a discretized calculation method is applied for the heat exchangers. Correction factors are then applied to these correlations to accurately represent the test data in both cooling and heating modes for the baseline R-410A resulting in a match of the experimental data within 3%. Pressure-drop and heat transfer is also calculated for the refrigerant lines which are used to connect the above components and a 4-way reversing valve which enables switching between cooling and heating modes. NIST REFPROP 10.0 [10] has been used to generate the refrigerant properties lookup table for each of the refrigerant mixtures simulated here. Moist air properties are sourced from TiL Media [13]. The refrigerant R-410A is used as a baseline for relative performance as well as R-454B as a baseline for matching capacity in AHRI 210/240 [12] A condition for adjusting the compressor speed for the low GWP alternative refrigerant options DR-4 and R-479A. The baseline compressor speed hereby set at 50Hz with higher adjusted speed for DR-4 and R-479A to accommodate the lower relative capacity of around 20% as determined in the thermodynamic model in the previous paragraph. The system model design in Dymola/ Modelica is shown in Figure 3.
The investigated conditions for cooling and heating operations include both standard test conditions as defined in AHRI 210/240 for cooling (A, B) and heating (H1, H3) as well as ambient temperature sweeps in cooling operation to investigate the performance at varying ambient temperatures. The investigated conditions are summarized in Table 2.

3. Modeling results

In cooling condition “A” the baseline capacity was established with R-454B at a compressor frequency of 50Hz. The determined cooling capacity was then matched with the low GWP alternatives DR-4 and R-479A and the compressor speed at this adjusted condition was maintained for the temperature sweep and heating conditions to obtain both performance results at drop in compressor speeds of 50Hz and adjusted compressor speeds. The results for relative COP compared to R-410A are shown in Figure 4.
R-454B has similar capacity compared to R-410A at a rating ambient temperature of 29.4°C. The low GWP alternative refrigerants DR-4 and R-479A have approximately 15% lower capacity compared to R-410A and have therefore been investigated at adjusted compressor speeds to match the higher capacity of R-454B. These adjusted compressor speeds were then used in the following conditions. DR-4 at baseline compressor speed of 50Hz provides a relative capacity of roughly 0.86 to 0.94 compared to R-410A with R-479A achieving 0.84 to 0.86. With adjusted compressor speeds both low GWP alternatives remain within ±5% of relative capacity compared to R-410A with slightly more improvement for DR-4 at elevated temperatures of 51.7°C exceeding 5% relative capacity. The adjustment of compressor speed therefore confirms a viable option to match relative capacity requirements. However, the increase in refrigerant flow rate while maintaining the rest of the system design unchanged has an impact on the system COP as shown in Figure 5.

The baseline system efficiency for R-454B shows improvement over R-410A throughout the investigated ambient temperature range within 2% to 8%. DR-4 has similar COP at lower ambient temperatures up to 30°C with benefits at higher ambient temperatures up to 10% at 51.7°C. R-479A has a similar response with comparable COP up to 40°C and improved values up to 4% at high ambient temperatures for the drop-in compressor speed of 50Hz. Adjusting the compressor speed to match relative capacity penalizes the achievable COP leading to a maximum penalty of approximately 8% at low ambient temperatures which decreases with increasing ambient temperatures up to parity with R-410A at 51.7°C. Another important system operating parameter is the compressor discharge temperature which needs to be evaluated closely to ensure compressor operation throughout the operating map is not affected. The compressor discharge temperature difference compared to R-410A is shown in Figure 6.
R-454B shows higher compressor discharge temperatures compared to R-410A between roughly 4K at low ambient temperatures increasing to around 8K for high ambient temperatures. For drop in compressor speeds of 50Hz DR-4 shows similar CDT with slightly elevated values within 2K. R-479A provides lower compressor discharge temperatures ranging from 1K at low ambient temperatures to 4.5K at high ambient temperatures. With adjusted compressor speeds to match R-454B capacities at “A” condition the relative compressor discharge temperature difference increases for both low GWP options by approximately 2K to 3K. R-479A still provides lower relative temperatures compared to DR-4 and maintains lower temperatures compared to R-410A at ambient temperatures above 35°C.

In heating operation, the investigation was done in a similar way with a drop-in situation using a compressor speed of 50Hz as well as the adjusted speed as determined in cooling “A” condition. The results for relative COP at condition H1 are summarized in Figure 7.

Both low GWP refrigerant blend options show relative COP compared to R-410A within 5% with similar results for both 50Hz and adjusted compressor speeds. R-454B due to its larger R-32 blend fraction has a match in heating efficiency compared to R-410A. The relative capacity results in Figure 8 show the impact of increased compressor speed to make up the inherent lower capacity of the low GWP blends due to their properties.

R-454B shows slightly lower capacity compared to R-410A at H1 condition with an ambient temperature of 8.3°C. DR-4 and R-479A have about 18% lower heating capacity at drop in compressor speed of 50Hz. This can be recovered with the adjusted compressor speed and brings it within 5% of R-410A and slightly above R-454B. The effect on compressor discharge temperature can be seen in Figure 9. Similar to cooling operation R-454B shows higher compressor discharge temperature with 4.5K over R-410A. Both DR-4 and R-479A provide lower CDT with 2K and 6.7K respectively. Adjusting the compressor speed reduces this benefit of
lower compressor discharge temperature by about 4K for both candidates which results in about 2K lower CDT for R-479A and 2.2K higher CDT compared to R-410A for DR-4.

![Figure 9](image1.png)

Figure 9. Compressor discharge temperature of R454B and low GWP options compared to R-410A at H1 condition

At even lower ambient temperatures of -8.3°C at H3 condition the relative performance of all investigated refrigerants decreases compared to R-410A as shown in Figure 10.

![Figure 10](image2.png)

Figure 10. Relative heating COP of R454B and low GWP options compared to R-410A at H3 condition

For adjusted compressor speeds DR-4 and R-479A achieve similar capacity to R-454B within 5% of R-410A. The relative capacity as shown in Figure 11 confirms the trends seen for cooling operation with drop-in capacity of about 80% compared to R-410A. By adjusting the compressor speed the relative capacity is recovered to within 5% with slight improvement for R-479A over DR-4. R-454B shows slightly lower relative capacity compared to R-410A while operated at the same compressor speed of 50Hz. The impact of compressor discharge temperature is shown in Figure 12 confirming the offsetting impact of necessary compressor speed increase to accommodate for the lower capacity of low GWP blends DR-4 and R-479A.

![Figure 11](image3.png)

Figure 11. Relative heating capacity of R454B and low GWP options compared to R-410A at H3 condition

![Figure 12](image4.png)

Figure 12. Compressor discharge temperature of R454B and low GWP options compared to R-410A at H3 condition
For the drop-in compressor speed lower compressor discharge temperatures of 9.1K to 4.7K are achieved for R-479A and DR-4 respectively compared to R-410A. When adjusting the compressor speed to make up the lower capacity of the blends the CDT increases to 4.7K and 0.6K lower values compared to R-410A.

4. Conclusions

This paper described the investigation of low GWP alternatives to R-410A for new system designs due to their flammable characteristics. The three investigated alternatives represent different GWP levels ranging from around 450 with R-454B as well as 300 (DR-4) and 150 for R-479A. R-479A is hereby utilizing the recently classified molecule R-1132(E) that provides a GWP<1. The thermodynamic model showed good agreement with the modeling results of a detailed system model of a unitary heat pump under standard rating conditions. The drop in case with same compressor speed confirmed the lower relative capacity for the low GWP options DR-4 and R-479A with approximately 17% lower capacity as seen in the initial thermodynamic model. Increasing the compressor speed allowed for recovery of relative capacity within 5% for all investigated conditions for both heating and cooling. The lower compressor discharge temperature that can be achieved with DR-4 and R-479A is offset when increasing the compressor speed but remains lower compared to R-410A and R-454B which can be beneficial to avoid limitations of the compressor operating map due to compressor discharge temperature limitations. The evaluation of a detailed system model that considers a physical compressor model as well as heat transfer and pressure drop provides good insight and indication of expectable performance. However, experimental evaluations are needed to validate these findings. In conclusion R-479A has been found to provide comparable to superior performance and operating characteristics to DR-4 while having approximately half the GWP. Further improvement of the system design is expected to improve the overall efficiency from the drop-in situation that was evaluated in this study.

Abstract

The unitary air-conditioning and heat pump application sector is one of the largest single consumers of refrigerant today mostly with R-410A having Global Warming Potential (GWP) of 2088 or R-32 (GWP 675). Legislative phase-down of fluorinated refrigerants is driving a search for alternatives for this application with target to lower average GWP – ideally below 300. While some alternatives such as R-454B (GWP 466) or R-290 have already been identified as technically feasible, the flammability and charge size of systems may present an additional barrier to use these fluids. Use of R-744 has been considered in the past but the energy efficiency and cost of prototype systems has rendered it unattractive.

A non-flammable refrigerant blend of R-744, R-1132a and R-32, working name LFR3 (submitted to standards bodies for classification), GWP 142, has been developed, which in testing has demonstrated significant energy efficiency advantage over R-744. A project is now underway to assess the feasibility of using this fluid for heat pumps. The goal is to develop baseline performance on a production system designed for R-410A then to retrofit the system with new heat exchangers and compressor suitable for use with R-744 and to assess whether comparable efficiency (EER) to the R-410A may be achieved. Performance testing with R-410A, with a near drop-in low-GWP alternative (R-468C, GWP 284)) and of the prototype high pressure system will also be presented.

Keywords: refrigerants; low gwp, HFO, heat pumps

1. Introduction

The direct impact of refrigerant emissions and their global warming effect, measured by Global Warming Potential (GWP), have been a long focus by regulators. With another HFC allowance step down scheduled in 2024 as set forth by the F-gas regulation and the Kigali Amendment to the Montreal Protocol, the HVAC&R industry worked diligently in developing lower GWP refrigerants while updating standards and procedures to safely use the increasingly common mildly flammable refrigerants in systems and buildings. In addition, the HVAC sector, heat pumps to be specific, has been identified as key in accomplishing net zero energy goals established by corporations as well as governments. The US Department of Energy (DOE) published an industry decarbonization roadmap [1] in September of 2022 that laid out pathways in reaching the net-zero GHG emissions by 2050 in the US. Amongst the four pillars that were identified by the DOE, it is clear that heat pumps will be an integral technology for the energy efficiency and industrial electrification pillars. With ever increasing demand for more efficient HVAC systems, it is critical to take a wholistic approach when selecting a new refrigerant beyond the GWP value.

Refrigerant development activities were centered around designing fluids as closely as possible to incumbent refrigerants that would allow for easy adoption for both new and retrofit applications. To that end, the first part of this paper will present a drop-in assessment of a lower GWP R-410A replacement refrigerant,

* Corresponding author. E-mail address: sarah.kim@kouraglobal.com
R-468C. The second part of the paper will focus on a very high pressure low GWP refrigerant LFR3, blend of R-1132a, R-744, and R-32 (10/69/21 in mass %), which was developed to improve the efficiency of R-744 and expand the fluid usage to warmer climate zones. It is also nonflammable as formulated, which can be a promising solution for applications with larger refrigerant charges. A R-744 based prototype unit was built within the R-410A system frame, which was then assessed for cooling and heating performance of R-744 and LFR3.

2. Description

2.1. Refrigerant properties

As described in the previous section, four refrigerants have been experimentally evaluated in this work. They can be further categorized into two groups based on the pressure ranges: high pressure and very high pressure. Thermodynamic properties of the fluids are summarized in Table 1.

2.2. Test description

A commercially available R-410A packaged heat pump with a capacity of 17.6 kW (5 Ton) was used for R-410A and R-468C drop-in testing. The thermostatic expansion valve (TXV) was set to maintain a superheat of 3 K for cooling at A condition and was not readjusted for other conditions. Capacity was measured for both air and refrigerant side, which showed good agreement throughout the testing.

Upon completion of the high pressure refrigerant testing, a prototype unit was built within the frame of the R-410A unit with a goal to maintain the same cooling capacity of 17.6 kW, Figure 1. The same baseline indoor blower (air flow rate) and outdoor fan were used while a reciprocating compressor, indoor and outdoor heat exchanger, internal heat exchanger (IHX), accumulator, and EEV designed for R-744 were implemented. The purpose of this study was to evaluate the feasibility of using very high pressure low GWP refrigerants (R-744 and LFR3) in heat pumps while maintaining the same footprint as existing equipment with lower pressure.
3. Results and Discussion

3.1. Drop in test results for high pressure refrigerants

Refrigerants were evaluated at two cooling (A and B) and two heating conditions (H1 and H3) as described in the AHRI 210/240 standard [2]. The optimum charge of R-468C was determined to be 5.8 kg, 9% higher than the R-410A baseline, where sufficient subcooling was observed while maximizing the cooling capacity and COP. Uncertainty values were determined as ±0.7% for COP and ±0.2% for capacity.

![Fig. 1. R-744 system components fitted into the R-410A unit frame](image)

![Fig. 2. Capacity of R-410A and R-468C at cooling and heating modes](image)
R-468C showed slightly lower capacity values than R-410A especially during heating mode, Fig. 2. COP also showed a similar trend where R-468C exhibited comparable results to R-410A at cooling mode and lower efficiencies at heating mode, Fig. 3. These results are similar, but somewhat lower compared to previous drop in test results conducted in a R-410A split system where R-468C was reported as LFR1C [3]. Low reported similar or higher COP of R-468C than R-410A especially in heating mode. One potential reason for this discrepancy could be due to the testing in this work being carried out and optimized around cooling mode, which may have inadvertently hurt the heating performance. Also, it was noted that the performance was sensitive to the TXV opening and thus the superheat values, however, the TXV setting was not adjusted once it was set for A condition. A use of an electronic expansion valve (EEV) may help better modulate between the two modes. R-468C also has a higher glide of 4 to 5 K compared to R-410A’s glide of 0.1 K, therefore the direction of flow in the heat exchangers can favor one mode over the other and provides an opportunity to optimize the system based on primary operations.

3.2. Test results for very high pressure refrigerants in the prototype unit

Three parameters can be changed to adjust the capacity and high side pressure of the R-744 based system:

1. Refrigerant charge.
2. Compressor speed, and
3. EEV opening.

3.2.1. Cooling mode
At each refrigerant charge, the EEV opening and thus the gas cooler inlet pressure was adjusted to maximize the COP. Then the corresponding compressor speed was set accordingly in order to match the cooling capacity of 17.6 kW. Summary of the test results at optimum refrigerant charge are shown in Table 2. Uncertainty was determined as ±1.0% for COP and ±0.3% for capacity. LFR3 operated at a higher compressor speed compared to R-744, but showed higher COP and compressor volumetric efficiency (\(\eta_{vol}\)) while exhibiting 20% lower optimal gas cooler pressure.

Fig. 3. COP of R-468C relative to R-410A at cooling and heating modes
Compressor speed and refrigerant charge found in A condition were kept constant for B condition tests. The result trends for B condition were consistent to those observed in A condition, Table 3. The consistently higher cooling efficiency of LFR3 over R-744 was also reported when tested in a heat pump system for bus applications [4].

### 3.2.2. Heat pump mode
As the prototype unit was not assembled as a reversible system, the unit needed to be modified and re-piped prior to heat pump testing. It was also noted that the IHX was probably oversized and the combination of IHX and the accumulator contributed to additional pressure drop. Therefore, the accumulator was removed during the conversion. For cooling mode, the evaporator was mounted in parallel flow in order to have the same heat exchanger performing in counter flow in heat pump mode. As LFR3 is a zeotropic refrigerant, it was expected that the performance would further improve from the flow direction. The EEV opening was adjusted to maximize the COP while refrigerant charge and compressor frequency were kept at the previously determined values. The uncertainty was found to be $\pm 0.6\%$ for COP and $\pm 0.3\%$ for capacity.

</tr>
</tbody>
</table>

LFR3 and R-744 showed similar efficiencies, which is contrary to previous testing of LFR3 in an air-source heat pump water heater designed for R-744 where 15\% higher heating capacity and 35\% higher COP of LFR3 relative to R-744 were reported [5]. These very high pressure refrigerants, however, showed approximately 25\% improvement in heating capacities at the H1 condition compared to R-410A. The noticeable frost formation during the LFR3 runs may have led to lower than expected COP value, which is due to the combination of glide as well as parallel flow in the evaporator that brought down the evaporator inlet temperature to below 0°C.

Further testing on H3 condition is on-going and will be presented at the conference.

### 4. Conclusion
R-468C and LFR3 were evaluated as low GWP solutions in a packaged heat pump system. R-468C showed comparable performance as a R-410A alternative while providing more than 85\% reduction in GWP. It should be noted that R-468C is an A2L safety class per ASHRAE 34 and should only be used in systems designed for mildly flammable refrigerants.

It was also demonstrated that it is feasible to use very high pressure refrigerant LFR3 while providing matching capacity and footprint as existing commercially available equipment. The heating results were particularly promising considering that a reciprocating compressor was used in lieu of a higher efficiency scroll compressor. While LFR3’s COP was measured to be approximately 20\% lower than R-410A in average, the
results are encouraging given that they were obtained from a first-generation prototype unit. Proper sizing and selection of components with optimized heat exchanger designs will allow for further performance improvement.

Investigation of the performance of a ground-coupled CO₂ heat pump for space and water heating

Thor Alexis Sazona*, Homam Nikpeya

aUniversity of Stavanger, Kjell Arholms gate 41, Stavanger 4021, Norway

Abstract

A parametric investigation on a ground-coupled CO₂ heat pump for space and water heating was performed using a model developed with Modelica. The CO₂ heat pump, with a tripartite gas cooler configuration, was modeled using the Thermal Systems library and then calibrated with experimental data, while the Borehole Heat Exchangers (BHEs) were modeled using the MoBTES library and sized following the ASHRAE methodology. Different design and operating parameters were varied to see their effects on the system’s coefficient of performance (COP). Simulations showed that there is an optimal high-side pressure that maximizes the COP. The evaporator’s water-side mass flow, the BHE’s length, the grout’s thermal conductivity, and the compressor speed all have an inverse relationship with the COP, while the low-side pressure of the heat pump and the valve’s throttle area are directly related to it. However, changing these parameters to increase the COP has limits because doing so decreases the amount of heat that the system can deliver. This study serves as a starting point for the design and optimization of a bigger system that utilizes other low-temperature resources with the CO₂ heat pump.

Keywords: trans-critical CO₂ heat pump; borehole heat exchanger; Modelica; Space and water heating

1. Introduction

Heating/cooling accounts for around 50% of the total energy consumption in Europe, the majority of which (~45%) comes from the residential sector [1]. Burning fuels just to provide for the thermodynamically-lower grade demands of space and water heating, which only requires ~40 - 80 °C, is highly inefficient. It wastes the thermodynamic potential of combustible fuels, resulting in large exergy losses, and leads to emissions that could have been avoidable [2]. Heat pumps are devices that can harness heat from low-temperature resources and increase it to useful temperature levels. Given the substantial consumption associated with residential heating, displacing the inefficient use of combustible fuels through heat pumps, which also promotes the use of diversified and local energy resources, can contribute to increasing energy security and to decreasing CO₂ emissions.

Most heat pumps nowadays operate through a sub-critical vapor-compression cycle that uses Hydrofluorocarbons (HFCs) as working fluid. HFCs replaced the once widely-used ozone-depleting Chlorofluorocarbons (CFCs) because they exhibited similarly good performance, efficiency, low toxicity, and non-flammability. However, they were later discovered to be very potent greenhouse gases. Recent initiatives seem to point out the inevitable phase-out of HFCs. The EU’s F-gases regulation (EC517/2014) aims to gradually decrease the usage of important fluorinated gases in the EU, such as R404A, R410A, R407C, and R134a to one-fifth of 2014 in 2030 [3]. In addition, in January 2019, the Kigali amendment to the Montreal Protocol, wherein several countries committed to cutting the production and consumption of HFCs by more than 80% over the next 30 years, entered into force [4].

The growing environmental concerns about the use of conventional synthetic heat pump refrigerants have revived the interest in natural working fluids. Carbon dioxide is one of the few non-toxic and non-flammable natural refrigerants that have zero effect on ozone layer destruction and a substantially lower global warming potential (GWP) relative to commercially available alternatives [5]. Lorentzen first proposed the modern use of CO₂ in a trans-critical heat pump cycle [6]. One of the notable configurations of the CO₂ heat pump includes the tri-partite gas cooler, first proposed by Stene [7], [8], as a way to allow simultaneous and separate production of space heating and domestic hot water in an integrated design that simplifies the heat pump layout and piping requirements.

Due to substantial irreversibility during compression and gas cooling, the performance of a CO₂ heat pump is generally lower than that of a system using a subcritical cycle [9]. In addition, the reliability of the system is not as good because of the large performance variations with operating conditions. One of the ways to improve the performance of the CO₂ heat pump is by integrating it with borehole heat exchangers (BHEs). Generally, ground temperature down to depths of 5 - 10 m is influenced by solar radiation and ambient air temperature. Below 15 m, the ground temperature remains undisturbed by seasonal temperature variations [2], [10]. The undisturbed ground temperature then increases with depth due to the heat from within the Earth’s core [11]. Stable temperatures on the ground provide a more reliable heat pump performance as compared to using air as the heat source, given that air temperature varies greatly with the weather. Vertical BHEs are usually around 50-150 m in depth and may have a single U-type, double U-type, or coaxial configuration [12].

Wang et al. [13] compared the performance of a CO₂ trans-critical heat pump system that uses a U-tube BHE with the performance of conventional R22 and R134a systems. Their results suggest that if the system is applied for space conditioning and tap water heating, where high water temperature is desired, then it could reach efficiencies similar to that of a conventional R134a cycle. Kim and Chang [14] focused on the development of a model that could perform a steady-state thermodynamic performance analysis of a CO₂ geothermal heat pump system that implements a suction gas heat exchanger (SGHX). The model was implemented in Digital Visual Fortran with the graphical user interface (GUI) implemented in Visual Basic. Their simulations indicated that, in cooling mode, the COPs of the cycle with SGHX were 2-6% better than the typical trans-critical CO₂ heat pump cycle COPs. However, in heating mode, the configuration that uses an SGHX got slightly smaller COPs than those of the basic cycle. Kim et al. [9] performed a simulation study of a hybrid solar-geothermal CO₂ heat pump system for residential space heating in the winter. They considered a system configuration where heat from both the solar collector and heat pump is collected in a thermal energy storage tank whose temperature is controlled at a designated level. Engineering Equation Solver (EES) was used to model the system components and calculate the thermodynamic properties of the refrigerant. This study is also limited to steady-state performance calculations.

Replacing HFCs with alternative refrigerants requires systems with comparable efficiencies. If the new system has significantly lower efficiency and if the electricity that runs the compressor is mainly generated with the use of fossil fuels, the replacement of the existing system will just contribute more to global warming [15]. To push for wider technology uptake, careful investigation of the effects of various design and operating conditions on the performance and operating characteristics of the system is needed. Bellos and Tzivanidis [16] performed a parametric investigation on a ground-coupled CO₂ heat pump using steady-state calculations with EES. Their analysis shows the effects of ten parameters on the system’s coefficient of performance, five from the heat pump and five from the BHE.

Similarly, this work performs a parametric investigation on a ground-coupled CO₂ heat pump for simultaneous space and water heating using a system model developed with the Modelica language [17]. Modelica is an equation-based, object-oriented modeling language that allows dynamic simulations. While most studies performed steady-state calculations, the model developed here can consider time-varying system characteristics, particularly the reduction of ground temperature as it is used for space and water heating. Different design and operating parameters from both the heat pump side and the BHE side were varied to see their individual effects on the system’s COP. The result of this study serves as a starting point for the design and optimization of a bigger system that utilizes other low-temperature energy resources integrated with the CO₂ heat pump, and the model developed can be utilized for further simulation studies that entail time-varying inputs and responses.

2. Methods

In this work, the model was developed using Modelica with the Dymola [18] user interface. The CO₂ heat pump was modeled using the Thermal Systems library [19] in Dymola and then calibrated with experimental
data; while the BHEs were modeled using the MoBTES library [20] and then sized based on the ASHRAE methodology [21].

2.1. CO\textsubscript{2} heat pump modeling

The CO\textsubscript{2} heat pump model developed in this work was based on a 6.5 kW prototype unit constructed and tested by Stene [7, 8]. It consists of the counter-flow tripartite gas coolers, an evaporator, a compressor, a throttle valve, an SGHX, a sub-cooler, and a low-pressure receiver. Although the prototype can function in three modes (space heating only, domestic hot water (DHW) heating only, and simultaneous space and DHW heating), the model in this work was only calibrated for simultaneous space and DHW heating. Preheating of the incoming water from the supply line occurs at the first gas cooler while further increasing its temperature to a useful level is achieved at the third gas cooler. The second gas cooler separately provides the thermal energy needed for space heating.

This reference system was then converted into a Modelica model using the Thermal Systems library in the Dymola GUI. The Thermal Systems library, also synonymous with the TIL suite, is a commercial Modelica library for modeling thermo-fluid systems. It can be used to model various components, such as heat pump cycles, hydraulic networks, ventilation, and so on. It uses the TSMedia library to calculate the thermophysical properties of fluid and fluid mixtures [19].

The CO\textsubscript{2} heat pump model developed is shown in Fig. 1. The control strategy implemented includes: (a) controlling the DHW temperature by adjusting the water pump speed, (b) controlling the supply temperature for SH by adjusting the water pump speed, (c) controlling the high-side pressure of the heat pump by adjusting the throttle area of the valve, and (d) controlling the low-side pressure by adjusting the compressor speed. All of these were implemented in the model using proportional-integral (PI) controllers (Fig. 1).

Table 1 shows the design conditions of the prototype CO\textsubscript{2} heat pump unit when utilized for simultaneous space and water heating. At design conditions, the heat pump unit gives off ~3 kW of heat to a floor heating system at a supply/return temperature of 35/30 °C and ~3.5 kW to heat to the DHW from ~5 °C to ~60 °C. The compressor discharge pressure is around 85 to 90 bars, and the evaporation temperature is -5 °C. The specifications for the compressor used in the prototype are given in Table 2.

During the calibration of the CO\textsubscript{2} heat pump, the mass flow and temperature of the BHE fluid (propylene glycol) entering the evaporator were fixed at 0.36 kg/s and 3°C, respectively. These were assumed using some rule of thumb given in the ASHRAE handbook [21] since this information was not available in the reference material used.

The measured data for the design condition at 85 bars were used to calibrate the model. The information available in Stene’s work [7] was used to set the values of some parameters in the different component models, including the tube diameters of all the tube-in-tube heat exchangers, as well as their weights, material of construction, and length; the size of the low-pressure receiver; and the compressor displacement and operating range. The parameters adjusted during calibration include (a) the coefficient of heat transfer in each heat exchanger and (b) the isentropic and overall efficiencies of the compressor. A compressor model with fixed efficiencies was utilized for simplicity.

2.2. BHE modeling and sizing

Fig. 2 shows the BHE model developed in Dymola using the MoBTES library [20]. The MoBTES library is a free and open Modelica library that comprises components for the simulation of BHEs and Borehole Thermal Energy Storage (BTES) systems. It is built with objects from the Modelica Standard Library (MSL) for fluid heat flow and heat transfer. MoBTES was developed in accordance with MSL version 3.4, but in this work, it was revised to work with MSL version 4.0.
The BHE was connected to the CO₂ heat pump model by considering the BHE fluid mass flow rate and temperatures. The temperature of the fluid entering the heat pump (evaporator’s water side) was assumed equal to the temperature of the fluid exiting the BHE, while the temperature of the fluid exiting the evaporator’s water-side was assumed equal to the temperature of the fluid entering the BHE. The mass flow rate of the fluid circulating through the BHE and the water side of the evaporator was calculated by following the ASHRAE methodology. For simplicity, the ambient temperature was fixed to a constant value equivalent to the annual average temperature in Western, Norway.

The sizing of the BHE was implemented using the ASHRAE methodology [21]. In this method, the length of the borehole required for heating purposes $L_h$ is calculated using the Equation below.

$$L_h = \frac{Q_a R_s a + Q_h (R_p + PLF_m R_{sm} + F_{sc} R_{sd})}{T_0 - \frac{T_{in, hp} + T_{out, hp}}{2} - T_p} \frac{COP_h - 1}{COP_h} \quad (1)$$

Where $Q_a$ is the net annual average heat transfer to the ground; $PLF_m$ is the part-load factor for the design month; $R_{sa}$, $R_{sm}$, and $R_{sd}$ are the effective thermal resistances of the ground to the annual pulse, monthly pulse, and daily pulse, respectively; $F_{sc}$ is the short-circuit heat loss factor; $R_b$ is the overall borehole thermal resistance; and $T_p$ is the temperature penalty for the interference of adjacent bores.

The overall thermal resistance $R_b$ is the sum of the heat exchanger thermal resistance $R_p$, which is the average of the thermal resistance of the tube $R_{tube}$ and the film thermal resistance of the fluid $R_{film}$, and the thermal resistance of the grout $R_{grt}$.

$$R_b = R_p + R_{grt} \quad (2)$$

$$R_p = \frac{R_{tube} + R_{film}}{2} \quad (3)$$

$$R_{film} = \frac{1}{\pi d_{in} h_f} \quad (4)$$

$$R_{tube} = \frac{\ln d_{out}}{2\pi k_{tube}} \quad (5)$$

$$R_{grt} = \left(k_{grt} b_0 \left(\frac{d_p}{d_{out}}\right)^{b_1}\right)^{-1} \quad (6)$$

Where $d_{in}$, $d_{out}$, and $d_p$ are the inner, and outer diameters of the tube, and the borehole diameter, respectively; $h_f$ is the convective heat transfer of the fluid; $k_{tube}$ and $k_{grout}$ are the conductive heat transfer coefficients of the tube and the grout, respectively; and $b_0$ and $b_1$ are coefficients found in the ASHRAE handbook specific to the position of the tube in the borehole.

The heat transfer coefficient of the fluid $h_f$ is calculated using the Colburn equation [22]. In this work, the Reynold’s number $Re$ has values in the turbulent regime, so it follows that:

$$Nu = 0.023 Re^{0.8} Pr_f^{1/3} \quad (7)$$
\[ Nu = \frac{h_f d_{in}}{k_f} \quad (8) \]
\[ Re = \frac{4m_{f,0}}{\pi d_{in} \mu_f} \quad (9) \]
\[ Pr_f = \frac{\mu_f c_{p,f}}{k_f} \quad (10) \]

Where \( Nu \) is the Nusselt number; \( Re \) is the Prandtl number; \( k_f \) is the thermal conductivity of the fluid; \( m_{f,0} \) is the mass flow of the geothermal fluid in one borehole; \( \mu_f \) is the fluid viscosity; and \( c_{p,f} \) is the geothermal fluid heat capacity.

2.3. Parametric simulation runs

The parametric investigation was implemented by varying the values of chosen parameters one at a time. Table 3 shows the heat pump and BHE parameters varied, with their default values and the ranges of the variations implemented. Five of these parameters pertain to the heat pump and the other three pertain to the BHE. During these simulation runs, the space and water heating demand were fixed to the value used during the calibration simulation. The mass flow of the BHE fluid was also fixed to the value calculated from the ASHRAE methodology (0.42 kg/s). Each simulation case was run for 980 hours [21]. Note that this only covers the full load hours in a year. Since the COP of the system changes with time, given that the input temperature of the heat source changes with utilization, only the COP values at the end of the simulation time were compared.

3. Results and discussions

In this work, the model was developed using Modelica with the Dymola [18] user interface. The CO\(_2\) heat pump was modeled using the Thermal Systems library [19] in Dymola and then calibrated with experimental data; while the BHEs were modeled using the MoBTES library [20] and then sized based on the ASHRAE methodology [21].

3.1. Calibration of the CO\(_2\) heat pump model

The heat pump model was calibrated using the measured data at the high-side pressure of 85 bars; this represents the design conditions of the heat pump. Some component specifications were obtained from the reference material while some were determined through the calibration process. Table 4 shows the values of the heat exchanger parameters while Table 5 shows the parameters for the other heat pump components, such as the low-pressure receiver and the compressor. During calibration, the values of the heat transfer coefficients were assumed equal for the two sides of each heat exchanger and then adjusted so that the heat flows and the available inlet/outlet temperatures (Table 1 (water) and Table 6 (CO\(_2\))) and temperature approach data (Table 1) are matched. Some of them required to have different water-side and CO\(_2\)-side heat transfer coefficients to match the data. The efficiencies of the compressor were adjusted to simulate measured heat flows, power consumption and CO\(_2\) inlet temperature. The effective isentropic efficiency (Table 4) also takes into account the supplied mechanical power.

*Values determined from the calibration process

Table 6 gives the results of the CO₂ heat pump calibration runs. The model was calibrated against the data for P_GC = 85 bars, while the other measured data were used to test the calibrated model. Calibration and test errors were obtained by comparing the measured and simulated COPs. As shown, the error generated by the calibrated model increases when it is used to simulate an off-design condition (design conditions: 85 to 90 bars, as given in Table 1). This can be partly attributed to the choice of using a simplified compressor model that assumes constant efficiencies.

Table 6. Results of the calibration CO₂ heat pump unit at ~60°C DHW temperature, ~35/30°C supply/return temperature for SH (data taken from [7]; 
\( Q_{DHW} = Q_{GC1} + Q_{GC2} \), \( Q_{GC2} \) is the heat for SH, \( T_e \) is the evaporator temperature in the CO₂ loop)

3.2. Modeling and sizing of the BHE

The parameters assumed to calculate the size of the BHE using the ASHRAE methodology are given in Table 7. As shown, it was assumed that 4 BHEs are needed to provide the ~6.5 - 7 KW heat required by the system. A yearly equivalent heating full-load hours of 980 h then was assumed based on the data given in the ASHRAE handbook for Portland, Maine [21], assuming that the weather there is comparable to that of western Norway. The ground was assumed to have the characteristics of Slate, one of the common rock types in some parts of Norway [23] while the thermal gradient was assumed to be 0.0125 K/m, similar to that of some wells drilled in Bergen, Norway [24].

Following the procedure in the ASHRAE method, a borehole length of 82 m/well was calculated. Consequently, the calculated BHE length, as well as the assumed BHE parameters, were inputted to the BHE model, and a simulation was run to see if it can maintain the output of the heat pump system to around 6.7 kW (value used in the calibration) for the equivalent full-load hours of 980 h.

The result of the simulation shows that a BHE length of 82 m was not enough to maintain the output of the heat pump system to at least 6.7 kW for 980 h of continuous operation. Of course, in reality, the heat pump is not expected to be operated continuously for 980 h at full load, so this BHE length might already be enough for the expected usage. However, it is normal to oversize the BHE to take into account the changes in the performance that can be expected from the changes in ground temperature upon utilization [25]. Therefore, the BHE length was increased until simulation shows that it can support at least 6.7 kW by the end of 980 h of continuous full-load run. From this, a borehole length of 95 m was determined and used as the base value for the parametric simulation runs.

3.3. Parametric Simulation Runs

Simulation runs were performed to see the effects of varying some of the heat pump and BHE design and operating parameters on the COP (Table 3). Before the parametric runs, the performance of the base model, which uses the default values of the parameters, was determined. Fig. 3 shows the COP, the heat extracted from the BHE, the total heat from the gas coolers, and the power input to the compressor with the time of the base model. It can be seen that the heat derived from the BTES and consequently from the gas coolers decreased with time. This is expected as thermal energy from the ground, as well as its temperature (Fig. 4), would decrease if it were continuously used to provide the heating demand without recharge. Nonetheless, the
COP throughout the full-load period of 980 h remained between 3.8 and 4.

Fig. 3. Performance of the base model with time

Fig. 4. Ground temperature with time

Fig. 5 gives the results of the parametric simulation runs. To make the comparison easier, only the performance values at the end of the 980 h simulation runs were used. It should be noted that the variation in the compressor speed and throttle valve area were both implemented by removing the PI controllers that maintain the high-side and low-side pressure at fixed levels. This means that for these two sets of simulation runs, the high- and low-side pressure varies with the parameter variation, unlike in the other parametric simulation runs performed here. Stene [7] pointed out that the high-side pressure of the CO₂ heat pump is controlled by using the low-pressure receiver and by adjusting the opening of the expansion valve, which temporarily changes the balance between the mass flow rate in the compressor and the valve. Reducing the valve opening accumulates more CO₂ in the gas cooler piping, thereby increasing the high-side pressure until a new balance point for the mass flow rate in the compressor and the valve is reached. The extra CO₂ charge needed to increase the pressure is boiled off from the liquid reservoir in the receiver. On the other hand, opening the expansion valve reduces the high-side pressure and the surplus CO₂ is stored as a liquid in the receiver.

It can be seen from Fig. 5a that an optimum high-side pressure that maximizes the COP of the system is present. In this case, it occurs at the design operating pressure of 85 bars. The compressor speed, the evaporator’s water-side mass flow, the BHE’s length, BHE spacing, and the grout’s thermal conductivity all have an inverse relationship with the COP. However, as any of these parameters were lowered to increase the COP, the amount of heat that the system can deliver also decreased. This points out that they can only be decreased to certain limits when they could still sufficiently provide the value of the heat demand. On the other hand, as the low-side pressure of the heat pump and the throttle valve area were increased, the COP also increased. Similarly, there are also limits on these since increasing their respective values decreases the heat that could be delivered by the system.

Given the assumed variation range of the parameters, it can also be observed that the performance of the heat pump is most reactive to the high-side (discharge) heat pump pressure and the throttle valve area, followed...
by the low-side (suction) heat pump pressure and the compressor speed. Conversely, it is least reactive to the variation in the BHE spacing and the grout thermal conductivity.

Fig. 5. Variation of COP with different heat pump and BHE parameters: (a) high-side pressure, (b) low-side pressure, (c) throttle valve area, (d) compressor speed, (e) evaporator water-side mass flow rate, (f) BHE length, (g) BHE spacing, and (h) grout thermal conductivity
4. Conclusion

A parametric analysis was performed on a ground-coupled CO$_2$ heat pump system that is designed to simultaneously provide for both space and water heating demands. The CO$_2$ heat pump model was first developed and calibrated using data from an experimental setup. Afterward, the BHE was modelled and then sized using the ASHRAE methodology.

The calibration shows that the model performs closely to the experimental rig when it operates within design conditions. The results of the parametric studies show that an optimum high-side pressure maximizes the COP of the system. The compressor speed, the evaporator’s water-side mass flow, the BHE’s length, and the grout’s thermal conductivity all have an inverse relationship with the COP, while the low-side pressure of the heat pump and the throttle area of the expansion valve are directly related to it. However, changing all these parameters to increase the COP has limits since they all impose a decrease in the amount of heat that can be delivered by the system. It was also observed that the performance of the heat pump is most reactive to the high-side (discharge) heat pump pressure and the throttle valve area, followed by the low-side (suction) heat pump pressure and the compressor speed. Conversely, it is least reactive to the variation in the BHE spacing and the grout thermal conductivity.

This work is planned to be further extended to investigate other performance indicators, such as the total annual cost, seasonal performance factor, and ground temperature change. It is also planned to expand the system to include a solar thermal collector component, a tank thermal energy storage, and energy demand specifications that follow realistic patterns for a given year.

Abstract

Transcritical CO₂ heat pumps have the potential to be environmentally friendly to decarbonize buildings. This technology is very efficient for water heating applications. However, they generally exhibit poor efficiencies for space heating due to high return temperatures. This paper presents new experimental test data obtained by operating a single screw industrial heat pump for space heating and cooling in large buildings. This transcritical CO₂ pilot-scale prototype has a maximum heating and cooling thermal capacity of 1.35 and 1.05 MW, respectively. The results show that decoupling the thermal load from the CO₂ heat pump by the use of thermal storage tanks increases substantially the coefficient of performance (COP) of the system compared to the reference case (without heat storage and temperature conditioning).

1. Introduction

Heat pumps are increasingly recognized as an efficient and low-carbon energy technology for heating, cooling and sometimes for providing hot water to buildings. The global heat pump market has expanded rapidly over the last few years, with around 190 million units in operation in buildings worldwide in 2021, the three main markets being in China (33%), North America (23%) and Europe (12%) [1,2]. Though being considered as a key and cost-effective component towards the reduction of carbon emissions in the residential and commercial sectors, heat pumps currently provide only 10% of the global heating need in buildings. In the 2050 carbon neutrality scenario, the world heat pump stock should reach 600 million by 2030, representing 20% of the global heating needs and having a more preponderant position to face the increased cooling needs. Countries currently develop different strategies (constraining building codes and standards, performance-based labels, grants to support system’s acquisition or privileged electricity tariff) to accelerate the deployment of heat pumps in residential and commercial buildings. Some markets also credit the heat supplied by heat pumps as renewable such that they get eligible to specific grants [1]. However, their market penetration remains relatively slow. Gaur et al. [3] discussed the main barriers to their integration: high upfront costs, uncertainty in policy, lack of standards, public acceptance and limitation of the electrical networks.

Heat pump technology allows to uplift low-grade temperature heat sources to a useful temperature level (sink) using electricity. Thus, they can operate using low-grade renewable energy sources (air, water, ground or solar), but also using waste heat. They can provide both heating and cooling (reversible heat pumps), separately or simultaneously, with no heat dissipation. They are then highly efficient with coefficients of performance (COP) typically ranging from 3 to 5 [4]. When the electricity used to drive the compressor comes from a renewable source (like hydroelectricity as it is the case in the Québec province for example), all the
useful heat provided by the heat pump gets zero-carbon. Besides the prime objective of efficient decarbonation, heat pumps may also play a role to enhance the energy security of countries.

As shown by Gaur et al. [3], the literature on heat pumps is quite abundant and the number of publications continues to rise exponentially. The interested reader can refer to the recent review of Ni et al. [5] for more details about heat pump systems for heating and cooling of buildings. The authors focused on air and ground heat pumps integrating a thermal energy storage under the form of water, phase change materials or ground. Wang et al. [4] discussed the main parameters affecting the performance of heat pumps: hybridization of the different heat sources and sinks depending on the temperature levels, compressor efficiency and potential integration of a thermal energy storage.

There is no consensus on the appropriate definition of a large-scale heat pump. For the European Heat Pump Association (EHPA), heat pump is considered large if its capacity exceeds 100 kW. Their potential integration for district heating systems and their impact are constantly investigated through case studies mainly in North Europe: Baltic countries [6], Germany [7] or Denmark [8] among other examples. These different works enable to compare the benefit of heat pumps compared to other sources (biomass [6], coal-fired combined heat and power system [7], mixed sources [8]) but also demonstrate that results are strongly case-dependent. David et al. [9] analyzed the existing electricity-driven heat pumps with a thermal capacity output equal or greater to 1 MW installed in Europe. They highlighted the huge potential for using sewage water and ambient water as the main heat sources followed by geothermal energy. Ground source heat pumps are indeed preferred over air source ones in Nordic climates as they are more constant and at higher temperature levels. Schlosser et al. [10] reviewed the applications, performance, economic feasibility and industrial integration of large-scale heat pumps. Their analysis, which gathers 155 large-scale heat pumps, covered all types of refrigerants, compressors, heat sources, etc.

As already mentioned, compressor efficiency plays a crucial role on the system performance. Jesper et al. [11] analyzed a database of 33 large-scale heat pumps from 11 different manufacturers. The distribution between reciprocating piston, screw and scroll compressors was well balanced. Screw compressor-based heat pumps exhibited the highest lift temperature difference and the largest nominal thermal output range. Wang et al. [12] proposed a matching strategy for a screw compressor integrated in a heat pump. It consists in the matching of the built-in volume of the compressor and the annual heating and cooling demands. They also introduced a new performance index denoted ACOPA (Annual integrated Coefficient of Performance under Actual operating conditions). For a ground-source heat pump, they showed numerically that such a strategy may improve the ACOPA by 6%.

R134a and R245fa are certainly the most used refrigerants in large-scale heat pumps [10, 11]. Due to their progressive phase-out, new low Global Warming Potential (GWP) refrigerants have to be considered. Hydrocarbons like R600 (n-butane) or R601 (pentane) have a low GWP but are highly flammable such that their filling capacity is limited to 2.5 kg in heat pumps in Europe, excluding them from potential large-scale applications. The use of alternative natural refrigerants in large-scale heat pumps with a low GWP and a favourable safety classification like R718 (water) or R744 (carbon dioxide), though being highly attractive, is still not state-of-the-art technology according to Jesper et al. [11]. As shown recently by Song et al. [13], transcritical CO₂ heat pumps are widely considered for water heating in buildings or for industrial processes and attention is now turned more on their performance optimization by ejector or vortex tube. Their application for space heating is scarcer. Schlosser et al. [10] proposed a correlation for the COP of transcritical CO₂ heat pumps based on four series from the same manufacturer, all using a reciprocating piston compressor. It represents 936 operating points in total. COP does not depend on the logarithmic mean temperature on the heat sink but depends only on the lift temperature difference.

To fully benefit from the heat pump potential, thermal energy storage is deemed necessary to continuously operate the system, shift the heat production to off-peak hours and decrease the thermal capacity to less than the maximum heating requirement among other benefits. It results in reduced installation and operating costs. Osterman and Stritih [14] proposed a recent review on compression heat pump systems including thermal energy storage (TES) for heating and cooling in buildings. Energy can be stored under three different forms, namely sensible storage, latent storage and thermo-chemical heat storage. Sensible TES through water storage tanks are the more simple and common solution. The authors found that in most cases, air is used as a balancing source and the capacities of heat pumps and the size of storage tanks remains relatively small. No study concerned the experimental investigation of a ground source transcritical CO₂ large-scale heat pump coupled to a TES for space heating and cooling, as in the present work. Liu et al. [15] considered a water source CO₂ heat pump with TES but at a small scale: 3 kW of nominal thermal capacity and small water storage tanks (around 170 L each for the hot and cold tanks). Alkhwidi et al. [16] developed a numerical model based on TRNSYS of ground source heat pump with hybrid TES (water and salt-hydrate) used to reduce the peak electricity demand of a 180 m² house in Toronto, Canada. A 2.5 m³ water tank was found sufficient to fully shift load. The results are theoretical and difficult to reproduce as no details on the type of heat pump and refrigerant used are provided.
Scientific and technical innovation is still required to improve the performance and durability of heat pumps, enhance their flexibility for the heating and cooling of large buildings and accelerate their market penetration. To the best of the authors’ knowledge, the present work is the first to demonstrate the potential of a single screw industrial transcritical CO₂ heat pump for space heating and cooling in large buildings at the pilot scale. The addition of a water storage tank having a thin thermocline separating its hot and cold sections drastically improves the performance of the system by enabling to decouple the thermal load from the heat pump. It also allows to feed the heat pump’s evaporator when the heat source is insufficient, which has never been demonstrated at this scale for this particular heat pump.

The paper is organized as follows: the experimental set-up and the associated instrumentation are described in detail in Section 2. The results are presented in Section 3. The discussion focuses on the benefit of decoupling the thermal load from the heat pump cycle by adding a large capacity thermal storage tank. Conclusions and future views are finally provided in Section 4.

2. Prototype Description

The test rig of the water source transcritical CO₂ heat-pump consists of three major components: water-loop system, heat-pump system, and data collection system. The schematic diagram of this experimental system is shown in Figure 1. It is composed of a gas cooler, an evaporator, a compressor, a flash tank, an internal heat exchanger, and an electronic expansion valve (EEV). The water loop system includes thermal storage tanks that decouple the thermal load from the CO₂ heat pump and allow performance enhancements. Detailed information about the main components is summarized in Table 1.

T-type thermocouples were adopted to measure the temperatures in the experimental system. The measurement accuracy is ±0.2 °C in the range of −10 °C to 150 °C. CO₂ mass flowrate was measured by a Coriolis mass flowmeter with the accuracy at ±0.1% in the range of 26 to 9,072 kg/h. Pressure transmitters with the accuracy at ±0.25% (0–6 MPa and 0–16 MPa, respectively) were used to measure the CO₂ pressures. Turbine volumetric flowmeters with the accuracy at ±0.5% were used to measure water flowrates.

---

2 The volume and geometry characteristics have been determined using CFD simulation.
Figure 2 shows the p-h diagram of the heat pump system under study. The main system cycle is 1-2-3-4-5-6-7-1. The refrigerant is compressed from point 1 (superheated vapour) to point 2 (supercritical fluid) by the compressor. The water is heated in the gas cooler by the heat released from point 2 to point 3. The water is cooled from point 7 to the gas saturation line by the CO₂ evaporation and CO₂ is overheating from the saturation vapour line to point 1 by the heat absorbed in the internal heat exchanger. (Point 3 to 4)
The CO$_2$ heat pump COP is calculated by the following relation:

$$COP = \frac{Q_h}{W_c}$$  \hspace{1cm} (1)

where $Q_h$ and $W_c$ represent the heating capacity and the compressor power, respectively.

$Q_h$ is calculated as follows:

$$Q_h = \dot{m}_g C_g (T_{go} - T_{gi})$$  \hspace{1cm} (2)

where $\dot{m}_g$ and $C_g$ denote mass flowrate and heat capacity, respectively, of the thermal fluid circulating in the gas cooler. $T_{go}$ and $T_{gi}$ are the outlet and inlet temperatures of the thermal fluid.

Similarly the combined COP for heating and cooling is determined by adding the cooling capacity $Q_c$ to the numerator of equation 1.

$Q_c$ is calculated as follows:

$$Q_c = \dot{m}_e C_e (T_{eo} - T_{ei})$$  \hspace{1cm} (3)

where $\dot{m}_e$ and $C_e$ denote mass flowrate and heat capacity, respectively, of the thermal fluid circulating in the evaporator. $T_{eo}$ and $T_{ei}$ are the outlet and inlet temperatures of the thermal fluid.

The root-sum-square method was applied for calculating uncertainties of measured variables as follows

$$\varepsilon_{\nu} = \sqrt{\sum_{i=1}^{k} \left( \frac{\partial \nu}{\partial \alpha_i} \varepsilon_{\alpha_i} \right)^2}$$  \hspace{1cm} (4)

where $\nu$ denotes the analyzed variable. $\alpha_i$ denotes the variable affecting $\nu$. $\varepsilon_{\nu}$ and $\varepsilon_{\alpha_i}$ denote the uncertainties of $\nu$ and $\alpha_i$, respectively. This method is utilized for calculating uncertainties of measured variables in Equations 1 and 2. Uncertainty of COP ($\varepsilon_{COP}$) is calculated by:

$$\varepsilon_{COP} = \sqrt{\left( \frac{\partial COP}{\partial Q_h} \varepsilon_{Q_h} \right)^2 + \left( \frac{\partial COP}{\partial W_c} \varepsilon_{W_c} \right)^2}$$  \hspace{1cm} (5)

where $\varepsilon_{Q_h}$ and $\varepsilon_{W_c}$ represent the uncertainties of $Q_h$ and $W_c$, respectively. $\varepsilon_{COP}$ is calculated by:

$$\varepsilon_{COP} = \sqrt{\left( \frac{\partial COP}{\partial \dot{m}_g} \varepsilon_{\dot{m}_g} \right)^2 + \left( \frac{\partial COP}{\partial T_{gi}} \varepsilon_{T_{gi}} \right)^2 + \left( \frac{\partial COP}{\partial T_{go}} \varepsilon_{T_{go}} \right)^2}$$  \hspace{1cm} (6)

where $\varepsilon_{\dot{m}_g}$, $\varepsilon_{T_{gi}}$, and $\varepsilon_{T_{go}}$ denote the uncertainties of $\dot{m}_g$, $T_{gi}$, and $T_{go}$, respectively. Using measured data, $\varepsilon_{COP}$ could be determined by Equations 1 to 6. Calculations shows that the maximum $\varepsilon_{COP}$ is 3.92%.

3. Experimental Results and Discussion

The prototype previously described has been operated in order to assess its performances and study the effect of some governing parameters such as: discharge pressure, compressor speed, heat source and sink temperatures. Experimental results are presented hereafter.

3.1. Discharge pressure effect

The effects of the discharge pressure upon the key parameters characterizing the transcritical CO$_2$ heat-pump system are illustrated in Figures 3–5. The other influencing parameters are kept constant.
As shown in Figure 3, upon increasing the discharge pressure, the CO$_2$ mass flowrate gradually decreases. This results from the regulation of the discharge pressure by adjusting the EEV opening. If the EEV opening is reduced, the mass flowrate of CO$_2$ flowing through EEV decreases, leading to an excessive accumulation of CO$_2$ in the gas cooler. As a result, the discharge pressure and temperature increase and consequently, the heat generated at the gas cooler increases as displayed in Figure 4. Since the water temperature at the outlet of the gas cooler is regulated by the water flowrate to keep it close to a setpoint, the water flowrate is adjusted automatically as the discharge pressure increases by a PID that controls the pump’s speed.

Figure 4 displays the heating-cooling output and the compressor power demand as a function of the discharge pressure. It observed that an increase of discharge pressure results in a higher heating and cooling capacities. As the EEV closes, the discharge pressure increases, and the suction pressure decreases. Consequently, the discharge temperature is higher, and the evaporating temperature is lower. Thus, water flowrates increase in both the gas cooler and the evaporator to keep the pre-set temperatures at the exists constant. This explains the augmentation of the heating and cooling capacities. Upon increasing the discharge pressure, the specific work of the compressor increases significantly due to the increase of the compression ratio. However, the CO$_2$ mass flowrate decreases with the increase of the discharge pressure. It is important to mention that the influence of the specific work is much larger than that of the CO$_2$ mass flowrate, hence, the cross effect of the two factors lead to the increase of the power demand of the compressor.
Figure 5 shows that with the increase of the discharge pressure, the COP rises steadily. Since the discharge pressures tested do not exceed 90 bar, it is unlikely to reach the optimum discharge pressure for which the COP is at its maximum. Based on the previous analysis, the power consumption increases monotonously with the increase of the discharge pressure.

![Figure 5. Effect of discharge pressure on HP performance](image)

3.2. Effect of compressor speed

Figure 6 presents the compressor power demand for different rotational speed: 2000 to 4200 rpm. As the compressor speed increases, the EEV opens to maintain the discharge pressure constant. Thus, the refrigerant flowrate increases as well as the flowrate of water since more thermal energy must be evacuated.

![Figure 6. Effect of compressor speed on flowrates](image)

Indeed, Figure 7 shows that the heating output through the gas cooler increases as the compressor’s speed evolves. It is worth mentioning that the decrease of the compressor speed reduces substantially the compressor power demand. For example, when the compressor speed drops from 4200 to 2000 rpm, the power demand is reduced by 57%.
It is important to point that the influence of the compressor speed on the COP is not pronounced namely for speeds exceeding 3300 rpm as displayed in Figure 8. Indeed, the performance decreases by only 12% when the compressor speed drops from 4200 to 2000 rpm. This finding is important as it has an important impact for demand response applications for which the compressor speed variation is an advantage.

3.3. Heat source temperature effect

Heat source temperature is represented by the inlet water temperature at the evaporator. This parameter has been varied from 12°C to 20°C while the temperatures at the inlet and outlet of the gas cooler have been maintained constant at 20°C and 60°C respectively. The compressor speed was set at 4200 rpm and the high pressure was fixed at 86.2 bar.

Figure 9 displays that an increase in the heat source temperature results in an increase of the flowrates on both sides of the gas cooler. The increase of the refrigerant flowrate is due to an enhancement of the evaporating kinetic as more heat is supplied to the evaporator even though the compressor speed is kept constant. Since more heat is absorbed by the evaporator, it is expected that more heat will be released at the gas cooler (Fig. 9). In this case, the water flowrate will increase to maintain the water outlet temperature at the set-point of 60°C.
Figure 10 displays the impact of heat source temperature on thermal outputs and compressor power demand. The increase of the heat source temperature at the evaporator increases the heat adsorbed and rejected by the heat pump as mentioned before. The power demand of the compressor rises as well because of an increase of the refrigerant flowrate occurs due to an enhancement of the vaporizing process in the evaporator. As a consequence, the performance of the heat pump is improved as shown in Figure 11.
3.4. Heat sink temperature effect

Figure 12 displays the variation of the COP for both heating and cooling as a function of the water temperatures at the inlet and outlet of the gas cooler for different discharge pressures. The compressor speed and the heat source temperature are kept constant at 3500 rpm and 12 °C, respectively.

Results show that for a constant outlet temperature at the gas cooler when the inlet temperature increases, the performance deteriorates. Since an increase in the inlet temperature results in an increase of the CO₂ temperature at the outlet of the gas cooler, the heat absorbed at the evaporator is less and consequently, the thermal output decreases.

On the other hand, when the inlet temperature is kept constant, any reduction in the outlet temperature will lead to an increase of the COP. In fact, the water flowrate through the gas cooler is higher when the outlet temperature is reduced.

![Figure 12. Effect of gas cooler inlet outlet temperatures on HP performance (3500 rpm and T\textsubscript{source} = 12°C)](image)

4. Conclusion

A transcritical CO₂ heat pump has been built at the pilot-scale to demonstrate the potential of such a technology to provide heating and cooling to large buildings. The heat pump is composed of an open single screw compressor, shell and tube heat exchangers (flooded at the evaporator), expansion valves, a flash tank and a copper brazed plates internal heat exchanger. The water loop system includes thermal storage tanks that decouple the thermal load from the CO₂ heat pump and enable performance enhancement. Detailed information about the main components is summarized in Table 1.

The influences of the discharge pressure, compressor speed, and heat source and sink temperatures on the main performances of the system have been quantified in detail and discussed. The main results may be summarized as follows:

- Both heating and cooling COPs are increasing as a function of the discharge pressure, compressor speed, and heat source / sink temperatures.
- The maximum heating and cooling power capacities are 1.362 and 0.988 MW, respectively.
- The maximum COP values are 2.75 and 2 for heating and cooling, respectively, leading to a maximum combined COP of 4.75. (Real COP measured based on heat outputs on the water sides).

This technology appears as a valuable way for the decarbonization and efficient electrification of large commercial or residential building. Future works include the detailed investigation of the water storage tank and more particularly its optimal design to manage the thermocline.

Abstract

The introduction of new process media like refrigerants with low GWP (Global Warming Potential) and the specific operating conditions of heat pumps can create challenges for traditional bearing technology: dilution of the lubricating oil by process media is increasing, lubrication films are getting thinner, and risk of corrosion and chemical compatibility need to be investigated upfront. Furthermore, the use of variable frequency drives (VFD) extends the speed range to both lower and higher values for which the bearings must operate reliably. In certain cases this even requires a change of bearing technology like from hydrodynamic to rolling element bearings. But also rolling bearings can suffer from above mentioned conditions. Therefore this article summarises the extensive research and development to provide state-of-the-art rolling bearing solutions and related engineering advice. This involves tribological testing and lubrication characterization of refrigerants and oil-refrigerant mixtures. The article also touches on the use of hybrid ceramic bearings, stainless materials, coatings, and advanced cage materials. The effect of oil dilution and poor lubrication and its impact on surface distress and rolling bearing life, as well as the effect of contaminating particles have been captured in models to allow engineers to give improved predictions of bearing performance and durability. Finally, different rolling bearing solutions to deal with the challenges related to lubrication and bearing life in heat pump compressors are described, all the way from oil-refrigerant mixture lubrication with moderate high dilution rates, up to a major innovation related to oil-free lubrication, so-called Pure Refrigerant Lubrication (PRL).

1. Introduction

In the UN COP26 conference on climate change in 2021 one of the priorities was securing agreements for reducing emissions, with the goal of limiting the increase of global temperatures to 1.5 °C. Investment in renewable energy sources is encouraged while phasing out fossil fuels is identified as crucial to delivering this target [1]. Heat pump technology is seen as a key technology to replace fossil fuel usage and reduce carbon emissions. One major advantage of heat pump technology is that heat can be collected from a variety of renewable or other sources, such as air and water as well as geothermal and waste heat, producing no direct local emissions (as long as heat pump drive energy is also renewable).

Industrial heat pumps and heat pumps for district heating often use waste heat from processes in industries like food & beverage, pulp & paper, cement and building materials industry, chemical and petrochemical industries as well as refineries, and even large computer or data centres that need significant cooling for their operations. Heat pumps can help to cut operating costs and enable the electrification of the heating process.

Different from chillers, compressors in heat pumps must enable higher temperature (and pressure) lifts, often with discharge temperatures larger than 100°C to be applicable e. g. for drying operations and steam...
production. The higher temperatures and pressures, together with the use of (new) refrigerants, lead to bearing lubrication regimes with a mixture of lubricant oil and refrigerant, in some cases with very high rations of low-viscous refrigerant in the oil. At higher temperatures the lubricating films become thinner than in conventional chillers, affecting the life of the bearings. The use of new low-GWP refrigerants, which are typically less chemically stable or more chemically active, or the use of ammonia as a refrigerant might in certain cases (like in the presence of humidity or water) harm the bearing materials by chemical attack, corrosion, ageing or close contact with hydrogen derivatives. The use of variable frequency drives (VFD) broadens the speed range in which the bearing solution must operate reliably. These challenges make rolling bearings one of the most critical machine elements in the evolution of heat pump technology, and reliable solutions need to be developed.

There is good amount of research work dedicated to rolling bearings lubricated with oil-refrigerant mixtures (ORM) and pure refrigerant lubrication (PRL). However, for the purpose of this publication, focus is put on the research that aims to describe and understand the effects of these types of lubrication on bearing performance and bearing life. For refrigeration compressors, the reader is kindly referred to the review paper published earlier by some of the current authors [2].

Early work in the 1990’s related to the ORM lubrication of bearings and life effects is described in [3-4]. The effect of refrigerant dilution in lubricated contacts and film thickness is studied experimentally and numerically in [5-9]. Detailed numerical work of the elasto-hydrodynamically lubricated (EHL) contacts with ORM, including thermodynamic effects in dilution is presented in [10]. Recent work related to the modelling of the lubrication quality in rolling bearings with ORM is described in [11-12]. Work related to describing damage and life effects in rolling bearings running under ORM conditions is found in [13]. In relation to study the film thickness and rheological properties of refrigerants in EHL conditions, several experimental and numerical works can be cited [14-18]. Rolling bearings lubricated PRL conditions are studied in [19-22].

The current publication describes the tribological challenges faced by rolling bearings in typical industrial heat pumps, including such that work beyond discharge temperatures of 100°C. It presents information on modelling and experimental aspects which provide explanations for successful technological solutions. It will be impossible to have a complete review of the topic, since there is a very large and diverse literature database, and more research is ongoing while this publication is written. However, the objective of this article is two-fold: (i) to briefly summarize application aspects of rolling bearings above mentioned conditions, including different bearing designs and technologies, and (ii) to more extensively present scientific aspects on lubricant properties of (pure) refrigerants and oil-refrigerant mixtures, including modelling of surface life in rolling bearings. This double objective is difficult to find in existing publications.

Description of Compressor Designs used in Heat Pumps

In heat pumps utilising the vapour compression cycle, the compressor is the main mechanical component. There are two important compressor types used in heat pumps of industrial size with typical drive motor power above 50 kW [23] where rolling bearings play a key role for compressor reliability and efficiency: screw and centrifugal compressors (Figure 1). For detailed description of these compressor designs and typical bearing arrangements, the reader is referred to [2] and [24].

![Fig. 1. Left: screw compressor. Right: centrifugal refrigeration compressor.](image)

The bearing arrangements are usually the same or very similar for refrigerant compressors used in air-conditioning (i.e. for chillers) or in heating applications. Nevertheless, the operating conditions are heavily influenced by the needed temperatures and used refrigerants. Every refrigerant has its own characteristics which is commonly visualised in the pressure-enthalpy diagram (Figure 2). Within the “vapour dome” (the two-phase region) pressure and temperature are linked with each other. Therefore, if the source and the sink temperature (evaporator and condenser temperatures) of a specific application are known, the characteristics of the used refrigerant will link it to the pressure levels – which set the suction and discharge pressure of the
compressor. A heat pump operating at higher temperature will create higher gas pressures leading to higher bearing forces. At the same time the change in pressure and temperature affects the dilution of the lubricant and its viscosity.

1.1. Description of Oils and Refrigerants

In the past, commonly used refrigerants for compressors were the low-pressure chlorofluorocarbon CFC-11, and medium-pressure refrigerants like CFC-12 and hydrochlorofluorocarbon HCFC-22. In 1989, a global ban of ozone depleting refrigerants – indicated by their Ozone Depletion Potential (ODP) - was agreed upon in the Montreal Protocol. New HCFC and hydrofluorocarbon (HFC) refrigerants were developed having low or no ODP. Low pressure refrigerant HCFC-123 replaced CFC-11 and medium pressure refrigerant HFC-134a became a substitute for CFC-12 and HCFC-22.

When global warming started to become a bigger concern in the 1990s, another unintended characteristic of refrigerants got more attention, namely their high Global Warming Potential (GWP). For example, HFC-134a has a GWP of 1300 times that of CO2. In 1997 the so called Kyoto Protocol agreement on reduction of global greenhouse gases was proposed - but not ratified by major countries and never fully implemented. In 2016 it was decided to use the more successful format of the Montreal Protocol to control phase down of HFCs, referred to as the Kigali Amendment of the Montreal Protocol.

The newer refrigerants were not necessarily simple substitutes for CFCs. HFC-134a refrigerant, for example, is incompatible (due to different molecular polarity) with common mineral oils normally used with CFCs. An important property of any refrigerant and oil combination is the ability to dissolve with one another. It is therefore necessary to use synthetic lubricants like Polyol-Ester (POE) or polyalkylene glycol (PAG). Refrigerant HFC-134a is used in screw and centrifugal compressors at higher speeds and its phase out is governed by the Kigali Amendment. Refrigerant HCFC-123 is still used mainly in centrifugal compressors and is being phased out in accordance with the Montreal Protocol.

1.2. Later Generation Refrigerants and Natural Refrigerants

1.2.1. Hydrofluoroolefins (HFO) and Hydrochlorofluoroolefins (HCFO)

New refrigerants with low GWP and zero ODP are now being developed and phased in by the global refrigeration and air conditioning industries. Two promising new refrigerants are low pressure refrigerant HCFO-123zd(E) and medium pressure refrigerant HFO-1234ze(E) and various blends containing these refrigerants. The GWP of the new refrigerants is less than five and the ODP is zero. These refrigerants have a very short atmospheric lifetime, thus they are chemically more active, which can lead to corrosion or material incompatibility, especially in the presence of moisture, adding an extra element in the equation. Besides all this, the thermodynamics of the new refrigerants make the oil-refrigerant mixtures more prone to having high concentrations of refrigerants (30 % or higher) during important times of the operation cycle.

1.2.2. Natural refrigerants

Natural refrigerants such as ammonia (NH3, R717) and carbon dioxide (CO2, R744) are also used increasingly, although ammonia has limitations due to some toxicity and flammability, and carbon dioxide is used at high pressures, which explains why mainly reciprocating compressors are applied for CO2 cycles.

Ammonia (NH3, R717) is toxic for humans, but its strong smell makes leaks easily detectable. There are different grades of ammonia based on application with different requirements on the water content. Industrial-grade anhydrous ammonia, commonly called metallurgical or refrigeration grade, has very little water.

![Fig. 2. Characteristics of a refrigerant in the pressure-enthalpy diagram.](image-url)
contamination. Refrigeration-grade ammonia has a maximum of about 150 ppm water content. Ammonia is flammable and has a lower explosive limit (LEL) of 15 percent and an upper explosive limit (UEL) of 28 percent. When the ammonia vapor is mixed with a miscible oil, the LEL can be as low as 8 percent.

Considering only its thermodynamic properties CO2 (R744) is not the ideal refrigerant candidate. However, this is compensated by its very good heat transfer coefficient, very low viscosity and its relatively insensitivity to pressure losses. From the environmental point of view, CO2 is very attractive, with OPD equal to zero and GWP equal to 1, and CO2 is non-corrosive and basically non-toxic. Recently, mixtures of CO2 and ammonia are considered to increase efficiency. NH3/CO2 mixture is extremely efficient for low and very low temperature applications (below −40 °C). And CO2 is also used in supercritical conditions (sCO2) for higher temperature regimes.

2. Lubrication with Refrigerants

In most refrigerant compressors (except e.g. such using magnetic bearings) the refrigerant plays a role in the lubrication of the bearings, either as a component in the oil-refrigerant mixture or as the sole bearing lubricant in pure refrigerant lubrication (PRL) applications. In any case, the knowledge of the lubricating properties of the refrigerants is needed. And of course, lubrication and tribological aspects are important parameters in the estimation of bearing life and other aspects like frictional losses.

2.1. Model for Oil-Refrigerant Mixtures

Studies have been carried out in the past to model lubrication properties of oil-refrigerant mixtures. In reference [7] the Eyring theory is used to derive equations for the piezo-viscosity coefficient and viscosity:

$$\alpha_{\text{mix}} = \frac{m_{\text{ref}}(\alpha_{\text{ref}}-\alpha_{\text{lub}})}{s_{\text{ref}}(m-1)+1} + \alpha_{\text{lub}}$$  (1)

$$\ln(\eta_{\text{mix}}) = (\ln \eta_{\text{ref}} - \ln \eta_{\text{lub}})\left(\frac{m_{\text{ref}}}{s_{\text{ref}}(m-1)+1}\right) + \ln \eta_{\text{lub}}$$  (2)

where $m = M_{\text{lub}}/M$, being $M$ the molecular mass of the component.

Bair [16] offers an alternative mixing law to equation (2). Reference [11] offers an adaptation to these equations in consideration of any refrigerant and lubricant, see equations (3) and (4). Equations (1) and (2) are modified with constants ($k_{al}, k_{et}$) multiplying the molecular mass ratio, as follows:

$$\alpha_{\text{mix}} = \frac{k_{al}m_{\text{ref}}(\alpha_{\text{ref}}-\alpha_{\text{lub}})}{s_{\text{ref}}(k_{al}(m-1)+1)} + \alpha_{\text{lub}}$$  (3)

$$\ln(\eta_{\text{mix}}) = (\ln \eta_{\text{ref}} - \ln \eta_{\text{lub}})\left(\frac{k_{et}m_{\text{ref}}}{(k_{et}m-1)s_{\text{ref}}+1}\right) + \ln \eta_{\text{lub}}$$  (4)

These constants are calibrated from measurements of viscosity of different oil-refrigerant mixtures, so calibration functions that depend on oil viscosity and working temperature can replace the originally constant parameters ($k_{al}, k_{et}$), thus:

$$k_{al} = f(\eta_{0\text{lub}}, T) \quad \text{and} \quad k_{et} = f(\eta_{0\text{lub}}, T)$$  (5a, 5b)

These equations have been proven to be more accurate than the original ones for several mixtures of refrigerants and oils when compared with measured values [19].

Now, in rolling bearing life calculation the lubrication quality parameter kappa ($\kappa$) is used as a measure of the lubrication condition in the bearing. This parameter is defined as the ratio between the actual viscosity used in the bearing at the working temperature and the required viscosity recommended by the manufacturer and it is properly defined and explained in ISO 281:2007 [34]. The required viscosity is a parameter provided by the bearing manufacturer. Thus, the only parameter that remains to be estimated for calculation of $\kappa$ in oil-refrigerant mixture conditions is the actual lubricant viscosity and equation (2) can be used for this purpose.

For bearing life calculations, reference [4] recommends increasing the required kinematic viscosity of the bearing ($\nu_{1}$) calculated as oil by multiplying it with a factor $f = 3$, for HFC-134a and POE oil. This is to
account for the reduction in piezo-viscosity plus other unaccounted effects (e.g.: lubricity reduction and chemical aggressiveness) in the actual viscosity estimated with equation (2). For very compressible refrigerants an extra increase factor should be derived for correction in the final calculated \( \kappa \), but here this will be disregarded. Bearing life can be calculated from this final adjusted value of \( \kappa \) called \( \kappa_{oil/ref} \). Therefore, according to [11] it is:

\[
\nu_{adj} = \nu f_{adj}
\]

where \( \nu \) is the actual kinematic viscosity calculated as oil but with the value obtained from the mixture. Thus,

\[
\kappa_{oil/ref} = \kappa_{oil}(f_{adj})
\]

with, \( \kappa_{oil} \) being the lubrication quality factor calculated as oil but with the viscosity of the mixture. And, by neglecting the difference in compressibility between oil and refrigerant,

\[
f_{adj} = \left[ \frac{\alpha_{mix}}{\alpha_{oil}} \right]^{0.7} \frac{1}{f_c}
\]

Where

\[
f_c = 1 + (f - 1)\tanh\left( \frac{4s_{ref}}{s_{ref,c}} \right)
\]

and \( f \) being the safety factor as described by Meyers [4], but because it was initially introduced by Jacobson it will be called the “Jacobson” safety factor here, defined at a reference refrigerant dilution fraction \( s_{ref,c} \). Notice that \( f_c \) will become 1 when the dilution of refrigerant \( s_{ref} \) becomes zero i.e. when there is no refrigerant mixed into the oil.

The above model has been substantially validated with several HFO, HCFO and HFC refrigerants, but it is likely that some adaptation will be required for Ammonia and CO2. Unfortunately, not much experimental data are available in the literature to either verify this model or to adapt it for those important natural refrigerants. For example, when it comes to ammonia only limited literature is available [25], mainly on the development of Daniel plots for mixtures of ammonia and various oils with dilution rates up to 6% ammonia in saturation conditions. And on the piezo-viscosity behaviour of ammonia no information has been found, (except for relatively low pressures [26], though it is likely that this simple molecule - similar to CO2 - will be an iso-viscous liquids, similar to water. So this could be a “safe” approach for design purposes until more data becomes available. Equation (1) is still valid for \( \alpha_{ref} = 0 \).

3. Rolling Bearing Life and Other Bearing Failure Modes

The typical life-critical issues in refrigerant compressor bearings, where usual maximum Hertzian pressures are below 2 GPa, are surface-related problems, caused by e. g. poor lubrication and contamination, which leads to wear and/or surface distress, also known as micropitting. Other surface failure modes are also possible e.g. smearing (or adhesive wear), however, those are less often observed in these applications since in general no large rotational accelerations are experienced. Thus, most of the effort invested to increase the life of the bearings goes to preventing or delaying surface distress from poor lubrication conditions. This is why the authors in an earlier publication [2] have included a special section to this topic. Details about performed reliability studies can be found in the following publications: on the accuracy of high reliability values in bearing life calculation [43] and on the accuracy of comparing life models with endurance testing [44].

In [2], the authors also included a modelling example for indications of surface distress occurrence and ways of mitigation. Surface distress is thus strongly influenced by high oil dilution rates, low viscosities of the oil-refrigerant mixture, low piezo-viscosity and higher compressibility of the refrigerants, plus sometimes some corrosive attack due to the chemical activity of the refrigerants, especially in combination with moisture. Note that in [27] a new bearing life model is described that separates the surface distress from subsurface fatigue. This model – which is briefly described in the next section - should be better suitable to handle life calculations in this type of diluted applications, not only because of its better link to physics but also due to its flexibility to accommodate different surface related failure modes.
3.1. The Generalized Bearing Life Model (GBLM)

Following [27] the bearing life equation associated to a reliability (S) can be written as:

\[
L = \left[ \frac{\text{ln}(S)}{u} \right]^{1/e} \left[ A \int_{\sigma} \left( \frac{\sigma - \sigma_u}{2} \right)^2 dV + B \int_A (\sigma_u - \sigma_u)^2 dA \right]^{-1/e}
\]

(10)

For nomenclature see the mentioned references. In rolling bearings the chosen reliability is usually 0.9, thus the life L will be known as the L0.9 life of the bearing. The first integral in equation (10) is the usual subsurface term [28], while the second integral is a new integral accounting for the fatigue damage at the surface, which can be assessed with a numerical model for e.g. surface distress [29] or indentations [30], etc.

In order to understand the different tribological processes happening at the surface of a rolling bearing, one can take the example of hybrid ceramic bearings, i.e. bearings that use rolling elements made out of ceramic materials instead of steel. It is well known that hybrid bearings are more resilient against poor lubrication conditions and indentations than steel-steel bearings [31, 32]. Therefore, the assessment of the surface integral in equation (10) for this type of bearings is customized [27, 33]. If the new GBLM model is applied [33] much longer lives for hybrid than steel-steel bearings are predicted under difficult conditions, i.e. poor lubrication and contamination. Of course, in case of good and clean lubrication conditions but heavy loads, subsurface fatigue will dominate and hybrid bearing life will be penalised by GBLM due to the higher elastic modulus of ceramics creating somewhat higher contact stresses – which is consistent with test results.

3.2. Bearing Damage due to Particles and Indentations

Particle entrapment in all-steel and hybrid bearings is discussed in [35] and [36]. In [35], the indentation process is described in addition to particle entrapment, presenting some modelling tools for this. The entrapment results where summarised with the use of an arbitrary indentation severity parameter defined as:

\[
IS = \frac{h_p s_p}{\phi a}
\]

(11)

Equation (11) refers to the schematics of an indentation profile along the rolling direction as depicted in Figure 3 left. Where \(a\) refers to the Hertzian semi-width along the rolling direction of the contact.

The reference discusses a simple entrapment model based on the friction coefficient between the particle and the bearing surfaces \(\mu_p\) and also based on the rolling element diameter \(D_w\) and negligible lubricating central film thickness \(h_c\). Giving the maximum size of a spherical particle to be entrapped as:

\[
d_{p,max} = \frac{D_w}{\cos(tan^{-1} \mu_p)} - D_w
\]

(12)

The fact that a particle is entrapped in a contact does not necessarily mean that it will indent the rolling surface and generate damage. It all depends on size, material and hardness of this particle in relation to the counter face. Very small particles will move through the lubricant film without causing any damage to the mating surfaces. Larger and very hard brittle particles may shatter in the contact producing many smaller particles. Figure 3 (right) depicts some predicted maximum entrapment particle diameters for varying rolling element diameter and particle-surface friction coefficient. The minimum particle diameter according to equation [37] that might still indent the bearing surfaces is also depicted in the plot (as a reference) using the horizontal black dotted line, notice that the minimum steel particle diameter causing an indentation would be of the order of the central film thickness \(h_c\) - for a typical heat pump bearing \(h_c \approx 0.1\, \mu m\). Notice that experiment estimated values for \(\mu_p\) steel-steel are reported in [35] of about \(\mu_p = 0.15\), but it will be lower for the case of ceramic rolling elements.

Of course, most contamination particles are not spherical, however the model is valid for particle diameters estimated from the shortest particle length, e.g. for a cylindrically shaped particle the parameter \(d_p\) would refer to the cylinder diameter and not to the length. The damage produced by indentations in the context of GBLM and EHL contacts is described in detail in [30].
Fig. 3. Left: Schematics of an indentation profile along the rolling direction of the contact. Right: Maximum entrapment diameter particle as calculated from equation (12). The horizontal black dotted line gives an indication of the minimum steel particle diameter that could produce an indentation on the bearing surfaces according to equation [37].

3.3. Surface Distress Phenomenon

Micropitting is a term widely used in the gearbox industry to describe micro surface spalls and cracks, which sometimes appear on the surface of rolling–sliding contacts. ISO 15243 [38] refers to this failure mode as surface distress or surface initiated fatigue, i.e. the failure of the rolling contact metal surface asperities under poor lubrication conditions and with certain amount of sliding motion causing the formation of (1) burnished areas (glazed; grey stained), (2) asperity microcracks, and (3) asperity micro-spalls, see Figure 4 (left). This failure mode will be described here using the term of surface distress. It is well known that surface distress is the result of the competition between surface fatigue and mild wear [29]. Mild wear (wear at asperity level) modifies the initial topography reducing the asperity heights and also removes fatigued surface layers - refreshing the exposed material and thus delaying surface fatigue. The modelling of this phenomenon is possible, and one of the current authors has developed a numerical model for surface distress [29] that can be applied for the present case of oil-refrigerant mixtures [2]. The model requires 3D digitised roughness data from several positions of the two contacting surfaces (inner - or outer - ring raceway and roller - or ball). A calculation example simulating the fatigue weakening by corrosion from refrigerants is given in [2].

3.4. Integrating Surface Failure Modes in GBLM

The model described in [29] can be used to generate tendency curves by simulating surface distress from using roughness samples of many bearings (all types and sizes) under different loads and lubrication conditions (In the bearing industry the parameter κ is used [34] rather than the film thickness/roughness ratio Λ used in other engineering fields to describe the quality of lubrication). In [29] a curve-fitted equation to model the surface integral representing surface distress is obtained from the simulations. An example of the graphical representation of this equation is depicted in Figure 4 (right), where the normalized value of the surface integral ($I_s$) is plotted for different normalised equivalent loads ($P/P_u$) under different lubrication qualities (κ).

The surface integral is defined as

$$I_s = I_s u^e \left( \frac{P}{P_u} \right) f \left( K \ln \left( \frac{1}{\kappa} \right) \right)$$

(13)

with $K$ being a scaling factor and,

$$I_s = B \int_A (\sigma_s - \sigma_a)^e dA$$

(14)

As can be seen in Figure 4 (right) when lubrication conditions deteriorate (low values of κ) the surface integral increases in value, this is an indication of higher probability of surface distress. When the load increases in general the integral increases, except in the cases of very poor lubrication where the integral is slightly reduced due to the increase of mild wear. The scaling and behaviour of these curves can be adapted
for the case of material weakness, e.g., due to corrosion from refrigerants and moisture. Other adaptations are possible depending on the balance wear and fatigue, or with the use of hybrid bearings [27], etc.

Fig. 4. Left: Surface distress in a raceway bearing surface; Right: Example of normalised surface integral for the GBLM model as a function of normalised equivalent load and lubrication quality in the bearing, as given in [29].

3.5. Relative Surface Fatigue Index in GBLM

One of the advantages of separating the subsurface and surface damage integrals is that they can be compared and in this way an indication of the most fatigued area can be determined. Consider the parameter called “relative surface fatigue index” denoted by the symbol $S_R$:

$$S_R = \frac{I_s}{I_s + I_{ss}}$$  \hspace{1cm} (15)

where $I_s$ is given by equation (14) and $I_{ss}$ by

$$I_{ss} = \tilde{A} \int_{V'} \frac{(\sigma_v - \sigma_u)^2}{2\nu} dV_v$$  \hspace{1cm} (16)

Notice that when $S_R \to 1$ the surface integral is dominant which means that the higher damage is expected at the surface. When $S_R \to 0$ fatigue is taken mainly by the subsurface. This parameter is important because when operating conditions are changed, changes in this parameter will indicate how the surface or the subsurface is being affected. The parameter $S_R$ can also be calculated locally, for example along the raceway profile in a roller bearing, reflecting the effect of the local stresses. Reference [30] shows good examples of the use of $S_R$ for the case of indentations and the interaction with the lubrication quality parameter.

4. Technical Bearing Solutions for Heat Pump Compressors

In the following, some technical solutions to address the challenges in heat pump compressors bearings as indicated above are presented.

4.1. Surface Treatments in Conventional Rolling Bearings

For oil-refrigerant mixtures under poor lubrication and/or high contamination, surface (heat) treatments that have a large potential for rolling bearings are nitriding and carbonitriding. The latter one is an added surface heat treatment with the addition of ammonia to the standard gas carburisation process. This introduces N and C atoms diffusing into the surface steel, improving the fatigue strength and reducing wear. Carbonitrided (HN code) bearings have been tested and compared with normal heat treated bearings in harsh contaminated conditions in [39]. Wear rate was reduced to about 45% of the normal bearings and bearing life was roughly doubled for those particular test conditions. In addition, the surface distress model described before was used to simulate the behaviour and provide understanding.
4.2. Semi-Hybrid Rolling Bearings

It has been verified by testing [40] that steel rolling bearings which contain at least one rolling element made of ceramic (Si3N4) material can substantially improve performance under poor lubrication and high contamination conditions. Therefore, the next “line of defence” after nitriding or carbonitriding for lubrication with oil-refrigerant mixtures should be this type of rolling bearings, sometimes also called “semi-hybrid” or “self-healing” bearings. The working mechanism is similar to hybrid bearings as explained in [35, 37].

4.3. Raceway Coatings

If a bearing raceway coating has to be chosen in harsh oil-refrigerant lubrication conditions, it is recommended to select a sacrificial coating that will mainly help to run-in the surfaces improving the tribology and smearing itself for the steel surfaces. In this way, it will also protect the surfaces from mild chemical attacks (mild corrosion). This is the case for special bearing-grade black oxide coating [41], which could be a rolling bearing performance improver in mild severity conditions of poor lubrication with oil-refrigerant mixture. An alternative coating solution against corrosion is zinc-coated bearings.

For lower refrigerant dilution rates other coatings may be used that can provide the bearings with some protection. This is the case for special DLC (NoWear™) with and without porosity seal, made to endure in poor lubrication conditions and to fight adhesive wear.

4.4. Hybrid ceramic bearings

For extreme conditions such as dilution rates much higher than say 20%, for very low operating viscosity, and/or very high or low speeds, hybrid bearings comprising ceramic rolling elements (usually made out of Si3N4/silicon nitride) and steel rings are a favourable solution. The reasons for the superior performance of hybrid bearings under such conditions was already explained in section 3.1. In case the chemical conditions in the compressor also bear the risk of corrosive attack, or if the bearings should be lubricated only by the refrigerant in oil-free compressors, the rings need to be made out of a bearing-grade corrosion resistant material with high toughness, see next section (Figure 5).

4.5. High-nitrogen stainless steel hybrid bearings

When the bearing rings cannot be protected by oil or grease against corrosive media in the machine, rings made out of stainless steel are often the most reliable solution. Various stainless material options exist, which have to be selected based on their corrosion resistance as well as their mechanical strength in rolling bearing application. Inner and outer rings made of through-hardened martensitic stainless steel with high nitrogen content show high corrosion-protection capability and fatigue toughness. It is of high importance to tune the steel making and heat treatment process parameters to obtain a fine microstructure that leads to high toughness and so making the steel an excellent material for the demanding conditions in highly loaded rolling contacts.

With thinner lubrication films or in media lubricated applications (like for PRL) also the raceway surface finishing quality tends to play a more important role for the bearing performance. This is why more stringent raceway honing specifications are applied related to surface roughness and imperfections, as well as to manufacturing process cleanliness applied for media lubricated applications.

For extreme conditions, a specific high-nitrogen steel with a dedicated heat treatment for high corrosion resistance, fatigue toughness and also higher temperature stability was developed. It was proven to be a reliable solution for applications like sour gas compressors, cryogenic pumps, and pure refrigerant lubricated compressors. Some examples for media- and mixed-media lubricated applications are presented in [42].

Figure 5: Special hybrid ceramic bearings with super-tough high-nitrogen stainless steel rings
4.6. Cage Material Selection

There is a large variety of cage designs and materials for any bearing type. In demanding application, the cage design choice is often either a massive metal cage or a lightweight polymer cage. Common materials for metal cages are brass, steel, or sometimes also aluminium alloys. Massive metal cages offer high mechanical strength and for very critical applications special pocket designs or surface coatings can be applied. Massive (stress-free) brass cages have also a proven track recorded in ammonia compressors.

Besides standard polymer cages, different high-performance polymers have been developed for bearing applications. Fibre reinforced PEEK (polyether-ether-ketone) is a very robust solution in demanding applications, especially where an extended temperature range, chemical stability, and a lightweight design are required. The combination of ceramic rolling elements and a polymer cage allows for a very low weight of the rotating components in the bearing which are not directly mounted on the shaft or in the housing, reducing their inertia which is especially beneficial in high acceleration or very low load conditions. PEEK cages have also been proven to work in ammonia compressors up to 120°C operating temperature.

5. Discussion

The present publication summarises the current status of rolling bearing technology for refrigerant compressor applications, with emphasis on the special conditions found in heat pumps, where the lubrication with oil-refrigerant mixtures is common practice and the bearing operating conditions are harsher than for most other compressor applications. It is suggested that standard bearing technologies for conventional refrigerants and requirements with oil-dilution rates usually lower than 20% will be increasingly challenged by new and more chemically active low-GWP refrigerants (according to Kyoto protocol requirements). Dilution rates up to 60% or even higher in some sections of the thermodynamic duty cycle, and also much higher process temperatures and pressures leads to challenging conditions for the rolling contacts in the bearings.

As a graphical summary of the application of the different rolling bearing technologies, the authors propose the schematics of Figure 6 to describe the possible usage ranges and technology sophistication level of the different rolling bearing technologies discussed in the current paper, as a function of the tribological and chemistry complexity and risks.

![Fig. 6. Schematics of potential solutions for rolling bearings depending on the application and tribological and corrosion risks.](image)

Notice that the ordinate in Figure 6 (mechanical & tribological complexity) represents a qualitative scale where no values are given, but it should illustrate the experience of the authors. The abscissa of the figure represents the risks related to chemical aspects. Note that tribological risks (i.e. due to very low viscosity or speeds) can be mitigated with the use of hybrid bearings. High chemical risks (high corrosion potential) can be mitigated with the use of special bearing-grade stainless steels. In the transition area between all-steel bearings to hybrid bearing and stainless steel rings, the use of special heat treatments, coatings, or semi-hybrid bearings can be an appropriate fit-for purpose solution – in economic and as well as technical terms.

6. Conclusions

The following conclusions can be drawn based on the above presented research and also practical experience:
1. Standard all-steel rolling bearing technology is currently challenged by the arrival of new, more environmentally friendly refrigerants in the industrial compressor sector, which bring higher refrigerant dilution rates, more chemically active compounds and – for heat pumps or also data centre chillers - much higher temperatures.

2. As a response to this challenge, different rolling bearing technologies are proposed, like the use of special heat treatments as well as hybrid ceramic rolling bearings.

3. A better understanding still needs to be obtained for specific lubrication mechanisms and failure initiation mechanisms in heat pumps with low-GWP refrigerants. This implies work to be done on tribological refrigerant characterisation, tribology contact modelling, tribo-testing, and bearing testing under representative compressor conditions.

Resorption heat pump development

a University of Warwick, Coventry CV4 7AL, UK

Abstract

The development of a resorption heat pump for domestic use is described. The cycle uses the alternate adsorption and desorption of ammonia between two salts – sodium bromide and manganese chloride. The equilibrium and dynamic behaviour of both salts with ammonia has been measured using the Large Temperature Jump (LTJ) technique and a good match found between experimental and modelled data. This has been used to design a nominal 2.5 kW heat pump as a demonstrator to confirm the results. The bench scale machine can be driven by a high temperature source of pressurised water at up to 170 °C, the low temperature input is from water between 5 and 15 °C and the output is between 40 and 60 °C. It uses a simple cycle consisting of one low-pressure phase followed by a high-pressure phase, without any heat recovery, moving ammonia from the Low Temperature Salt (LTS) sodium bromide reactor to the High Temperature Salt (HTS) manganese chloride reactor and vice versa. A practical machine would have two such sets of reactors and recover heat between them, but this level of complexity is avoided in the demonstrator. Despite this, initial results are extremely encouraging having achieved repeatable ammonia cycling between the reactors.

Keywords: Ammonia; Heat pump; Resorption.

1. Introduction

The chemisorption of ammonia into halide salts has been studied over many years: it was first observed by Faraday [1] who recognised its potential for generating a heating or cooling effect; more recently it gained attention in the ‘80s and ‘90s, primarily by Spinner [2], and many others: Goetz et al., [3], Lebrun and Spinner, [4]; Mazet and Spinner [5].

Cycles using chemisorption can be applied to refrigeration, heat pumping, and thermal transformation and many either use a single salt in a reactor together with a system for evaporating and condensing the refrigerant, or a resorption cycle in which the refrigerant is adsorbed or desorbed between two salts. More complex three salt cycles with varying degrees of complexity and heat recovery are also possible. A simple heat-pumping cycle is illustrated in Figure 1.

A Low Temperature Salt (LTS) and a High Temperature Salt (HTS) are contained in separate reactors that are connected, the whole being in the presence of ammonia that is either present as a gas, or a chemically adsorbed phase with the salts. The equilibrium lines for the reaction with each salt are illustrated on the Clapeyron diagram, Figure 1. In reality, there can be hysteresis between adsorption and desorption, but this is omitted for clarity. Starting at low pressure, the LTS is heated from ambient, perhaps at 0°C, which desorbs 5.25 mols are desorbed. The ammonia is adsorbed in the HTS (4 mols for MnCl2) generating useful output at 60°C. When the reactions are complete in the low-pressure phase, heat can be removed from the LTS at 60 °C whilst more heat enters the HTS at 150 °C. The reactions proceed at a nominal constant temperature until complete and the LTS again contains its maximum quantity of ammonia. To return to the...
starting condition in the low-pressure phase, the LTS is cooled back to ambient whilst the HTS is adiabatic. A real machine would most likely feature two sets of reactors operating out of phase so that heat from the cooling LTS could be used to pre-heat the other HTS. Advantages of a resorption cycle are the absence of an evaporator, condenser, or any refrigerant control valves, plus a wide range of salts to choose from that may be matched to required temperatures.

![Fig. 1. Simple resorption heat pump cycle. Red, orange and blue arrows indicate heat flows, black arrows are used for ammonia flow.](image)

However, practical difficulties have prevented successful exploitation of the cycle in the past. These are mainly due to slow reaction dynamics (hour-long cycles) and agglomeration of the salts (when used in bulk form) leading to a loss in reactivity. Both drawbacks can be overcome by dispersion of the salt within a porous matrix. Keeping the crystals small and separate prevents agglomeration. Additionally, if the matrix is highly conductive, such as Expanded Natural Graphite (ENG), the overall heat transfer is improved and reaction times reduced, as reported by van der Pal [6]. In this study the salts are impregnated into ENG sheet (SIGRATHERM® Graphite Lightweight Board, ECOPHIT® L10/1500). The measured sheet density is 196 kg m\(^{-3}\) and the thermal conductivity in the plane of the sheet is 26 Wm\(^{-1}\)K\(^{-1}\) as obtained from the manufacturer’s data sheets.

2. Material Thermodynamic and Rate Equations

The methodology used to determine properties and governing rate equations is described by Hinners et al. [7]. The Large Temperature Jump (LTJ) technique is used on small (approx. 10 mm diameter impregnated ENG discs) samples that are rapidly heated or cooled. The reactor vessel is connected to an empty buffer vessel which maintains a nearly constant pressure, similar to that in a full system in desorption (or adsorption), whilst careful measurement of the small increase in pressure yields the time history of ammonia evolution (or devolution). Matching the experimental results with a simulation model reveals the controlling parameters that can be used to design a full system. The reaction is dominated by heat transfer, but chemical reaction rate parameters are also revealed, together with the proportion of the impregnated salt that is able to take part in the reaction. The reaction rate equation used is:

**Desorption**:  
\[
\frac{dX}{dt} = A_{DES} \left( 1 - \frac{p_{EQ}}{p} \right) (1 - X)^{n_{DES}}
\]  

**Adsorption**:  
\[
\frac{dX}{dt} = A_{ADS} \left( 1 - \frac{p_{EQ}}{p} \right) (X)^{n_{ADS}}
\]

where:  
- \(X\) = reaction advancement \((1 > X > 0)\)  
- \(t\) = time \((s)\)  
- \(p\) = pressure  
- \(p_{EQ}\) = equilibrium pressure  
- \(A_{DES}, A_{ADS}, n_{DES}, n_{ADS}\) are constants
When there is hysteresis the lines on the Clapeyron diagram indicating adsorption and desorption are not equilibrium lines and so the slope does not correspond to the enthalpy of reaction which is determined as in [7], by heating the sample slowly and isosterically in a vessel with minimal void volume.

An interesting outcome of identifying the different parameters is that the overall power density and rate of ammonia sorption/desorption is found to be dominated by heat transfer rather than chemical kinetics. We suppose that in previous studies insufficient attention was paid to heat transfer. In particular, the overall cycle time (for a complete reaction) is highly sensitive to the thermal contact resistance between the ENG and the metal surface used to conduct heat in and out of it.

3. Design of 2.5 kW Demonstrator

The LTJ tests were carried out on 10 mm diameter ENG-salt composite discs contained within the tube of a heated, or cooled, stainless steel double-pipe heat exchanger. However, this would not be a suitable design for a demonstrator since the sensible heat load of the stainless steel would result in low COPs. Instead, the design was based on hexagonal ENG plates with a central hole, Figure 2 (a). Many such ‘nut-shaped’ discs may be mounted on a stainless-steel tube which heats or cools them from their centre. The model parameters and heat transfer properties were used in a simulation model to explore the design trade-off between COP and power density with different central hole diameters and across-flat dimensions. There is no precise optimum, but one criterion was to achieve a mean power density of at least 1 kW per litre of reactor volume.

The dimensions decided on were a central hole diameter of 12.7 mm and 32 mm across the flats, Figure 2 (a), with a predicted power density of 1.4 kW per litre [8]. Since several metres of tube would be needed the concept was to have seven tubes in a hexagonal bundle within a stainless-steel shell that contains the ammonia, as in Figure 2 (b) and (c).

![Fig. 2. (a) ENG-salt composite dimensions, (b) longitudinal cross-section through the reactor design concept with a bundle of seven tubes and (c) frontal cross-section through the reactor design concept.](image)
The complete demonstrator is connected to the laboratory ‘ThermExS’ test stand which can supply pressurised water from three different thermostatically controlled baths. Pneumatically controlled valves are used to switch hot water to the HTS reactor during the high-pressure phase, cold water to the LTS during the low-pressure phase and to remove heat (simulating the heat pump load) from both reactors as required, as in Figure 1. Inlet and outlet stream temperatures are measured using PRTs and the flow rate is measured by Coriolis meters. In addition, the mass flow of ammonia gas moving from one reactor to another is measured using a Coriolis meter. The demonstrator is controlled and monitored by an NI cDAQ linked to a PC and using LabView™. Figure 3 shows the nearly completed demonstrator being charged with ammonia, whilst monitoring the pressure and temperature.

4. Preliminary Results

At the time of writing a limited number of test conditions have been conducted and not fully analysed; however, initial results show that the resorption machine operates well.

In the following figures the test conditions were:

- 4 cycles at 165/40/15 °C with a cycle time of 2600 seconds (43 minutes 20 seconds).
- 5 cycles at 170/40/15 °C with a cycle time of 2500 seconds (41 minutes 40 seconds).

The cycle times were designed to allow full ammoniation and de-ammoniation of each salt reactor in both pressure phases, therefore allowing the resorption reaction to run to completion. Figure 4 shows the mass flow rate of ammonia being transferred from one salt reactor to the other, taken directly from the Coriolis meter. Positive values are during the low-pressure phase, peaking at around 1.6 to 1.7 g/s of ammonia, and negative values are during the high-pressure phase, peaking at -0.5 to -0.6 g/s.

Figure 5 shows the pressure variation over the cycles between the low- and high- pressure phases. Note there are three pressure transducers in the ammonia line (LTS-side, Mid and HTS-side), which match well across the pressure range. In the 165/40/15 °C tests, the demonstrator cycles between 0.35 bar and 9.00 bar. In the 170/40/15 °C tests, the pressure cycles between 0.35 bar and 9.45 bar.

Although the preliminary data is encouraging in showing the consistency of the resorption cycle, when analysing the initial data during the first cycles, the power output is less than the designed target of 2.5 kW. However, the cycle times used are much longer than optimal to ensure the resorption reaction completes. Future work will test the demonstrator at a variety of temperature and cycle time conditions to ascertain overall system performance; in particular, by optimising and reducing the cycle time the power should increase.
5. Conclusions

A resorption heat pump cycle using ammonia as the refrigerant, sodium bromide as the low temperature salt and manganese chloride as the high temperature salt is proposed. The salts are dispersed in ENG to improve conductivity and remove any danger of salt agglomeration. LTJ testing on small samples was used to determine equilibrium properties, hysteresis effects, heat transfer and reaction rate limitations. This data was used to design a nominal 2.5 kW demonstrator. The reactors utilise seven parallel heating/cooling tubes in a shell and tube arrangement, with pressurised water on the tube side and the ENG-salt composite on the ammoniated shell side. Each tube fits tightly within many ENG hexagons impregnated with a salt.

Initial testing is very encouraging, showing repeatability and good transfer of ammonia between salts during resorption. Further testing will optimise the cycle time and enable a performance envelope to be calculated and checked against theory. A practical machine would use two pairs of reactors with a heat recovery phase between reactors to enhance the performance.

Abstract

The operation of air conditioning installations may respond to different thermal load scenarios with variable or intermittent modulations of the compressor speed and expansion valve opening, according to the native control system. Therefore, the representativeness of the standard performance rating procedures obtained at a fixed compressor speed is limited and may be misleading for the efficient development of this technology. The emulator-type performance assessment technique was developed by combining the equipment of air-enthalpy testing facilities for real-time measurement of the cooling capacity supplied by the air conditioner and a room emulator to reproducibly generate arbitrary indoor load conditions. This study demonstrates the ability of the developed assessment approach to characterize the performance of air conditioners in response to variations in the indoor air state according to the native control system. Specifically, an R32 ceiling-type commercial unit was tested under the conditions necessary for the calculation of the annual performance factor over a load range between 25 and 100\% of the nominal system capacity for a 147 m\textsuperscript{3} virtual room with a total thermal capacity of 1470 kJ/K. The steady, fluctuating, and intermittent controllability of the system was captured. Finally, the efficiency of the system operating according to its native control system was compared with the results obtained according to the current standard procedure defined by the Japanese Industrial Standard at a fixed compressor speed.

1. Introduction

The need to decarbonize the energy sector through efficient energy management has steadily become more relevant in recent years as policymakers and stakeholders, as well as manufacturers, are reacting to the rising climate threat. Air conditioners and heat pumps are among the most frequently deployed devices worldwide, with billions of operative installations. Although vapor compression air conditioning is generally recognized as a well-developed technology, the actual performance of these systems remains largely unknown. Specifically, standard testing and rating methods were conducted with a fixed compressor speed while deactivating system control. Therefore, the rated performances are not representative of the actual operation of air conditioners (AC). In addition, the sensors required by conventional measurement techniques are too costly and complex to capture the actual performance of a statistically meaningful number of AC installations. For example, air flow meters are too bulky, and the installation of refrigerant pressure sensors and flow meters requires cutting refrigerant pipelines. Consequently, owing to this gap in knowledge regarding the actual performance of ACs, optimal control strategies that are able to efficiently respond to different building structures, occupant lifestyles, and climates of different air conditioning installations are yet to be understood and developed. Sholahudin et al. 2021 [1] demonstrated the ability of machine learning techniques to deal with the latter issue through broadly applicable and cost-effective performance-monitoring techniques. Nonetheless, this monitoring approach requires training data to be collected with dedicated testing methodologies. However, standardized testing methodologies are conducted with a fixed compressor speed while deactivating the system

\textsuperscript{*} Corresponding author. E-mail address: damiano@moegi.waseda.jp
control, thus deviating from the actual performance of operating installations. To overcome this challenge, an emulator-type testing facility was designed and built for load-based tests. Contextually, the time evolution of indoor conditions, such as temperature and humidity, is recreated by a condition generator to represent the dynamic thermal response of the conditioned room in accordance with the system capacity and building loads. The system reacts to deviations from the setpoint of the thermostat according to its native control with variable compressor speed and fan speed, allowing this testing method to capture actual field operation performance. Although standardization of such a methodology is yet to be conclusively defined, load-based testing methodologies have been recognized as an effective approach for capturing system controllability and representative performance [2-4]. Accordingly, load-based testing methodologies are being endorsed to form the basis for new rating standards (CSA [5]) and are being investigated to ensure test reproducibility [6-9]. In this study, the current Japanese standard testing methodology (JIS B 8615-1/2:2015) [10] was compared with the proposed emulator-type load-based testing methodology to clarify the difference between the two approaches and discuss the advantages of capturing the interdependencies between the controllability and system performance. The testing conditions were defined according to the requirements for calculating the seasonal performance index adopted in Japan (Annual Performance Factor, APF). Finally, the APF was evaluated with reference to the test results obtained from the testing facility and from the manufacturer.

2. JIS test methodology

JIS tests are conducted with reference to the JIS B 8615-1/2:2015 [10] regulations. The system is operated at a maximum volumetric air flow rate, constant outdoor conditions, and return conditions to the indoor unit while overriding the native control of the system to constantly maintain the prescribed compressor speed and valve opening. These tests adopt the air-enthalpy method for cooling and heating capacity measurement.

3. Testing Facility and Methodology

Load-based tests require a real-time evaluation of the supplied cooling capacity for the considered system operating under constant load conditions and the set value of the indoor temperature. During operation, the native control of the system is kept active, regulating both the valve opening and compressor speed. To perform load-based tests, it is necessary to calculate and reproduce the time variation of the indoor condition in its interaction with the variable-speed control of the air conditioner (Figure 1).

The experimental setup was composed of two psychrometric rooms. Both rooms were equipped with a condition generator to reproduce the operational environment, and a measurement chamber instrumented for the measurement of the sensible and latent cooling capacities with dedicated temperature and humidity sensors. Other round-robin tests are in progress with other companies that possess calorimetric testing facilities to statistically confirm the conclusions of this study and spread the effectiveness of this methodology in capturing the controllability and dynamic performance of air conditioners.

![Testing Facility schematic.](image_url)
4. Emulator

The virtual room emulator is a central element for the reproducibility and representativeness of the time-dependent response resulting from the interaction of the system control with specific heat load conditions.

The numerical model of the room (schematically represented in Figure 2) accounts for heat infiltration from the external environment, ventilation, and heat transfer from solar radiation through windows. Furthermore, the model considers the internal generation of sensible and latent heat from the occupants, lighting, and indoor equipment, in addition to heat and moisture accumulation owing to the heat and mass capacities of the volume of indoor air, fixtures, walls, and floors.

\[
\dot{m}_{\text{out}} = \dot{m}_{\text{in,o}} + \dot{m}_{\text{in,e}} \\
C_S \frac{dT_i}{dt} = Q_{ac,s} + Q_{\text{bld,s}} \\
M_L \frac{dx_i}{dt} = \dot{m}_{ac} (x_{ch} - x_i) + L_g \\
Q_{ac,s} = \dot{m}_{ac} c_p (T_i - T_{ch}) + \alpha_{ch} A_{ch} (T_i - T_{ch})
\]

In the present study, the mathematical model was based on the continuity of indoor air (Eq. 1), energy balance (Eq. 2), moisture balance (Eq. 3), and the auxiliary relations for heat and mass transfer of walls and fixtures considering the thermal and moisture capacity of a 147 m³ room (details of the present formulation can be found in [9]). In the following tests, the terms \(Q_{\text{bld,s}}\) and \(L_g\) summarize the combination of effects defining the sensible and latent load scenarios, respectively, and are kept constant during the load-based tests. The cooling capacity \(Q_{ac,s}\) accounts for the sensible part of the overall system capacity and, in these preliminary tests, it is calculated as in Eq. (4). Accordingly, it accounts for the sensible heat transfer between the return air conditions and the supply air condition measured at the measurement chamber, plus the correction factor that represents heat infiltration through the chamber walls. Here the factor \(\alpha_{ch}\) indicates the thermal conductance of the chamber, which is measured at standard conditions as in [10]. More detailed investigations on the influence of such measurement methodology for the supply air condition is referred to [7].

5. System

The system tested in this study is an R32 ceiling-type air conditioner that features a nominal cooling/heating capacity of 10 kW/11.2 kW with the main specifications summarized in Table 1.

6. Annual Performance Factor

The Annual Performance Factor (APF) is an index used in Japan to assess the seasonal efficiency of thermal systems such as air conditioners and heat pumps, accounting for both geographical and seasonal conditions. The tests conducted under the conditions listed in Table 2 were referenced for defining a COP value for each outdoor temperature and calculating the APF index as an overall value weighted on the annual hourly distribution of each temperature bin. During the JIS tests, the load condition was defined with reference to the maximum compressor speed, whereas for load-based tests, it refers to the nominal cooling/heating capacity of the system. In accordance with JIS B8615 [10] and JIS B8616 [11], the APF can only be obtained in the cooling mode, heat pump operation, or both. The temperature distribution used in the Tokyo area is shown in Fig. 3.

7. Data analysis

7.1. JIS tests

The COP obtained under the aforementioned operating conditions for the JIS standard testing methodology is reported in Table 3, along with the load-based test results. Peak efficiency was demonstrated at low-load conditions for the cooling operation, whereas for the heating mode, the highest COP was achieved at half-load operation. JIS standard testing results reported in the study are obtained from the manufacturer catalogue of the specific system used in load-based tests. Because of the regulation on such performance tests [10-11], the test condition is set by fixing the compressor speed and setting the valve opening to achieve a safe degree of superheating at the compressor suction. Operating conditions set in this manner are not necessarily resulting in a cooling/heating capacity equivalent to the percentage of the rated value reported in Table 2.
7.2. Load-based tests

The following charts represent the four conditions used to measure the cooling performance of the system, as listed in Table 2. COP, power consumption, and cooling capacity were calculated with reference to the interval between the vertical dotted lines, representing an integer number of regular cycles.

Figure 4 illustrates the results of a load-based test conducted for a load equivalent to 25% of the nominal cooling capacity at 29 °C outdoor temperature. In this operating condition, the control system is driving the air conditioner with on-off cycling operation. This type of regulation is required when the inverter is unable to stably maintain a low compressor speed, such as the one imposed during JIS tests. Such cycling operation, along with a lower air flow rate led to a 35% gap in COP when compared with steady operation JIS test.

The load-based test results reported in Figure 5 and 6 demonstrate the ability of the variable speed control to achieve a close-to-stationary operation (except for minor compressor speed adjustments owing to oil management processes), but a lower air flow rate than the corresponding JIS test results led to a lower COP value for load-based tests. Under this load condition, the control system operated the air conditioner with a supply airflow rate that was approximately half of the maximum value used during the JIS measurements. Accordingly, the compressor speed required to compensate for the less efficient heat exchange was
approximately 20% higher, resulting in a higher power consumption to balance the same heat load and maintain the target indoor temperature.

The test results obtained at full capacity at 35 °C outdoor temperature are shown in Figure 7. Under this limiting condition, it was necessary to override the air flow rate of the native control system during load-based tests to achieve the target room air temperature. Figure 7 demonstrates that the system control manages this load with a variable speed and results in a lower COP than that obtained during the JIS tests at a constant compressor speed.

Consequently, the heating performance of the system was evaluated with reference to the four representative conditions listed in Table 2. Correspondingly, COP, power consumption, and cooling capacity, were evaluated in the time interval between the vertical dotted lines, representing an integer number of regular cycles. In accordance with the cooling case, in the heating mode, the on-off operation is performed at low loads (Figure 8), and to ensure a comfortable temperature for blowout air flow, a further adjustment of the compressor speed is performed between cycles.
As shown in Figure 9, the same observations for the half-load cooling conditions could be made. Despite relatively steady functioning, the lower air flow rate led to a less efficient heat exchange and compression ratio; thus, the COP values obtained were 36% lower.

In Figure 10, it is possible to notice an unsteady operation performed by the native control system aimed at maintaining a comfortable blowout air flow rate and temperature, lowering the airflow when the blowout temperature is low, and increasing the compressor speed between peaks to avoid relatively colder air blows that may result in discomfort for users.

In Figure 11, the full-load and low outdoor temperatures represent the most demanding operating conditions for the system. They present the overall lowest COP in both the load-based and fixed compressor speed rating methods. Moreover, this is the only condition where the load-based COP value is higher than the steady-state counterpart, and the ability of the control system to maintain the room temperature around the set point value of 20°C with cyclic operation and a high air flow rate, along with a relatively broad dead band of the thermostat around the set value, results in a higher system COP when compared to the full load JIS test where the compressor speed is maintained at its maximum value.

*Average values, ** Air flow rate manually managed
As shown in Table 3, the results of the measurement process in the testing facilities lead to 10–44% lower COP values compared with the data reported in the manufacturer catalogue, obtained through fixed compressor speed testing following the JIS guidelines.

The corresponding APF values are listed in Table 4 for a standard office in the Tokyo area. This result provides evidence for a difference of approximately 27% between standard and load-based tests, which is sensitively related to the number of hours of functioning encounter cycling on-off or modulating variable speed mode when driven by the native control system. Further, this may sensitively depend on the interactions with the specific building characteristics and load scenarios of different installations.

8. Conclusions

In this study, an emulator-type load-based testing methodology was proposed to overcome the limitations of the current JIS testing procedures conducted at constant compressor and fan speeds by disabling the native control system of the air conditioner. The proposed method allows the system to respond to the dynamic variation in the return air condition according to its native control system, as it responds during field operation. This was made possible by combining an emulator simulating the time variation of the room condition during its interaction with arbitrary load scenarios and air-enthalpy testing equipment for the real-time measurement of the output capacity.

The ability of this testing methodology to capture the controllability and dynamic response of air conditioners to constant load and set indoor temperature conditions is presented and discussed herein. The heating and cooling operation performance of an R32 ceiling-type air-conditioning unit was investigated under the prescribed conditions required for the characterization of the annual performance factor. A qualitative and quantitative comparison between the results of the JIS constant-speed tests and emulator-type load-based tests was conducted to clarify the differences and connotations of the two approaches.

During the cooling mode operation at high loads, the COP difference between the JIS and load-based tests was approximately 10% and it increased with decreasing cooling load, showing no substantial difference for the two different conditions at half load (23 and 24% COP difference) despite the different outdoor temperatures, reaching the maximum gap for the low-load condition (35% COP difference). For heat pump operation, the efficiency comparison follows the same trend, but with higher discrepancies of up to 44% for lower loads. These results, even though affected by the aforementioned discrepancies of cooling/heating capacities between JIS and load-based, show a substantial performance difference between the fixed compressor speed and native control-driven functioning, especially at lower loads, where the divergences between the on and off cyclic operation and steady operation are significant and closely related to the specific control method integrated in the system.

Accordingly, the results suggest the importance of accounting for the system controllability, load scenario, and room characteristics to improve current standard rating procedures and demonstrate the ability of the proposed emulator-type load-based testing methodology to capture these operating characteristics. The use of such an emulator-type load-based testing approach is critical for effectively developing high-efficiency control methods for air conditioners and heat pumps.

Abstract

Heat recovery becomes increasingly important for the decarbonization of industry. In addition to direct heat recovery, industrial heat pumps are increasingly used to valorize low-temperature waste heat for industrial processes. Increased utilization temperatures of heat pumps in recent years allow for generation of steam, serves as an efficient medium for heat transfer and as a process reactant in industry. For that, different types of heat pumps are available, but nearly no reference plants. In the H2020 project BAMBOO, different heat pump systems were investigated and a demonstrator consisting of a water-to-water heat pump and a flash tank system was built and tested to analyze steam production and efficiency in different operating conditions. Furthermore, a market potential assessment for steam-generating heat pumps in European countries was done, considering production volumes, steam demand for selected products, and energy prices for different consumption bands (generally speaking different company sizes), showing the influence of different boundary conditions on the economic potential of integrating heat pumps in specific sectors. This paper describes the measurement results of the demonstrator and the results of the market study.

1. Introduction

The growing interest in industrial heat pumps already shows their great potential for decarbonizing process heat. On the one hand, by increasing energy efficiency through the use and recovery of waste heat, and on the other hand, by using electricity from renewable resources to power heat pumps, it is possible to completely decarbonize process heat.\textsuperscript{[1]} For low and medium temperature levels in industrial processes, heat pump applications are projected to cover 30\% of total heat demand by 2050. Thus, to achieve the International Energy Agency’s “Net-Zero Emissions by 2050” scenario, heat pump capacities of about 500 MW need to be installed each month over the next 30 years.\textsuperscript{[2]}

As far as European industry is concerned, low-temperature process heat forms a significant proportion of energy consumption. About 30\% of the process heat is in a temperature range below 200°C. In many cases, steam is used as efficient heat transfer medium for production processes (e.g. drying, sterilization and cooking) and as a reactant. The use of steam is not only well proven in practice but steam itself can also be classified as environmentally safe.\textsuperscript{[3]}

Due to the attractive market potential, there are already some developments in the European market for industrial high-temperature heat pumps that offer the provision of saturated steam up to 5 bar\textsubscript{a} for industrial processes.\textsuperscript{[4], [5], [6]} Nevertheless, there is still a lack of reference and demonstration plants to prove and

visualize the functionality of these novel steam supply systems - especially under real operating conditions. Apart from the European market, steam-generating heat pump systems at high TRL with several 100 kW, to a few MW, heating capacity for saturated steam generation up to 9 bar, can only be found in Japan. [7], [8] In this context, the system studied by Kaida et al [7] is comparable to the one analyzed in this publication, but has a higher heating capacity and a lower level of utilization temperature. In the publications of Bless et al [9] and Wilk et al [10], different cycle and technical approaches to heat pump-based steam generation have already been theoretically investigated. Marina et al. presented experimental results of a steam generating heat pump system for up to 4.8 bar, saturated steam. [11]

Within this publication, results and findings of initial experimental investigations of a heat pump-based steam generation system using flash tanks are shown, which are based on the previous work of Helminger et al [12], Wilk et al [10], and mainly on Riedl et al. [13], among others. Extending these works within this publication the heat pump of the steam generating system is focused on.

Results from market potential analyses already carried out [14] [15] indicate potentials for high-temperature heat pumps in selected production areas (food, paper industry, wood-based materials industry, etc.). The market potential assessment for steam-generating heat pumps (< 150 °C) presented in this paper, which takes into account country-specific production volumes from statistics databases [16] and process-specific steam demand volumes for the production of selected products, and current energy prices of European countries, extends the works of Windholz et al. [17] by analyses with prices for different consumption bands (generally speaking different company sizes).

The paper is organized as follows: After this introduction, the steam-generating heat pump system is described, followed by measurement results and findings. After the market potential study is presented, the paper concludes with a summary.

2. Description of the steam-generating heat pump system, [13]

As stated in [13], Figure 1 shows the complete steam-generating heat pump system (SGHP) in the laboratory of EDF LAB Les Renardières. It is composed of the high-temperature heat pump (HTHP) HeatBooster HBS4 of the no longer existing manufacturer Viking Heat Engines (VHE), and a flash tank unit (FT) for steam generation from hot pressurized water.

The water-to-water HTHP is equipped with four oil-cooled reciprocating compressors and is capable of providing a maximum useful temperature of 160 °C by using HFO-R1336mzz(Z) refrigerant. It has a nominal heating capacity of 200 kW.

The FT was designed and manufactured specifically for the HTHP (i.e., 200 kW) and for test operation in the laboratory and subsequent demonstration operation in a semi-industrial environment. With this FT it is possible to generate saturated steam up to about 5 bar, (~152 °C).

According to the schematic representation of the SGHP in Figure 2 the idealized steam generation of the SGHP works as follows [13]:
- The refrigerant circulating in the heat pump (HP) extracts heat from the heat source by its evaporation, and after compression is in compressed form with higher temperature. By liquefying the refrigerant in the condenser, it adds heat to the circulating pressurized water on the secondary side, increasing the water temperature (ideally isobaric) to a still subcooled state.
- The speed of the water circulation pump and the use of its bypass together with the opening degree of the flash valve mainly define the circulation flow and the pressure drop of the pressurized water along the flash valve. The (ideally isenthalpic) expansion (exergy loss) of the subcooled water flow causes partial evaporation of the water, resulting in a certain steam quality after the flash valve. The higher the pressure drop, the higher are steam quality but also the exergy loss.
- In the flash tank, saturated steam is subsequently separated from the saturated liquid and discharged in a usable manner (ideally isobaric).
- The mass predominant saturated water collects in the flash tank and is pumped back to the condenser by the circulation pump (ideally isentropic), increasing its pressure.
- To keep the water level in the flash tank constant or to refill the flash tank, the evaporated water is replenished via the feedwater pump.

Since the studied object is a heat pump-based energy system, in addition to the COP of the heat pump COPHP, the COP of the SGHP COPsystem was also calculated, also considering the performance of the circulation pump.

3. Measurement results and findings

To the knowledge of the authors, the data of the measurement campaign are the first ones of a steam generating heat pump system like this, i.e., a saturated steam pressure of up to 5.5 bar, with a high-temperature heat pump using a low GWP refrigerant and a flash tank.

As partly stated in [13], a maximum steam pressure of 5.5 bar (~155 °C) was reached, and a maximum saturated steam mass flow rate of 218 kg/h was achieved. Relevant system conditions at these two maximum operating points are listed in Table 1.

In [13], results of stationary operating points were presented by COP_{system} and corresponding steam mass flow, see Figure 3. The COP_{system} was broken down by saturated steam pressure (2/3.5/5 bar), source-side inlet temperature of the heat pump source (65/80 °C), and whether the circulation pump bypass valve was open or closed (cmp. scheme in Figure 2).

Figure 3: COP<sub>system</sub> and different steam mass flows, broken down by saturated steam pressure (2/3.5/5 bar), source-side heat pump inlet temperature (65/80 °C), and whether the circulation pump bypass valve was open or closed. Adapted from [13]

Extending the earlier work of the authors, a deeper analysis of the heat pump’s COP<sub>HP</sub> (without flash tank system) is carried out within this paper to gain knowledge about the demonstrator and improve the design of future SGHPs. During the measurement campaign, the boundary conditions and setpoints of the SGHP were changed systematically, e.g., inlet/outlet temperatures and mass flows. Due to different issues (i.e., operation at operating limits, controls of the components and the test rig) not all combinations of boundary conditions and setpoints delivered stationary operation of the SGHP. The boundary conditions of the resulting 31 stationary operating points are shown in Figure 4. The diagram shows the volume flows on the sink and the source side of the heat pump, as well as the resulting temperature lift between sink outlet and source outlet at 100% rotational speed of the compressor. While the flow rate on the sink side had a range of 8.5 to 38.0 m³/h (ratio 1:4.5), the volume flow rate on the source side had only 2 concrete values 9.9 and 12.0 m³/h (ratio 1:1.2). The allowed volume flow range is 5 to 50 m³/h on both sides of the heat pump. The resulting temperature lift ranged from 49.2 to 79.2 K (ratio 1:1.6), distinguished within the diagram by 5 K groups (color and marker).

Given these boundary conditions, Figure 5 shows the resulting COP<sub>HP</sub> of the heat pump at different temperature lifts between sink outlet and source outlet, broken down by the temperature difference (spread) of the pressurized water (sink). The authors focused on lift and spread since the lift is known to have a strong influence on the COP<sub>HP</sub> of a compression heat pump (rising lift generally decreases COP<sub>HP</sub>), and the spread on the sink side is also expected to play a role (at constant lift, rising spread reduces condensation pressure thereby increasing the COP). Analyzing the available measurement data, the expected trends are not fully confirmed, lift and spread are apparently not the only relevant parameters for the COP<sub>HP</sub>, as can be seen especially at the operating points having a lift of about 78 K but different COP<sub>HP</sub> values from 1.6 to 2.1 for different spreads, and on the other hand having nearly the same COP<sub>HP</sub> values of around 3.5 (lift around 50 K) at spreads from 2 to 7 K. Unambiguous influences of other parameters could not be obtained with the available data.
The second law efficiency presented in the following compares the actual COP\(_{HP}\) with the maximum possible COP of a Lorenz cycle. For the correct calculation of this efficiency value, the difference of the logarithmic mean sink and source temperatures takes the place of the above used simple temperature lift between sink outlet and source outlet. But again, temperature difference between sink and source (though calculated differently) and spread was focused on since they are expected to have influence on the second law efficiency. The results for the available operating points are shown in Figure 6 with the corresponding volume flows on the heat source and the heat sink shown in Figure 7 over the resulting temperature difference between sink and source, broken down by the temperature difference (spread) of the pressurized water (sink). The diagrams indicate a lower second law efficiency at a higher difference between sink and source temperature (esp. spread group [1-2] K, having occasional comparable volume flows). Considering the spread on the heat sink (different colors and marker symbols) at comparable temperature differences between sink and source temperature (esp. 75 K), the second law efficiency tends to rise with rising spread.
Another observation at a temperature difference between sink and source of around 75 K and a constant source volume flow (spread groups [1-2) K and [3-4) K) is a decrease of second law efficiency with rising sink volume flow. This effect is not that strong at lower temperature differences between sink and source.

The current findings within this paper are that the second law efficiency (Lorenz cycle) of the heat pump is far from being constant, it increases when the temperature difference between sink and source is decreased, and with a rising temperature difference between sink and source the second law efficiency increases with rising spread of the pressurized water (respectively a lower sink volume flow). Even though unambiguous influences of all the parameters could not be obtained with the available data, the so far derived trends can help to operate the SGHP more efficient.

4. Market potential

Within this paper, the market potential assessment of steam-generating high-temperature heat pumps up to 150 °C by Windholz et al. [17] is extended by analyses with prices for different consumption bands. Prices for different annual consumption bands of electricity and gas were extracted from the eurostat database [16] for the year 2021, see Table 2. Figure 8 shows the calculated effective ratios of electricity to gas prices in various European countries.

As stated in [17] for consumption bands IF/I4 (centre): Countries with relatively cheap electricity - above all Finland and Sweden - are particularly suitable for the substitution of gas by electricity, for example with heat pumps. In contrast, the implementation of heat pump projects in countries with relatively expensive
electricity - especially Slovakia, Ireland and Germany - is only economically viable over longer periods of time, if at all.

In comparison with the maps in the left (consumption bands IA/I1) and the right diagram (consumption bands IG/I5), price ratios – against first expectations – do not decrease with higher consumption bands in each country. In Bulgaria, Portugal, and Sweden, price ratios increase strictly monotonically from IA/I1 over IF/I4 to IG/I5. In Ireland, Hungary, Austria, Romania and Finland, price ratios only increase from IF/I4 to IG/I5.

4.1. Pulp and paper sector

Windholz et al. [17] found a total installed heating capacity in the paper industry in the European countries considered of around 12.6 GWth. Germany achieves the highest individual value in this respect with 3.0 GWth, followed by Finland and Sweden with 1.3 GWth each. The technical potential for the use of steam-generating high-temperature heat pumps (< 150 °C) in the paper industry in various European countries was found to be around 6.1 GWth or, at 48%, almost half of the installed heating capacity that could be provided by heat pumps - a heat recovery measure that saves primary energy.

The economic viability of heat pump systems is strongly dependent on the energy price ratio (electricity to natural gas) and the pricing of greenhouse gas emissions. Under the assumption that the use of heat pump systems must be financially worthwhile for the operator in addition to the primary energy savings, at a certificate price of 60 €/t and the three different price ratios of consumption bands a heating capacity of 1.3, 1.7 or 1.9 GWth of HT heat pumps can be installed, i.e., only around 22, 28 or 31% of the technical potential in the paper industry.

As can be seen in the upper three images in Figure 9, Finland and Sweden as well as the Netherlands, Hungary and Croatia can leverage 100% of their technical potential with financial gain already with price ratio IA/I1. In Estonia and France this goal can only be reached with price ratio IG/I5. Note: Relevant information for the evaluation is missing for the countries shown in white.

An increase of the emission pricing (certificates) to e.g., 200 €/t increases the economic efficiency of heat pump systems, so that with the three different price ratios a total of about 1.4, 3.4, or 3.6 GWth, or a share of 24, 55, or 58% of the technical potential can be raised in an economically profitable way, see in the lower three
images in Figure 9. While with price ratio IA/I1 6 countries could possibly leverage 100% of their technical potential, this number increases to 15 or 14 with price ratios IF/I4 or IG/I5, respectively (As before: Relevant information for the evaluation is missing for the countries shown in white).

![Diagram showing economically feasible technical potential for steam-generating heat pumps (< 150 °C) in the paper industry in various European countries with a certificate price of 60 €/t.](image)

**Figure 9:** Economically feasible technical potential for steam-generating heat pumps (< 150 °C) in the paper industry in various European countries with a certificate price of 60 €/t. Left: Price ratio IA/I1; Center: IG/I4; Right: IF/I5. Top: 60 €/t; Bottom: 200 €/t.

4.2. **Dairies, breweries, and meat processing**

Windholz et al. [17] found a total installed heating capacity in subsectors (Dairies, breweries, and meat processing) of the food & beverage sector in the European countries considered of around 5.1 GWth. Ireland achieves the highest individual value in this respect with 1.1 GWth, followed by France with 875 MWth and United Kingdom with 558 MWth. The technical potential for the use of steam-generating high-temperature heat pumps (< 150 °C) in these subsectors of the food & beverage sector in various European countries was found to be around 2.2 GWth or, at 44%, almost half of the installed heating capacity that could be provided by heat pumps - a heat recovery measure that saves primary energy.

The economic viability of heat pump systems is strongly dependent on the energy price ratio (electricity to natural gas) and the pricing of greenhouse gas emissions. Under the assumption that the use of heat pump systems must be financially worthwhile for the operator in addition to the primary energy savings, at a certificate price of 0 €/t and the three different price ratios of consumption bands a heating capacity of 136, 106 or 134 MWth of HT heat pumps can be installed, i.e., only around 6, 5 or 6% of the technical potential in the considered subsectors of the food & beverage sector, see upper three images in Figure 10. These not really rising but partly even decreasing numbers are a direct consequence of the increasing price ratios with increasing consumption bands in some countries as explained above. While with price ratio IA/I1 three countries (Finland, Sweden, Netherlands) could possibly leverage 100% of their technical potential, this number decreases to two or one with price ratios IF/I4 or IG/I5, respectively.
An increase of the emission pricing (certificates) to e.g., 60 €/t increases the economic efficiency of heat pump systems, so that with the three different price ratios a total of about 151, 300, or 545 MWth, or a share of 7, 13, or 24% of the technical potential can be raised in an economically profitable way, see middle three images in Figure 10. While with price ratio IA/I1 three countries could possibly leverage 100% of their technical potential, this number stays three or decreases to one with price ratios IF/I4 or IG/I5, respectively. On the other hands, in countries with decreasing price ratios (with rising consumption bands), e.g. France and Denmark, the economic potential rises from IA/I1 to IG/I5.

An increase of the emission pricing (certificates) to e.g., 200 €/t increases the economic efficiency of heat pump systems, so that with the three different price ratios a total of about 284, 1084, or 1318 MWth, or a share of 13, 48, or 59% of the technical potential can be raised in an economically profitable way, see lower three images in Figure 10. While with price ratio IA/I1 three countries could possibly leverage 100% of their technical potential, this number increases to eleven or eight with price ratios IF/I4 or IG/I5, respectively. On the other hands, in countries with decreasing price ratios (with rising consumption bands), e.g. Poland and Spain, the economic potential rises from IA/I1 to IG/I5.

The current findings add a new aspect to the results of Windholz et al. [17], namely that in some countries the price ratio of electricity to gas is not strictly monotonically decreasing with rising consumption bands, but
even increasing. This means, that in the countries concerned, smaller companies in the considered subsectors of the food & beverage sector, due to their better price ratio, have more economic potential to integrate heat pumps than larger companies (generally speaking having price ratios of higher consumption bands). However, despite the same price ratios, this effect was not found in the results of the pulp and paper sector, mainly due to different annual operating hours (8000 h/a in pulp & paper, 6000 h/a in the food & beverage sector) as boundary conditions.

Nevertheless, the influence of certificate prices on the economic potential of heat pump integration is clear, higher prices increase the economic potential.

5. Summary

Within this publication, results and findings of initial experimental investigations of a heat pump-based steam generation system using flash tanks were shown, which are based on the previous work of Helminger et al [12], Wilk et al [10], and mainly on Riedl et al. [13], among others. Extending these works within this publication the heat pump of the steam generating system was focused on. The current findings within this paper are that the second law efficiency (Lorenz cycle) of the heat pump is far from being constant, it increases when the temperature difference between sink and source is decreased, and with a rising temperature difference between sink and source the second law efficiency increases with rising spread of the pressurized water (respectively a lower sink volume flow). Even though unambiguous influences of all the parameters could not be obtained with the available data, the so far derived trends can help to operate the SGHP more efficient.

Results from market potential analyses already carried out [14][15] indicate potentials for high-temperature heat pumps in selected production areas (food, paper industry, wood-based materials industry, etc.). The market potential assessment for steam-generating heat pumps (< 150 °C) presented in this paper, which takes into account country-specific production volumes from statistics databases [16] and process-specific steam demand volumes for the production of selected products, and current energy prices of European countries, extends the works of Windholz et al. [17] by analyses with prices for different consumption bands (generally speaking different company sizes). The current findings add a new aspect to the results of Windholz et al. [17], especially for the considered subsectors of the food & beverage sector, namely that in some countries the price ratio of electricity to gas is not strictly monotonically decreasing with rising consumption bands, but even increasing. This means, that in the countries concerned, smaller companies in the considered subsectors of the food & beverage sector, due to their better price ratio, have more economic potential to integrate heat pumps than larger companies (generally speaking having price ratios of higher consumption bands). However, despite the same price ratios, this effect was not found in the results of the pulp and paper sector, mainly due to different annual operating hours (8000 h/a in pulp & paper, 6000 h/a in the food & beverage sector) as boundary conditions, increasing the economic potential.

Nevertheless, the influence of certificate prices on the economic potential of heat pump integration is clear, higher prices increase the economic potential.

Abstract

Due to the increasing share of renewable sources in the energy mix, large-scale energy storage systems are becoming essential to ensure secure and stable energy supply. Carnot batteries, a combination of a power-to-heat, a thermal storage and a heat-to-power system, could provide a possible solution. Heat pump systems have been considered as the power-to-heat technology for Carnot batteries. However, it is not clear which grid services these heat pumps could deliver. To answer this question, a 1 MW vapour compression heat pump, suitable for integration in a Carnot battery, was modelled in Modelica. Quasi-steady state operation of compressor and expansion valve was considered, while dynamic finite volume models were used for the heat exchangers. Behavior of the sensible storage tanks was assumed ideal and quasi-steady boundary conditions were imposed. Furthermore, a control strategy driven by the requirements of the electrical grid was proposed. The dynamic model simulates and evaluates the heat pump’s response to the qualification test profiles for grid balancing services. It was found that the heat pump can deliver a symmetric capacity of 125 kW for primary reserve while maintaining a correct delivery temperature to the thermal storage system. In addition, the system qualifies for delivering a capacity of 250 kW for secondary and tertiary reserve. These results indicate that the delivery of grid balancing services could be another revenue stream to increase the financial feasibility of Carnot battery systems and it is thus worthwhile to investigate its potential financial benefits.

1. Introduction

1.1. Carnot batteries

The share of renewables in the worldwide energy generation is continuously increasing, peaking at 23.2% in 2019. This increase was even steeper in member states of the European Union, where renewable electricity production accounted for 33.2% \cite{1}. This large deployment of variable renewable energy sources (RES) challenges the stability of the electrical grid due to their intermittent nature. Energy storage can address these problems by power and voltage smoothing, energy management, frequency regulation, peak shaving, load leveling, seasonal storage and standby generation during a fault \cite{2}. Therefore, energy storage is considered one of the main drivers to provide the flexibility needed to completely decarbonize the electricity grid \cite{3}.

Carnot batteries are an emerging large-scale electrical energy storage (EES) concept that may provide additional flexibility to the grid. The concept involves three steps. First, electrical energy is converted into heat using a heat pump or joule heater after which the heat is stored in the second step.

E-mail address: Robin.Tassenoy@UGent.be.
Finally, heat engine technology is used to convert the heat back to electricity when needed. One of the Carnot battery’s subsets is pumped thermal energy storage (PTES), in which an electrically driven heat pump is used to deliver heat to a hot store and/or extract heat from a cold store [4]. The majority of studies currently available have focused on the steady-state analysis and optimization of the storage concept and the obtainable round-trip efficiencies [5]. More recently, the techno-economic optimization of PTES have gained interest as well [6, 7]. Vecchi et al. [7] collected and compared the techno-economic performance data of different Carnot battery systems in literature. Moreover, they discussed the applications of Carnot batteries at energy system scale and the most recent commercial developments in Carnot battery technologies. Their literature review reveals that Carnot batteries have been considered mainly for load-shifting and arbitraging services. The authors concluded that these services alone may not be sufficient to recover the investment cost of the technology. The importance of a portfolio of grid services to provide different revenue streams is thus highlighted.

1.2. Grid balancing services

Within the portfolio of grid services, providing grid flexibility is highly promising as the need intensifies due to the large deployment of variable RES [8]. Grid flexibility is usually defined as the possibility of modifying generation and/or consumption patterns in reaction to an external signal (e.g. price) to contribute to the power system stability in a cost-effective manner. At the transmission grid level, flexibility is linked to grid balancing services offered to transmission system operators (TSOs) [9]. These services match the instantaneous electricity production and demand, which is essential to ensure stable grid operation. According to their time scale, three balancing products can be distinguished: primary or frequency containment reserve (FCR), secondary or automatically activated frequency restoration reserve (aFRR) and tertiary or manually activated frequency restoration reserve (mFRR). The FCR stabilizes the frequency deviation on the European grid at a stationary value, after which the aFRR and mFRR restore the frequency to its original value [10]. An overview of the main service characteristics is presented in Table 1.

1.3. Dynamic modelling of PTES and large-scale heat pumps with respect to grid balancing services

From the discussion above, it is clear that PTES-dynamics are essential for the delivery of grid balancing services. However, there is a lack of research on these dynamic characteristics which makes it difficult to predict, regulate and optimize the performance of PTES in actual operation processes [14].

This knowledge gap has partially been addressed for Brayton-based PTES recently [14, 15]. Lu et al. [14] constructed a dynamic simulation model of a PTES based on the closed Brayton-cycle with a nominal charging- and discharging power of 2.27 and 1.49 MW, respectively. The model was used to optimize the control strategy and dynamic performance of the system during the start-up process. It was found that the rotational speed increase rate had a negligible effect on the system startup time for the charging process but affected the start-up time of the discharging process significantly. Moreover, high rotational speed increase rates caused fluctuation and overshoot in the rotational speed. Depending on the control parameters, start-up to full load took 50 min in charging mode and 15 min in discharging mode. While the start-up was discussed, the system’s reaction to disturbances of electrical power input in nominal operation was not studied. This topic was addressed by Yang et al. [15] for a 5 MW Brayton-heat pump in a PTES-system. Next to a study of the step response to the system control parameters, a closed loop inventory control strategy was proposed to ensure correct storage temperatures and high efficiency even at part-load. Although control of the system to maintain a desired power uptake, as needed for delivery of grid balancing services, was not discussed, the authors showed the system’s capability to maintain correct charging conditions for the storage system despite reduced electrical power input.

To the best of the authors’ knowledge, no study on the dynamics and control of a full Rankine-based PTES-system or of a heat pump cycle to be implemented in a PTES-system is currently available. Stand-alone large-scale Rankine-based heat pumps are currently mainly used in district heating applications and are thus not
optimized to react quickly to the needs of the electrical grid. Consequently, providing grid flexibility using large-scale Rankine-based heat pumps is not well understood [16]. Meesenburg et al. [17] were probably first to address this issue. A detailed numerical system model of a two-stage ammonia heat pump used in district heating applications was developed and calibrated based on experimental data. Rooted on this model, they assessed how fast large-scale heat pumps can adapt their load according to grid requirements, the dynamic effects during fast-regulation and the limitations of currently implemented units with regard to fast-regulation. It was found that after optimization of the control structure, the heat pump power could be regulated from 250 kW to 175 kW in 54 s and from 250 kW to 100 kW in 99 s without the risk of condensation in the suction line.

1.4. Scope of this study

As illustrated by the discussion above, the dynamic response and control of PTES driven by requirements of the electrical grid is a clear gap in literature. For Brayton-based PTES, the dynamic response to power disturbances has been addressed. Nevertheless, control of the system to follow a desired electrical consumption or production profile as required for grid balancing has not yet been studied. For Rankine-based PTES, no study discussing the dynamic response of the complete system has been found. In fact, only one study addressing this subject for a stand-alone large-scale heat pump has been identified. However, this study focused on an existing heat pump for district heating, which means the topology, working temperatures and temperature requirements of the heat transfer fluid to the thermal storage were less strict compared to PTES-applications. As such, it remains unclear whether PTES is capable of delivering grid balancing services. This study aims to make a first step towards answering this question by focusing on the heat pump component of Rankine-based PTES. A dynamic model of a 1 MW Rankine-based heat pump cycle suitable for implementation in a PTES was constructed. Then, a suitable control strategy to follow the desired power uptake was developed, while maintaining correct storage temperatures. Finally, the controlled system was validated against pre-qualification tests of the European grid to assess its technical potential to deliver grid balancing services.

The system description, nominal operating conditions, sizing and dynamic modelling of the components and test conditions, are described in Section 2. The modelling results are shown and discussed in Section 3. First, the Modelica model is validated by a steady-state comparison to the Python cycle calculation. Then, the maximum capacity is determined and the qualification tests for mFRR, aFRR and FCR are successively discussed before a conclusion is formulated in Section 4.

2. Methodology

2.1. Carnot-battery lay-out and heat pump boundary conditions

This work focuses on the dynamic modelling of a vapour compression heat pump to be implemented in a Carnot battery. These PTES-systems usually consists of a heat pump, a thermal storage system and a thermal engine, as shown in Figure 1.

![Carnot-battery lay-out](image)

Fig. 1. Schematic representation of a Rankine-based, thermally integrated Carnot battery.
Rankine-based PTES typically takes advantage of a low-grade heat source to boost the electric round-trip efficiency of the system [18]. Apart from low-grade geothermal heat and solar thermal energy, heat sources of suitable thermal capacity and temperature level can be found mostly in the industrial sector. Marina et al. [19] inventoried these industrial residual heat sources suitable for heat pump integration. The amount of residual heat available reduces with increasing heat temperature. Balancing the heat availability and efficiency improvement of the PTES, a residual heat source of 65°C was adopted in this study.

Sensible liquid heat storage is often applied as it is reliable, mature and cost-efficient. A two-tank configuration guarantees almost constant charge and discharge profiles and was therefore selected instead of a single tank solution, despite the cost of doubling the storage volume [18, 20]. Pressurized water tanks were opted for as they are cheap, have low environmental impact and are suitable for a single tank solution, despite the cost of doubling the storage volume [5, 21]. As typical temperature lifts of heat pumps reported in literature range from 40 to 80 °C [22, 23], the tank temperatures were chosen to fit within this lift range. The temperature of the hot tank was chosen as 125 °C, while a cold tank temperature of 95 °C was assumed.

A basic heat pump cycle was chosen in this work. It has four main components: an evaporator, a compressor, a condenser and an expansion valve (see Fig. 1). In literature, more advanced cycles have been proposed [20, 22, 24]. Although these systems have higher coefficients of performance, the additional components increase the thermal inertia of the system and are thus expected to slow down the system’s dynamic response. Therefore, the most basic system was assessed first. If this topology proves to be suitable to deliver grid balancing services, more complex topologies can be addressed in future work.

### 2.2. Nominal operating conditions and refrigerant selection

Once the temperature range of the heat pump had been fixed, the working fluid was selected. Based on different studies, R-1233zd(E) was selected because of its good thermodynamic performance in the intended operating range and low global warming and ozone depletion potential compared to refrigerants commonly applied [25, 26].

The steady-state operating conditions were calculated using a Python toolbox to model basic and advanced heat pump concepts [27]. Fluid property data were imported from REFPROP 10.0 [28]. Based on these estimates, more detailed component selection and modelling were performed, as discussed in Section 2.3. An overview of the modelling assumptions and resulting nominal conditions is given in Table 2.

### 2.3. Component selection and modelling

A dynamic heat pump model was built in the object-oriented modelling language Modelica [29], using the simulation software Dymola 2022 [30] and the TIL-library [31]. The component models of this library were used, and extended when necessary. The piping pressure losses on the low and high pressure side were merged in one common pressure loss model at each pressure side to ensure right inlet and outlet pressure for the compressor. Fluid properties were calculated using the REFPROP-database [28]. In the following subsections, the component selection and assumptions made for their modelling are briefly discussed.
2.3.1. Heat exchangers

Plate heat exchangers (PHE) were selected for both the evaporator and condenser because they are relatively cheap, compact and have a modular design [20, 32]. Funke [33] produces gasketed PHE with capacities up to 30 MW and volume flow rates up to 4500 m³/h. SWEP [34] manufactures smaller capacity heat exchangers, but provides an intuitive sizing tool for high-level sizing of the heat exchangers. Based on this tool, five VH500TM PHEs and two B500TM PHEs were selected as evaporator and condenser respectively. The PHEs were modelled using the finite volume (FV) model available in the TIL-library [31], assuming countercurrent flow. Instead of modelling five separate evaporators, only one PHE model was used with the total amount of plates. The dimensions of one plate were based on the actual heat exchanger. A similar approach was implemented for the condenser. The suitability of FV-models for dynamic simulation of evaporators and condensers has extensively been demonstrated [32]. Moreover, the PHE model from the TIL-library used in this study has been successfully used to simulate a two-stage ammonia heat pump with a thermal capacity of 800 kW [17]. The authors validated the model to experimental measurements of an actual heat pump with shell-and-plate heat exchangers under identical operating conditions. Despite the different heat exchanger type, the alternative heat exchanger model accurately represented the general trends of the heat pump behavior during load change and could thus be used to assess to study the system control. In the current study, not all model parameters were made available by the PHE manufacturer. Therefore, the values reported by Meesenburg et al. [17] were used initially and adapted so that the heat exchanger mass, volume and heat exchanger area matched the values proposed by the SWEP-software [35]. Consequently, the inertia of the modelled heat exchangers is representative for the selected components. On the refrigerant side, following heat transfer correlations were applied: Shah Chen [36] for evaporation, Chen [36] for condensation and Gnielinski Dittus Boelter for single-phase flow [37]. Heat transfer at the water side was modelled by the VDI Plate alpha correlation [38]. Finally, all pressure drops in the heat exchangers were assumed proportional to quadratic mass flow [17].

2.3.2. Compressor model

A screw compressor or centrifugal compressor would be most suitable for the nominal flow rate and pressure ratio [39]. However, performance data at variable rotational speeds was not found for both. Therefore, performance maps for an axial compressor, suitable for higher flow rates, were retrieved from the GasTurb performance map collection [40] and scaled to the intended nominal conditions. An important remark to make is that the performance map used is representative for gas compressors, while in the current study a refrigerant was used. Nevertheless, the performance map of the gas compressor allowed to construct a performance map-based compressor model. The reported isentropic efficiencies range from 65 to 87 % depending on the operating conditions, which corresponds with common assumptions in performance studies for Carnot batteries. Therefore, this assumption was considered acceptable for the current purpose and the results can be updated when more suitable performance data becomes available. Immediate response of the compressor was assumed [17, 41, 42].

2.3.3. Valve model

The valve model was retrieved from the TIL-library [31]. The operating point was adapted by regulating the effective flow area of the valve.

2.3.4. Other components

The sensible storage was not modelled in detail. Instead, it was assumed that the tank was perfectly stratified and the water temperature at the inlet of the condenser stayed constant. A boundary model was used to impose a constant pressure and temperature, while the mass flow could be regulated.

2.4. Controller design

The control system should make sure the heat pump responds quickly to a desired power uptake, while maintaining correct storage temperatures and maximizing operational efficiency. Therefore, three inputs were controlled using PI-controllers: the compressor rotational speed, the valve through-flow area and the water mass flow rate in the condenser. Variable speed control of the compressor is an effective way to modulate the power uptake. A PI-controller compared the desired power consumption with the effective one and changed the rotational speed accordingly. As the operating point is determined by the intersection of the compressor- and valve characteristic, the effective through-flow area of the valve was varied to acquire the mass flow corresponding with the maximal efficiency of the compressor for a given pressure ratio. The value of the
refrigerant mass flow was calculated based on a fourth degree polynomial derived from the efficiency map of the compressor optimizing the relation between pressure ratio and mass flow rate. Finally, the water mass flow rate in the evaporator was adapted by a PI-controller to maintain a hot storage temperature of 125°C. All PI-constants were determined by analyzing the corresponding system step response using a dedicated online toolbox [43]. The resulting PI-constants are summarized in Table 3.

2.5. Test conditions for ancillary services

The Belgian TSO Elia provides prequalification tests for all balancing services discussed in Table 1. All tests follow the same approach. A power profile that represents the most extreme testing situation is provided. The service is then evaluated in terms of the full activation time (FAT), the maximum power delivery, the duration of the service and the deviation of the power. The delivery of FCR is always symmetric and the capacity should react linearly to the frequency deviation of the grid. aFRR and mFRR on the other hand can deliver up- or down regulation separately, or do both. It should be noted that Elia sets a minimum capacity bid for aFRR and mFRR at 1MW, but it is allowed to split this capacity over multiple assets. The main criterion is that the requested power uptake or production (within predefined accuracy) is reached within the prescribed maximum activation time. In this study, the combination of up- and down regulation was not tested as it follows from the separate tests. The pre-regulation tests also aim at verifying that the service can be delivered for a sufficiently long time. For Carnot batteries, this duration is closely related with the capacity and state-of-charge of the thermal storage system. Here, focus was given to the reaction time and it was assumed the TES was sized adequately, fulfilling the duration requirement.

3. Results and discussion

3.1. Steady-state model validation

A direct validation of the separate component models to experimental data is not possible, as this data is not available. Instead, the component sizing and modelling are partially validated by comparison of the steady-state results to the steady-state Python calculation. The dynamic model (and implemented control) are tested by simulating the steady-state system response to constant controller setpoints. An overview of the assumed boundary conditions, controller setpoints and corresponding simulation results is given in Table 4. The simulation results show good correspondence with the steady-state cycle calculations in Table 2. The deviation can be explained by the model strategy. While the thermodynamic states are fixed directly in the Python model, they follow from the physical component characteristics and choice of controlled parameters in the Modelica model. A one-on-one match is thus not to be expected. Nevertheless, the good correspondence between results indicates proper sizing and modelling of the different components. Moreover, the controllers reach the desired setpoint illustrating the effectiveness of the implemented control method.

\[ P_{P_{\text{condenser}}} = 8.096 \text{ °C} \]
\[ \eta_{\text{is,compressor}} = 0.86 \text{ -} \]

3.2. Maximum power regulation

To assess the possibility of delivering grid balancing services, the maximum capacity available should be determined first. The minimum part-load capacity the system can run at is determined by:

- The minimum rotational speed of the compressor, which is 50% of the nominal speed according to the performance map.
- Condensation of the refrigerant at the inlet or outlet of the compressor due to insufficient superheating.
- The condenser temperature, as the heat pump may not be able to sustain a water outlet temperature of 125°C to the storage tank.

In order to test which condition limits the part-load capacity of the system, the compressor power setpoint was gradually reduced. This was done sufficiently slow so that all operating points could be considered steady-state and the operating range was not determined by transient responses. The superheating at the outlet of the compressor became insufficient first, at a compressor power uptake of 750 kW. The compressor power can thus be modulated between 750 and 1000 kW. The potential capacity for aFRR and mFRR is hence 250 kW. As FCR should always be delivered symmetrically, the potential power band for FCR is limited to 125 kW around a nominal operating point of 875 kW.

3.3. Tertiary reserve

The Carnot battery should fulfill two requirements in order to qualify for mFRR: the system should have a sufficiently low response time and should be able to maintain the correct charging temperatures to the TES.

The mFRR has a maximum FAT of 15 min, implying that the full offered capacity should be activated within 15 min. In Figure 2, the step response of the heat pump system to a step change in compressor power setpoint in the downward- and upward direction is shown. As summarized in Table 5, the FAT of the heat pump is well below the limit of 15 minutes. The response time found is significantly shorter than the minimal regulation time of 54 s obtained by Meesenburg et al. [17], who made similar modelling assumptions. This difference can be attributed to the more complex system lay-out. The one-stage heat pump reacts significantly quicker than a two-stage variant because of its lower system inertia and omitted control of the intermediate pressure level. Yang et al. [15] studied the dynamic response of a 5 MW Brayton-based heat pump integrated in a Carnot battery and found a response time of 14.28 s for a 250 kW downward ramp. The response times found for the 1MW Rankine-heat pump are thus lower, but have a similar order of magnitude for the same mFRR capacity delivered.

</tr>
</tbody>
</table>

Table 5. FAT of a 1 MW heat pump system in downward and upward direction.
Next to this suitable response time, it is crucial that the delivery temperature to the TES-system remains correct during the power modulation. In Figure 3, the variation of the water temperature at the outlet of the condenser is shown for the downward and upward step. The maximum absolute deviation is 0.59 °C and 0.66 °C for the downward and upward step, respectively. Besides, the duration of the deviation is lower than 50 s. Despite this short duration, it is still noticeable that the temperature response is significantly slower than the power response.

To better understand this delayed thermal response, the system’s reaction to a 250 kW downward step in compressor power setpoint ($P_{\text{set}}$) is investigated. The response to the upward step is analogous. In Figure 4, it can be seen that the PI-controller of the compressor reacts immediately on the reduced power setpoint by lowering the compressor speed ($n$). Consequently, the refrigerant mass flow ($m_r$) reduces. Moreover, the evaporator pressure drops and the condenser pressure increases, which results in a reducing pressure ratio (PR) over the compressor. As both changes happen quickly, the compressor power settles rapidly at the desired setpoint. The delayed temperature response of the sink water can be explained by the thermal inertia of the heat exchanger. As visualized in Figure 5, the thermal inertia causes the condenser heat rate ($Q_{\text{cond,out}}$) to drop slower compared to the refrigerant mass flow and enthalpy of the refrigerant at the compressor outlet. Therefore, the water temperature at the sink outlet drops more slowly as well. As the heat sink PI-controller reacts based on the difference between this temperature and the desired temperature setpoint, its reaction is delayed compared to the compressor PI-controller that reacts directly on the desired electrical power consumption. The sink PI-controller’s response is thus cushioned by the inertia of the heat exchanger. Nevertheless, the PI-controller of the sink reacts sufficiently quickly to maintain a suitable water temperature at the condenser outlet.
Fig. 4. System response for a 250 kW downward step in compressor power: (a) relative compressor speed, (b) refrigerant mass flow rate, (c) pressure ratio.

Fig. 5. System response for a 250 kW downward step in compressor power: (a) refrigerant temperature at compressor outlet, (b) condenser heat rate, (c) water mass flow heat sink.
As the FAT is well below the required limit while maintaining adequate supply temperatures to the TES, it can be concluded that the heat pump system is capable of delivering a capacity of 250 kW mFRR in both the upward and downward direction. However, it is important to note that the power control acts directly on the compressor setpoint and that this compressor is modelled assuming quasi-steady state. Given the low FAT found, taking the compressor dynamics into account may thus be important for grid supporting applications in contrast to traditional heat pump applications where the heat pump is controlled based on heat demand. The sensitivity of the system’s response to the compressor inertia will be evaluated in future work.

3.4. Secondary reserve

Compared to tertiary reserve, aFRR requires a faster response with a FAT lower than 7.5 min. This limit will be reduced to 5 minutes by 17/12/2024 [12]. As discussed in Section 3.3, the heat pump meets this requirement while maintaining suitable TES-temperatures. Next to the FAT requirement, the heat pump should be able to follow a synthetic load pattern within a margin of 7.5 %. Figure 6 shows this load-pattern for upward and downward aFRR, which corresponds to lowering and increasing the compressor power consumption respectively. A maximum power deviation of 0.85 % and 0.79 % is observed for the upward and downward aFRR product, which is within the allowable limit. The corresponding maximum absolute deviations of the water temperature at the outlet of the condenser are 0.30 °C in both directions. The heat pump thus qualifies for an aFRR capacity of 250 kW in the upward and downward direction.

3.5. Primary reserve

The qualification test for FCR consists of two parts. First, the FAT of the full contracted reserve should be delivered within 30 s in both directions, a requirement which is met as shown in Table 5. Besides, the system should react adequately to step changes of one fourth of the contracted capacity. The maximum allowable deviation after 12.5 s is 10% of the step (3.125 kW). As explained in Section 3.1, the heat pump is tested for a symmetric capacity of 125 kW. Figure 7 shows the system response on the stepwise decrease and increase of the requested compressor power. The deviation values per step are summarized in Table 6. The maximum absolute deviation of the water temperature at the outlet of the condenser over the whole ramping interval is 0.27 and 0.13 °C for the stepwise decrease and increase in requested compressor power, respectively. The system thus qualifies for a symmetric FCR capacity of 125 kW.

4. Conclusion

The possibility to deliver grid balancing services with large-scale heat pumps in Rankine-based Carnot battery systems was investigated. Therefore, a basic Rankine-based 1 MW heat pump cycle, suitable for implementation in a Carnot battery using two-tank liquid storage, was modelled dynamically in Modelica. Afterwards, a suitable system control strategy was developed and the system was evaluated according to the pre-qualification tests for grid balancing services in the European grid. Under the assumption of quasi-steady state compressor modelling and ideal behavior of the sensible storage tanks, the heat pump can deliver a symmetric capacity of 125 kW for FCR while maintaining correct delivery temperatures to the TES. Alternatively, the system can offer a capacity of 250 kW for aFRR and mFRR in both the upward and downward direction. These results indicate that the delivery of grid balancing services could be another revenue stream to increase the financial feasibility of Carnot battery systems and it is thus worthwhile to investigate the potential financial benefits. In future work, the sensitivity of the results to the compressor’s inertia will be validated and the dynamic model will be extended to a full dynamic Carnot battery model including detailed modelling of the TES and organic Rankine cycle, hence further investigating optimal system scheduling within the energy system.

Abstract

Simplified heat pump models are needed for design of ground heat exchangers used with ground-source heat pump systems. Design engineers commonly have only manufacturer’s data with which to construct a heat pump model that can predict heat extraction given building heating load. Earlier work has used simple polynomials to predict the ratio of heat extraction to heating. Unfortunately, manufacturers’ catalog data do not always provide sufficient support to calculate the polynomial coefficients. Therefore, in the absence of experimental data, there is a need for simplified and acceptably accurate models exploiting a limited number of operating points. This paper presents a study of available manufacturers’ data in North American and European markets. The available data vary from country-to-country, depending on the standards in use in each country. Then, a range of models are investigated, characterizing the results by the required inputs and the root mean square error. Results show acceptable accuracy of the models when compared to catalog data and allow providing recommendations on models to be used or avoided, depending on the available data.

Keywords: Ground-source heat pump: simplified models;

1. Introduction

Ground source heat pumps (GSHPs) represent a good solution to abate energy usage and reduce greenhouse gas emissions. However, the design of ground heat exchanger (GHE) fields is crucial to minimize installation costs and guarantee high efficiencies of the system for long-term operation. The heat pump selection is important to the design of ground heat exchangers because it affects heat extraction from the ground during heating operation. Conversely, the ground heat exchanger performance (specifically, fluid temperatures provided to the heat pumps) affects the heat pump performance. In the common situation where systems are designed to meet building-specific hourly heating loads, simulations are used to predict the combined performance of the GSHPs and the ground heat exchanger field to achieve a solution that provides the needed heating capacity while minimizing energy consumption and installation cost.

Besides affecting the electrical consumption of the system and related operating costs, the choice of heat pumps directly affects the size of the ground heat exchanger field. Therefore, GSHP models are needed to design the ground heat exchanger field.

Detailed models of heat pumps, e.g. those that are based on vapor compression cycle simulations, are widely described in the literature. However, for most designers, only limited heat pump data from manufacturers’ catalogs are available. The availability of data and temperature ranges for which data are provided vary from country-to-country, often depending on local standards. For example, North American manufacturers usually provide a wide range of operating points; fewer data points are presented in European catalogs and, in some cases, limited to a few specific rating conditions recommended by the standards.

\* Corresponding author. Tel.: +39-049-827-6895;
E-mail address: sara.bordignon@unipd.it.
Therefore, simpler heat pump models are needed to calculate the ground heat extraction. In contrast to detailed models, these models should depend on easy-to-obtain catalog data rather than specific measurement campaigns.

International and national standards play a key role in defining the minimum energy efficiency requirements for new heat pumps and providing manufacturers with guidelines regarding the testing conditions and the documentation to be made available to users. Standards suggest performance calculation methods and define standard rating conditions for each country or area. In many cases, the standard rating conditions suggest a minimum data set to be presented in manufacturers’ catalogs. Commonly, the performance of a heat pump is defined using the Coefficient of Performance (COP), which corresponds to the heating provided, divided by the heat pump’s electrical consumption.

ISO 13612-2 Appendix A [1] describes a method to calculate a heat pump performance matrix with a single test result. The model is based on the Carnot method for calculating the COP of the heat pump, knowing the performance at the rating conditions. The Carnot COP corresponds to the COP for an ideal inverse thermodynamic cycle at specific operating temperatures. If the value of the actual COP is known for the real heat pump working at the same operating temperatures, it is possible to define how much worse the real inverse thermodynamic cycle is compared to the ideal one, using the Carnot effectiveness \( \eta_{Carnot,\text{os}} \) (also known as 2nd law efficiency). As stated in [1], the accuracy of this model drops when the operating conditions are far from the rating point. A higher level of accuracy can be obtained using a larger number of operating points.

Some standard energy simulation programs incorporate simplified heat pump models with various levels of detail. In Energy Plus [2], two types of models for water-to-air and water-to-water heat pumps are used: equation fit models [3], [4], based on simple non-dimensional curves and parameter estimation models [5], incorporating a vapor compression cycle simulation, with parameters for internal components that require estimation.

In TRNSYS [6], the TESS [7] library contains a water-to-water heat pump model that linearly interpolates between the performance data provided in manufacturer’s catalogs, given the values of the air flow rate, fluid flow rate, and entering fluid temperature. Users who want to provide their own performance data must adhere closely to the syntax of the sample file [8].

In a previous work [9], a novel TRNSYS type was developed modeling a heat pump with a vapor compression cycle simulation that incorporated the compressor’s performance polynomials. The type is also available with a link to Refprop [10] for deriving the properties of the refrigerant. Although it is very flexible, the need for compressor polynomials might be a problem when they are unavailable from heat pump manufacturers or when the compressor brand and model are not specified in catalogs.

For GLHEPRO [12], [13], manufacturer’s data are used to fit 2nd order polynomials for the ratio of heat extraction to heat pump heating capacity and heat rejection to heat pump cooling capacity as functions of heat pump entering fluid temperature.

Similar equations used to quantify the performance of water-source heat pumps have been described in the literature. Proposed simplified models are generally based on industrial surveys and field test trials [14]-[16] used to derive the COP of ground source heat pumps.

This paper provides an overview of catalog data availability for the North American and European markets and reviews the literature on simplified and acceptably accurate models for predicting the ratios of heat extraction to heating. A range of models are tested for different data availability scenarios, and finally recommendations are made for models that can be used within ground heat exchanger design tools. The basis for most of the work is manufacturers’ catalog data.

2. Methodology

Generally, water-source heat pump catalogs provide data on heat pump performance and heating capacity, depending on the source and load side temperature levels. Once the performance of a heat pump is known, it is possible to compute the heat extraction, given building heating load, using Eq. 1.

\[
HE = HC \cdot \left(1 - \frac{1}{\text{COP}}\right)
\]
Therefore, once the building heating load is determined using building simulation software and is assumed to be met by the heat pump, simplified models for calculating the COP make the calculation of extraction extremely straightforward. This formulation neglects compressor shell losses, which are usually small (less than 5% of the heating provided [17]).

After presenting the main characteristics of water-source heat pump datasheets, some selected catalogs are used in this paper to evaluate several models for extraction calculation for GSHP design purposes. This section presents the characteristics of the utilized data and the proposed models, along with conventions for labeling the data.

2.1. Availability of manufacturers’ data

The availability of manufacturers’ data strongly affects the accuracy of models that do not rely on user-measured experimental data. As already mentioned, standards influence the documentation that manufacturers publish. However, many manufacturers provide data that goes beyond the minimal requirements, e.g., several values measured at different inlet temperatures when only a single point is required. The available data often differ from country to country, even for the same heat pump, depending on the selected market. In North America, data about the heat pump performance outside the rating conditions are often available and complete. The range of inlet water temperatures at the ground-coupled side of the heat pump is usually broad and covers temperatures that can go outside standard operating conditions. When available, manufacturers’ data of operating points outside rating conditions are more limited in Europe than in North America. Characteristics and features of ground source heat pumps can also vary in different areas: for example, in North America, water-to-air heat pumps are the most widespread, while in Europe, ground-source heat pumps are generally water-to-water.

In order to characterize the data availability for the selected water-to-water heat pumps operating in heating mode, the data sets are labeled using the following code composed of five letters and one number:

\[
\text{WNAH}f
\]

Where:

1. The first letter defines the type of heat carrier fluid at the heat pump load side, W-water;
2. The second and third letters represents the market’s area, NA-North America, NE-Northern Europe, SE-Southern Europe;
3. The fourth letter defines the heat pump mode, H-Heating;
4. A sequential number is used to identify the different investigated units;
5. The last letter clarifies if the data refer to p-partial or f-full load operation.

The symbol reported under each variable in Table 1 indicates if it can be found in the catalog, varying for the different operating conditions (“Yes”), if it is omitted (“No”), or if it is derivable (“Der”) using other information provided in the datasheet. The last row of Table 1 reports the rating heating capacity of the specific heat pump.

In Table 1, data sets of water-to-water heat pumps in heating mode can be subdivided into three main categories. The first group (“Group 1”) includes data from North American manufacturers, characterized by the wide availability of operating points and variables, given for a range of entering temperatures and flow rates. In the second group (“Group 2”), catalogs do not provide data about the source and load fluid flow rates and leaving fluid temperature (typical of Central/Northern Europe). The third group (“Group 3”) collects catalogs typical of Southern European manufacturers. In this case, generally, data are provided for a range of source and load side temperatures, considering a fixed temperature difference between the inlet and the outlet of the heat exchangers. Catalog WSEH4f, of a machine produced in South Europe, is part of Group 3. However, in this case the number of available operating points is limited to four rating points, provided for heating model only.

2.2. Proposed Models

Depending on the data availability discussed in the previous section, several models to calculate the performance of ground source heat pumps have been assessed based on the methods from the literature. First, these models have been applied to catalog data of the selected heat pump models. Afterward, based on the data availability, some models have been modified to reduce the RMSE in the COP calculation. Each model can or cannot be applied to a specific group of catalog data, depending on the data availability, as discussed in the previous section 2.1.

Once the COP is computed, the heat extraction can also be calculated using heating capacity reported in the datasheets using Eq. 1.

Table 2 summarizes the models applied to the catalogs of water-to-water heat pumps operating in heating mode. Some points can be made regarding the models:

- Models applicable to catalog data of the heat pumps produced in Northern Europe are different than the models suggested for North American and Southern Europe catalogs. The differences are because information about the source fluid flow rate and load fluid entering temperature are generally unavailable in the Northern European cases.
- Wh01 is the most complex model, as it is a function of the SFr, the SEFT, and the temperature difference between the load-side outlet and the source-side inlet and its square. The equation’s coefficients can be generated using the generalized least square (GLS) method from the catalog’s data. The generalized least squares method is used to generate the equations’ coefficients starting from the catalog data at determined reference conditions, giving the least differences between the model outputs and the catalog data. This model can be used when data for more than four operating conditions are available, due to the high number of required coefficients.
- Model wh03 uses generic coefficients given in [14]. Model wh02 uses the same equation form as wh03 but fits the coefficients using the GLS method.
- Model wh04 is the same proposed in [16], and coefficients can be computed using the GRG (Generalized Reduced Gradient) non-linear solver implemented in Microsoft Excel [18]. (The GLS method fits coefficients for linear combinations of functions, but cannot handle, for example, the multiple terms used to form an exponent in wh04).
- Equation wh05 is supposed to improve method wh04 using SEFT and LExF as inputs, instead of SExF and LEFT, as these data are generally available in all catalogs.
- Model wh06 is based on the work presented in [15], with a difference: the method consists in computing the COP starting from catalog data, while in [15], it was derived only after calculating the electrical power and heating capacity. This variation reduces the computational effort and allows the calculation in case data about the electrical consumption are unavailable.
- Model wh07 improves the wh06 by considering the whole temperature lift between the heat pump source and load sides, using the LExFT instead of the LEFT.
• Model wh08 is based on the Carnot method, but the COP is calculated differently from the standards. For the sake of simplicity and for minimizing the assumptions, it directly depends on the entering source and load side temperatures (the same is done for the Carnot COP at rating conditions), as in Eq. 2, instead of depending on the condensing and evaporating temperatures. The set temperature difference can be adjusted so that the COP does not reach remarkably high values (for example, higher than 8) for low temperature differences. In this work, the computation of the COP is calibrated using the available data sets. If only one rating condition is available, the $\Delta T_{set}$ can be set equal to 15°C and, the user can reduce or increase this value if the considered operating conditions lead to high values of COP.

$$COP_{Carnot} = \frac{\text{LEFT} + 273}{\Delta T_{set}}$$  \hspace{1cm} (2)

• For the Northern European catalogs, the LExFT replaces the LEFT in the equation, and the control on the Carnot COP is done on the SEFT: if the SEFT is higher than 13°C, it is considered equal to 13°C.

• Model wh09 is an alternative to model wh01 when data on the SEFT and the SFfr are unavailable, like in Northern European datasheets. When at least three operating points at rating conditions are available, they can be used to compute the coefficients for a model dependent on the temperature differences between the LEFT and the SEFT in North America (wh11) and the LExFT and the SEFT in Northern Europe (wh10).

The models presented in this section are evaluated using the RMSE (Eq. 3) calculated for the COP and heat extraction from the ground in heating operation. In Eq. 3, $y_i$ is the catalog value, $\bar{y}_i$ is the modeled value, and $N$ is the number data.
3. Results

The present section analyzes the performance of the models characterized by RMSE. Figures 1 and 2 show the RMSE values calculated as in Eq. 3 for each set of catalog data of water-to-water heat pumps. The RMSE is relative to the COP (Figure 1), computed by applying the models discussed in section 2.2, and to the heat extracted from the ground (Figure 2). This last value is calculated using Eq. 1, starting from the thermal load demanded by the building, and met by the heat pump at different operating conditions, according to the catalog data. If the error is higher than 15%, in the graphs, a control bar is shown in the pink area (RMSE>15%) in place of the actual value for the specific model's RMSE. In the case of non-applicable models, the RMSE value is not shown.

\[
RMSE = 100 \sqrt{\frac{1}{N} \sum_{i=1}^{N} \frac{(y_{ci} - y_{mi})^2}{y_{ci}}} 
\]

(3)

Fig. 1. RMSE for COP for the different catalogs and models.

Fig. 2. RMSE for HE for the different catalogs and models.
In general, the deviation between catalog and simulated data is higher for \( \text{COP} \) values than for the heat extraction values. For example, the application of models \( \text{wh03} \) and \( \text{wh08} \) to all selected data sets leads to an average \( \text{RMSE}_{\text{COP}} \) of 21% and 17%, respectively, but only to an \( \text{RMSE}_{\text{HE}} \) of 6% and 4%. Moreover, models \( \text{wh03} \) and \( \text{wh08} \) are likely to overestimate the \( \text{COP} \) and the HE, compared to catalog data. The application of model \( \text{wh01} \) leads to very good results when a wide range of data is available. However, model \( \text{wh01} \) leads to high \( \text{RMSE}_{\text{COP}} \) and \( \text{RMSE}_{\text{HE}} \) when the number of operation conditions provided in the manufacturer’s catalog is limited, like for the case of the WSEH4f data set.

The application of model \( \text{wh11} \) leads to an \( \text{RMSE}_{\text{COP}} \) up to 20% (WNAH1f) but results in an \( \text{RMSE}_{\text{HE}} \) of only 6%. The application of the other models to the catalog data leads to an average maximum \( \text{RMSE}_{\text{COP}} \) of 5% and an average maximum \( \text{RMSE}_{\text{HE}} \) equal to 3%.

### 4. Recommendations

This section provides recommendations for applying the proposed models based on the available quantity of manufacturers’ catalog data. In Section 2.1, the type of data available was used to divide the heat pumps into three groups. Table 3 shows the average \( \text{RMSE}_{\text{COP}} \) and \( \text{RMSE}_{\text{HE}} \) for each group of water-to-water heat pumps operating in heating mode. In the table, when a model is applicable to the catalogs, the average RMSE is highlighted with a color: (a) green if the RMSE is lower than 5% (the results of the model are good), (b) light orange if its value is between 5% and 10% (the results of the model are acceptable), (c) orange when the RMSE is higher than 10% (the model is not recommended for that set of data). When the model is not applicable to a specific group of catalogs, it is indicated with “N/A”.

Therefore, a decision-making process for choosing the most suitable model can be outlined as follows, depending on what types of catalog data are provided for the heat pump:

- If only one data point is available, the only applicable models are the ones derived from the Carnot efficiency calculation (\( \text{wh08} \)) or from an experimentally derived curve (\( \text{wh03} \)). These models, in general, lead to higher \( \text{RMSE}_{\text{COP}} \) but more than acceptable \( \text{RMSE}_{\text{HE}} \).
- If only rating conditions (three or four operating points) are available, models \( \text{wh10}, \text{wh11} \) can be used. However, model \( \text{wh08} \) can also be a good option.
- If more than four operating points are available in the catalog data, the corresponding group from Table 1 can be identified by comparing the data available for the type of heat pump and operation mode to the data available for each group in Tables 1. With the group identified, Table 3 can be used to identify the best choices – that is the model or models with the lowest \( \text{RMSE}_{\text{HE}} \). A secondary consideration may be the model performance in predicting \( \text{COP} \), also summarized in Table 3. Taking first the model performance in predicting HE, and secondarily, the model performance in predicting \( \text{COP} \), a final recommendation is made for each group in Tables 3. A “x” is used to identify the recommended model or models.

* \( \text{model wh01 is considered not-applicable to catalog WSEH4f, where only four operating points are provided.} \)

The results of the models are strongly affected by the accuracy and the level of detail of the manufacturer’s catalog data: if the accuracy is high, the agreement between the models’ results and field measurements will also be high. Moreover, the accuracy of the models improves if the catalog contains detailed information about the operation of the heat pump, for example, correction factors for different temperature differences at the load
and source sides, or for the use of a mixture of water and glycol, or, in general, if it includes a relevant number of operating points.

Although the primary objective of these models is to derive the heat extraction from the ground, they might also be used to compute the COP of the heat pump. As already pointed out, the COP results are more accurate when the catalog data are numerous and precise.

5. Conclusions

This paper addresses a problem encountered when designing ground heat exchangers that are used with ground-source heat pump systems. Engineers designing the system typically only have catalog data for the heat pumps and the data provided vary with manufacturer and location. This paper focuses on simple models that can be used to determine the GSHP heat extraction required to meet building loads.

A review of available manufacturers’ catalog data for water-to-water heat pumps in North American and European markets is presented, and catalog data are categorized by data availability. A range of models are investigated; their accuracy is evaluated by their ability to reproduce the catalog data and recommendations on which model to use are provided. The recommended models give acceptable accuracy in the calculation of the heat extraction, with no more than 3% RMSE when compared to catalog data. Nevertheless, the model accuracy depends on the range and quantity of catalog data.

The recommended models presented in this paper are suitable for single-speed water-to-water heat pumps in heating mode and quasi-steady operation. Further work is in progress to address water-to-air heat pumps and cooling mode. Additional research is needed to treat multi-stage and variable-speed heat pumps.

The investigation presented here is limited by its use of catalog data, which is based on steady-state operation and, in many cases, by proprietary models developed by the manufacturer. Comparisons against field measurements are in progress. However, additional comparisons to field measurements would be welcome.

Abstract

The energy efficiency improvement potential in industrial buildings is often significant, considering all unutilized waste heat flows. Cost efficient and innovative renovation concepts are needed for a good balance between cost savings and investment costs including energy grants for new energy systems. The paper presents a case study, motivated by financial savings and CO\textsubscript{2} emission reductions for an industrial building in Finland based on realized costs and measured energy consumption. The building belongs to a company with multiple industrial facilities in Finland and around the world and the company fulfils its energy program Mission to Zero, significantly reducing the carbon footprint of its buildings. The energy renovation concept studied in this study relies on a novel heat pump-based energy recycling system utilizing boreholes for thermal storage and free cooling. Sources for energy recycling are the cooling and pressurized air systems serving the production line. The long-term renovation plan is included to improve the overall cost efficiency. The energy concept is compared to the initial situation and a conventional ground source heat pump system utilizing free cooling from the boreholes. The measurements indicate that the performance, (SCOP 3.3) and heating energy covered by the heat pump system (about 97%), has been better than expected based on the energy calculations.

Keywords: ground source heat pump; energy recycling; hybrid heat pump system;

1. Introduction

The demand for energy efficiency measures in energy intensive industrial buildings is rising to cope with the rising energy prices and to meet the ambitious goals of leading companies to cut down the CO\textsubscript{2} emissions. A key issue is to find the most efficient measures to reach the goals with a decent price tag. However, some measures might even be free of charge such as set-point adjustments, which are important to trace before any major energy renovations are planned. Utilization of waste heat flows is on the contrary not free of charge but extensive utilization of waste heat flows in a heat pump-based energy recycling system will most likely pay itself back in 5 to 8 years depending on the system design. For the customer paying the investment, it is also important that the energy system will receive the maximum amount of government grants to produce a decent payback time. For example, in Finland 20\% lower investment costs can be achieved if energy system design fully complies with the grant requirements.

The ABB Group is an example of a leading industrial company that strives to significantly reduce its carbon footprint through its own energy efficiency program Mission to Zero. The investigated industrial building in this study, ABB assembly parts, is located near the Gulf of Finland in the city of Porvoo approximately 50 km from the Helsinki capital. It is characterized by both high heating and cooling demand, making it ideal for a heat pump-based energy recycling system. Firstly, to live up with the expectations, the objective was to design a cost-efficient hybrid heat pump system utilizing all feasible heat sources. Secondly, a high heating energy coverage rate (at least 95\%) by the heat pump system should be reached.

The investigated heat pump system in this paper, designed by the Granlund company, has been operational and monitored since November 2021. The objective of the presented study was to compare the installed hybrid heat pump system to a conventional ground source heat pump system utilizing free cooling as concerns the energy performance of the system and financial viability.

Energy recycling systems coupled with boreholes have been studied in the Nordic climate and a key dimensioning parameter is the relation between extracted heat from the ground and heat loaded into the ground and how it affects the average COP (Coefficient of Performance) in the long run [1]. For a pure ground source heat pump system, a conventional COP value to be used in energy calculations is 3.0 for a building in the cold climate (Nordic countries) and 3.6 in an average climate [2].

2. Methods

2.1. The investigated industrial building

The present study was made for an industrial building located in southern Finland as a part of an energy efficiency project carried out by Granlund Oy. The industrial building in question has high cooling demand all year round due to cooling intensive manufacturing process. The manufacturing line is operating from Monday to Friday implying that energy recycling from the cooling process is not available during the weekend. Another source for energy recycling in the building is heat from the pressurized air compressor also used from Monday to Friday. The original compressor (nominal motor power 75 kW) was air cooled but as a part of the energy efficiency project it was replaced with a liquid cooled version (nominal motor power 90 kW) suitable for the energy recycling system.

Heating consumption in the investigated building is mostly space and ventilation heating divided between the office and manufacturing parts of the building. The warehouse itself is energy intensive in terms of heating as the ventilation system and the circulation air heaters consume the most part of heating in the manufacturing area. Volume flow rates and heat recovery used in the ventilation system are 3 m³/s in the office region (plate heat exchanger for heat recovery) and approximately 12 m³/s in the manufacturing area (glycol-based heat recovery). The building is connected to the local district heating system and initial heating consumption before the heat pump project was approximately 960 MWh in 2019. Cooling is managed through two chiller units utilizing free cooling, one for the office area and the second for the manufacturing area. The cooling demand for the manufacturing part was estimated to be 840 MWh.

2.2. Description of the installed energy recycling system with boreholes

The installed heat pump system is a hybrid heat pump system consisting of energy recycling and boreholes. Boreholes are primarily used to support the energy recycling system especially during weekends when no recycling potential is available and to store unused heat from the energy recycling system into the ground. The borehole field is primarily charged during the summer months providing free cooling to the process cooling network. Free cooling is limited by the ground temperature and the cooling system temperature levels 8 / 13 °C, thus leading to a maximum brine temperature of 9 - 10 °C. However, the brine temperature supplied to the ground may increase even higher during the summer when the boreholes are charged with heat from the pressurized air compressors. A schematic drawing of the hybrid heat pump system is presented in Fig. 1.

![Fig. 1. Schematic drawing of the hybrid heat pump system.](image-url)
Altogether three on-off controlled heat pump units are used in the heat pump system with a total heating capacity of about 330 kW. Buffer tanks were included in the heat pump system on the condenser side, 2 m³ for space and ventilation heating and 2 m³ for domestic hot water heating. On the evaporator side, the buffer tank was left out because the energy recycling potential was known to be almost constant during the workdays. Dimensioning parameters of the heat pump system are shown in Table 1.

</tr>
</tbody>
</table>

*) The actual heating curve in the building automation system was higher at 0 °C, approximately 52 °C.

The chosen heat pumps are on-off controlled with two compressors per heat pump, altogether 6 compressors in the whole system. All heat pumps take advantage of superheating of the refrigerant R410A to produce small fractions of domestic hot water at a high COP value. Domestic hot water is produced separately with one of the heat pumps particularly during the summer months. The borehole field, 18 x 250 meters, was sized based on the heating capacity requirements especially during the weekends when no energy recycling is available. Despite of heating capacity-based dimensioning of the borehole field, temperature is still very stable from year to year due to balanced extraction and loading of the boreholes.

Compared to a conventional heat pump system utilizing geothermal energy, the most significant difference is energy recycling from the pressurized air compressors and loading of unused heat in the ground to stabilize the temperature profile in the borehole field. Energy recycling from the cooling networks and free cooling from the ground can be seen as the conventional approach in the Nordic countries. The existing chiller is used as backup whenever the heat pumps are not able to recycle heat from the cooling network to the heating networks or when the free cooling capacity from the ground is insufficient.

2.3. Simulation model for the hybrid heat pump system

The energy system simulations were performed with the energy simulation tool IDA ICE 4.8.2 (Indoor Climate and Energy) in combination with its ESBO plant interface (Early Stage Building Optimization) for simulation of energy systems. IDA ICE is especially used in the Nordic countries for building energy simulation purposes and it is extensively validated in previous studies [3-7]. In this work the original ESBO plant model for energy system simulations has been reworked to match more closely the real heat pump system. Moreover, the original heat pump model has been replaced by a parametric heat pump model working accurately based on performance data given for a specific heat pump model at all possible operation points as also parametrized in [1]. Measurement data from the heat pump manufacturer Gebwell (heating capacity and COP at different operation points) was used in the simulation model describing the Taurus EVI 110 heat pump. Despite of the real on-off controlled compressors in the heat pump, the part load behaviour of the heat pump
was modelled in line with the standard EN 14825 degradation coefficient $C_c$ [8], with a given value of $C_c = 0.97$. The same modelling approach is also used in the original heat pump model included in IDA ICE.

It has been shown that the original heat pump model in IDA ICE can be used quite accurately within an error of $\pm 1\%$ in energy system simulations if the heat pump is calibrated using 7 calibration parameters against measured data [9].

An overview of the customized energy system interface in IDA ICE is shown in Fig. 2 and the most important components of the model are numbered and explained below. Calculation of supplied and extracted heat to and from the energy model is done in dedicated macros, but in this context the details of the model are not discussed.

![Customized energy system interface](image)

**Fig. 2.** The customized energy system interface in IDA ICE for energy system simulations.

**Numbering and explanations referring to Fig. 2:**

1. Space and ventilation heating systems in the building. Set points for the supply and return water temperature are given according to the heating control curves (7) and the measured heating power is used as input data.
2. Heat recovery from the pressurized air compressors including temperature control on the primary and secondary sides of the heat exchanger (brine / water). The measured heating power data of the compressors is used as input data.
3. Cooling network connected to the brine side with a heat exchanger including temperature controls. The measured and partly estimated cooling heating power data is used as input data.
4. Borehole field and its temperature control.
5. Consumption of domestic hot water. The estimated domestic hot water profile is used as input data.
6. Additional heating (district heating) supplied to the domestic hot water network if necessary.
7. Supply and return water set point curves as a function of the outdoor air temperature. The maximum supply water temperature is 66 °C at the outdoor air temperature of -28 °C.
8. Parametric heat pump model and a snapshot of it showing its pipe connections. On the condenser side there are pipe connections for space heating and for super-heating supplied to the DHW tank. One of the three heat pumps is working in alternating mode (space heating / DHW heating) and therefore four hot pipes are connected to the DHW tank in the simulation model.
9. Additional heating (district heating) supplied to the space heating network if necessary.
Exemplified profiles for estimating the energy recycling potential are shown in Fig. 3 for cooling as well as for the pressurized air networks. The profiles were determined from the building automation system before the beginning of the heat pump project. Both energy recycling profiles are almost constant during workdays Monday to Friday. Heat recovery potential from the pressurized air compressors is 50 – 70 kW and heat to be recovered from the cooling network 100 – 140 kW. The energy simulations were performed based on measurement data from the original air-cooled compressors (motor power 75 kW), although it was known that the recoverable power from the new water-cooled versions (Atlas Copco GA90, motor power 90 kW) would be somewhat higher than before. The manufacturing line is closed from Friday evening to Monday morning, implying that the system works as a pure ground source heat pump system during weekends.

Duration curves of the heating demand and energy recycling potential throughout the year are shown in Fig. 4. The duration curves for the heating demand are presented both without the ventilation adjustments (initial situation in the project planning phase) and with the adjustments to show the final situation.

![Energy recycling profiles for one week during the heating season.](image1)

![Duration curves of the heating demand and energy recycling potential throughout the year.](image2)

The temperature profile in the borehole field was investigated in the GLHEPRO simulation software using the simulated heat extraction and loading profiles from the single year IDA ICE simulation. GLHEPRO is developed at the Oklahoma State University, and it has been validated against measured data from working ground heat exchangers [10] and compared with the ASHRAE Handbook method [11]. The GLHEPRO
simulations performed on a monthly level and for a period of 40 years will show if the dimensioning of the borehole field is sufficient.

3. Case study

3.1. Simulation of the installed heat the pump system and comparison to a conventional ground source heat pump system

The installed hybrid heat pump system was investigated using the energy system interface in IDA ICE described earlier. Attention was especially paid to the heat extraction and loading pattern of the borehole field and that all available heat is either recycled or stored in the ground. The target was to achieve a high heating energy coverage rate using the heat pump system, at least 95% in accordance with the ABB’s energy program “Mission to Zero”. Hourly simulation results shown in this paper are calculated based on the measured district heating consumption from 2019 without any ventilation adjustments to represent the initial situation at the project planning phase. The heat extraction and loading rates (kW) of the borehole field are presented in Fig. 5 for the installed system and for the conventional ground source heat pump system with free cooling.

Simulation results for the installed hybrid heat pump system show, that heat is mostly extracted from the borehole field during the weekends and heat is stored in the ground almost during the whole year with emphasis on the summer months. The peak heat extraction from the boreholes is about 38 W/m and loading 9 – 13 W/m depending on the ground temperature. The amount of heat stored in the ground is primarily limited by the temperature level of the liquid in the cooling network, but slightly more heat can still be stored in the ground from the pressurized air compressors if the free cooling mode is not available due to a high brine temperature. The rest of the cooling demand in the manufacturing area, which cannot be produced through energy recycling or by utilizing free cooling from the ground is covered by the existing chiller either as free or mechanical cooling.

An overview of the utilization of the installed hybrid heat pump system compared to the conventional ground source heat pump system with free cooling is presented in Table 2. The results are focusing on the energy balance of the borehole field and on the amount of free cooling available.

The energy simulations indicate that extensive loading of the ground comes at a price when it comes to the utilization of free cooling from the ground. Hence, 139 MWh less cooling energy (17% of the cooling demand) is utilized either through energy recycling or through free cooling from the ground. Considering possible free cooling with the existing chiller, the amount of compressor cooling is increased by 86 MWh (10% of the cooling demand). Altogether 103 MWh of more heat is still utilized in the installed energy system either through energy recycling or by loading the borehole field. From the numbers it can be observed that the
borehole field is almost fully charged bearing in mind the liquid temperatures in the cooling network (8 / 13 °C) and that all available heat from the pressurized air compressors is used in the energy system.

</tbody>
</table>

Monthly averaged liquid temperatures in the borehole field are compared in Fig. 6, for an anticipated life span of 40 years (480 months). The results shown with a thick blue line belong to the installed system and the results shown with a thin green line represent the conventional ground source heat pump system with free cooling. The number of boreholes is identical 18 x 250 m in both energy systems because dimensioning of the borehole field was made based on the required heat extraction rate (kW) and secondly to enable an adequate brine flow rate (dm$^3$/s) on the evaporator side of the heat pumps. Dimensioning parameters of the borehole field are as follows: Heat conductivity of the ground 3.1 W/mK, undisturbed ground temperature 7.5 °C, collector pipe diameter DN45, borehole thermal resistance 0.12 K/(W/m) and distance between the boreholes 20 meters. Thermal response tests for the ground were not made during the project, implying that the parameters used in the calculation are commonly used in ground source heat pump applications.

According to the simulation results, the monthly averaged temperatures in the borehole field fluctuate between 4 – 9 °C during the whole investigation period of 40 years. The temperature level in the conventional system is on the other hand constantly decreasing with same borehole dimensioning but it is still on the safe side regarding freezing. Without heat recovery from the air compressors, a constantly fluctuating temperature profile can be reached with free cooling only, but according to the simulations the energy system would need 8 – 10 additional boreholes (depth 250 m) to reach that level.

The simulated seasonal coefficient of performance (SCOP) for the installed heat pump system is 3.19 and as seen from the monthly average liquid temperatures shown in Fig. 6, the SCOP will not decrease during the
lifecycle of the heat pump system. During the heating season the COP value fluctuates between about 3.5 during workdays and close to 3 during weekends when no energy recycling is available. The corresponding simulated SCOP for the conventional heat pump system with free cooling is 3.08 during the first year of operation and 3.04 on average.

3.2. Energy monitoring of the installed heat pump system

The installed heat pump system has been operational since November 2021 and its performance is monitored through a new building automation system interface provided by Schneider Electric. Key temperatures, status information of control valves as well as capacity data in the heat pump system are monitored at a time interval of 10 minutes. Measurements indicate that the building has consumed only 28 MWh of district heating since November 2021 and all additional heating took place in December 2021 and January 2022, approximately 80% in December and 20% in January. Compared to preliminary simulations performed in 2020, district heating consumption should have been approximately 34 MWh during the whole year when calculated with the measured district heating consumption data from 2019. During the year 2019 the amount of degree days (S17 degree day method) was 3419 in the Helsinki region and in 2021 correspondingly 3831. That is to say, the heating demand should be approximately 12% higher with the 2019 weather data compared to the year 2021. The before mentioned heating degree days are maintained by the Finnish Meteorological Institute [12].

An explanation to lower district heating consumption is that a schedule-based ventilation strategy has been deployed in the manufacturing spaces since mid-December 2021. A ventilation schedule with 100% air flow rate is used at workdays from 7 – 20 and a lower air flow rate of 67% of the nominal flow rate has been introduced to lower heating consumption at periods of absence. The operational hours of the ventilation unit serving the office region were also readjusted to further lower heating consumption. The adjustments to the ventilation system were proposed as a part of the energy efficiency project, leading to a 17% smaller heating energy consumption compared to measured consumption data from 2019. The total district heating consumption should have been higher if the ventilation system had operated as initially simulated, considering the ventilation adjustments at the end of 2021 and that 80% of the district heating was consumed during 2021. Measured consumption data from 2021 and the corresponding calculated data using district heating consumption from 2019 are compared in Table 3. DH in Table 3 stands for district heating.

Energy simulations comparing the installed and the conventional heat pump system with free cooling indicate that there is only a minor difference of about 9 MWh in the district heating consumption in favour of the installed heat pump system (34 MWh compared to 43 MWh).
3.3. Analysis of life cycle costs and reductions of CO₂ emissions

The life cycle costs, and payback time of the hybrid heat pump system were investigated with a typical life span of 20 years including yearly maintenance costs and compressor renewals after 15 years of operation. All presented life cycle costs are proportioned to the initial state of the building: all heating energy is purchased from the district heating network and chillers with free cooling produce the cooling energy. Energy tariffs used in the calculation were gathered in November 2022, tariffs for district heating (energy tariff €/MWh and capacity fee €/kW) and the transfer fees for electricity (consumption related tariff €/MWh and power related fee €/kW). Especially the year 2022 has shown, that the electricity price has heavily fluctuated in Europe and the future is therefore difficult to predict. Due to the before mentioned uncertainties, the life cycle cost calculations were made based on two assumptions: 1. Energy tariff for electricity is 55 €/MWh without tax (assumption that the price will be stabilized to the same level as before the energy crisis in Europe) 2. Energy tariff for electricity is 80 €/MWh without tax (assumption that the price will not return to the same level during the upcoming decades). Hence, the total tariff in the first scenario is 84.7 €/MWh including the transfer fee, tax, and the energy tariff and 109.7 €/MWh respectively in the second scenario. An additional power fee of 2.4 €/kW/month is charged for the electrical power peak consumed every month. The district heating tariff is 68.2 €/MWh and the capacity fee is determined by $2604.26 + Q \times 13.31$ €/kW, where Q stands for the peak capacity during one year. The CO₂ reduction potential of the installed heat pump system was determined using averaged emission factors for a district heating network and electricity generation in Finland. Emission factors used in the calculation are 177 kg CO₂/MWh for district heating and 89 kg CO₂/MWh for electricity production [13].

Life cycle cost savings, investment costs, payback time and reduction of CO₂ emissions compared to the initial state are presented in Table 4 using the electricity tariff 55 €/MWh. The calculation results are shown both for the installed heat pump system and the alternative conventional heat pump system with free cooling.

<tr>
<td>Reduction of CO₂ emissions</td>
<td>148.5 ton CO₂/year</td>
<td>148.5 ton CO₂/year</td>
</tr>
</tbody>
</table>

*¹ The electricity consumption of the installed heat pump system is 280 MWh/year and electricity consumed by the chillers 155 MWh.
*² The electricity consumption of the installed heat pump system is 292 MWh/year and electricity consumed by the chillers 126 MWh. The initial level electricity consumption of the chillers is 269 MWh without any heat pump system.

A higher electricity tariff of 109.7 €/MWh (scenario 2) compared to 55 €/MWh would increase the payback time by 0.6 years and reduce the life cycle cost savings by 75 k€ with energy grants (-20% of the investment cost).

4. Discussion

The investigated hybrid heat pump system in the industrial building owned by the ABB Group in Finland has been operational since November 2021 and monitoring of the system indicates that the performance has exceeded the expectations. The most obvious explanation for better performance compared to the energy
calculations shown in this paper is the ventilation adjustments in the manufacturing area lowering net heating energy consumption during off hours. The adjustments to the ventilation system were proposed as a part of the energy efficiency project but the heat pump system itself was dimensioned based on the original consumption profile of the building. A dimensioning approach on the safe side was chosen because it was unclear if the proposed changes would be implemented due to high quality requirements of contaminant removal from the air. Secondly, the safe side dimensioning approach was motivated by the fact that the operation line at the industrial building will most likely be active also during the weekends in the future. The extended operation time would noticeably increase the net heating consumption of the building, but then again also the energy recycling potential would increase leading to a better overall system performance. In the present situation the COP of the heat pump system is approximately 3.5 during workdays and close to 3 during weekends during the coldest winter months. With the extended operational hours in the future, the seasonal COP value (SCOP) would consequently be over 3.5 when the current value is 3.3.

Compared to a conventional heat pump system with free cooling from the boreholes, the current situation reveals that the installed system is slightly over dimensioned proportioned to the net heating demand of the building. That is, the life cycle savings are even slightly higher in the conventional approach and same borehole dimensioning is applicable in both cases. From the design viewpoint, the pressurized air compressors would anyway have been replaced soon in the alternative approach by adding a separate liquid cooler on the roof of the building transferring waste heat into the outdoor air. Waste heat transfer into the outdoor air was, on the other hand, not in line with the ABB Group energy program Mission to Zero and secondly it was not a future proof solution bearing in mind the extended operational hours of the manufacturing line in the future. Hence, the conventional heat pump system (alternative approach) would have required more boreholes with a future proof dimensioning to cope with the increased heating demand, which then again would have influenced the profitability of the energy system negatively. The installed heat pump system can be seen as an encouraging example for other hybrid heat pump systems to be used within the ABB Group. In other industrial buildings a pure energy recycling system without boreholes might for instance be the only option due to strict ground water requirements in the area and in these cases an energy recycling system with a solid performance is the most valuable solution. For the investigated building ABB assembly parts in Finland, the use of a pure energy recycling system would have led to a decent heating energy coverage ratio of 63%.

The energy system simulation model in IDA ICE turned out to produce reasonable results compared to the measurements. The greatest uncertainties in the modelling relate to the borehole field, the properties of the ground and the amount of heat loaded into the borehole field by the new liquid cooled air compressors. Thermal response tests for the ground were not carried out during the project because the dimensioning on the energy system was known to be well on the safe side. The energy simulation of the borehole field was, on the contrary, made with conservative input parameters and the heat load of the air compressor was estimated based on measured data from the smaller old compressor (old compressor 75 kW and new compressor 90 kW). From this point of view, it was known that energy modelling would not overestimate the energy performance. The most significant uncertainties in heat pump modelling itself were found in the part load behaviour of the on-off controlled heat pumps at small loads and the effect on the average COP value.

5. Conclusions

The hybrid heat pump system investigated in this study was a part of the energy efficiency project carried out by the Granlund company to significantly improve the energy performance of an industrial building owned by the ABB Group in Finland. An incentive to the chosen design approach came from the ABB Group, aiming to significantly reduce the carbon footprint of its buildings in line with the energy program Mission to Zero. Monitoring of the installed heat pump system has revealed that the industrial building has been almost self-sufficient after the proposed adjustments to the ventilation system were made to lower the net heating consumption of the building. In fact, the hybrid heat pump system is for the present use of the building slightly over dimensioned and economically not the most feasible alternative compared to a conventional ground source heat pump system with free cooling. The system was on the contrary dimensioned for the future usage of the building when the manufacturing line is used every day instead of the present usage pattern from Monday to Friday. Hence, extensive energy recycling will pay itself well back in the future compared to a conventional heat pump system requiring more boreholes to cope with the increased heating demand.

The current design approach emphasises a good collaboration with the end user, understanding the current situation and future evolution. A key premise to success is to consider the long-term investment plan and include additional useful investments into the project, improving the overall cost efficiency of the project and making use of the energy grants for investments promoting the use of new energy technology. In this case the
existing air compressor was at the end of its life cycle, meaning that it should have been replaced anyway soon. The integration of the compressor to the energy system for energy recycling and loading the borehole field was a key measure in this project improving long-term energy efficiency of the heat pump system. A lesson learned was the importance of reducing unnecessary heating in the building, in this case unnecessary ventilation during off hours and dimensioning the heat pump system based on new heating consumption. The investigated heat pump system was dimensioned on the safe side based on the higher heating demand and by considering the future needs. Hence, the energy system could have been optimized slightly further and made somewhat cheaper but as a conclusion, it matches or even exceeds the expectations of the Abb’s own energy program Mission to Zero. The energy recycling approach investigated in this study is applicable to all kinds of buildings, either as a pure energy recycling system or coupled with boreholes for additional heat extraction and buffering of waste heat into the ground. The system is also scalable in terms of heat pump capacity and the energy recycling sources and dimensioning of the system is tailored to match the consumptions profiles of a specific building. The payback time of the investigated system is without energy grants approximately 9 years and with the energy grants in Finland (~20% of the investment cost) approximately 7 years. The energy performance of the energy recycling system could be optimized further based on the readings from the building automation system. With the present setpoints the supply water heating curve has been too high at warmer air temperatures, especially at 0 – 5 °C, over 50 °C. The temperature setpoint should according to the design parameters be more than 5 °C lower, implying that the seasonal COP (SCOP) could be close to 3.5 instead of the measured 3.3.

From the energy modelling point of view, the most important need for future research is to validate the energy system model used in the calculations especially at part loads but also on system level considering the operation of buffer tanks and mixing valves. The existing heat pump calculation models are generalized, and they are not related to a particular heat pump type, in this case to the on-off behaviour of the compressors.

Acknowledgements

The study presented in this conference paper was carried out as an individual research project as an extension to the project work performed at Granlund Oy. The authors would like to thank especially ABB in Finland for the research opportunity and for providing measurement and investment cost data for the project.

Enabling Electrification of Domestic Hot Water and Space Conditioning with Multi-function Heat Pumps

Subhrajit Chakraborty, Stephen Chally, Timothy Levering

Abstract

Heat Pumps, although imperative to eliminate building onsite emissions, are required to be both energy efficient and capable of retrofitting in existing homes. In this study, we focus on Multi-function Heat Pump (MFHP) system, that uses one outdoor unit to provide both domestic hot water (DHW) along with space cooling and heating. An air-to-air MFHP, demonstrated in this study, reduces barriers to home electrification by avoiding electric resistance and lowering peak demand. The MFHP system is retrofitted in a 2000 sq-ft residential home to evaluate ease of installation, reliability, energy efficiency, and thermal comfort in terms of the space and water temperatures. Performance metrics of the MFHP are monitored over the summer in various modes and reported in this study. Coefficient of Performance (COP) of the AC mode was observed to be about 2.8 for an outdoor dry bulb of 35°C and COP of the water heating mode was observed to be about 2.3 for an outdoor dry bulb of 19.7°C. MFHP system provides a unique opportunity to move the heat from space into the DHW tank while operating in a simultaneous space cooling and hot water heating mode. The simultaneous mode performed 36% better than individual two modes if operated separately. The study demonstrates energy savings potential with MFHP while adequately meeting multiple loads in residential buildings without electric resistance heating. Refrigerant charge optimization and advanced controls to increase the run-time of the simultaneous AC and DHW mode are the next steps to improve the air-to-air MFHP system.

Keywords: Heat Pump; Domestic Hot Water, Electrification, Residential Building

1. Introduction

Residential buildings generate about 20% of the United States (US) energy-related greenhouse gas (GHG) emissions mainly from heating, cooling and hot water heating [1]. The main source of residential onsite emissions is from burning fossil fuels (mainly natural gas) for space and water heating which contributes about 323 million metric tons of GHG yearly [2]. Thus, residential heat pumps (HP) for domestic hot water (DHW) and space conditioning along with a clean electricity grid is the future of the decarbonized world. It is observed that even for the current predictions of the electricity grid, installation of heat pumps to replace natural gas furnaces for residential space heating leads to an average of 45% GHG emission reduction across the US over the lifetime of the equipment [3]. Electrifying existing space and water heating with heat pumps is a critical step in building decarbonization and poses a big challenge with electrical service upgrades. Requirements for home electrical service upgrades add cost and installation delays for retrofit customers who are considering HP for space conditioning and or hot water heating [4]. Around half of all homes are expected to need electrical service panel upgrades that cause system installation delays to fully electrify [5]. Furthermore, heat pump water heaters (HPWH) come with space constraints for closet installations and require air supply for the evaporator coil.
Multi-Function Heat Pumps (MFHP) use one efficient compressor and outdoor heat exchanger coil to provide space cooling, space heating, and domestic hot water heating. Air-to-air MFHP systems (shown in Figure 1) use refrigerant to provide end-use heating and cooling services and have the potential to be easily retrofitted in ducted central air-conditioned (AC) homes and eliminate the need for electric resistance backup heaters. Eliminating electric resistance backup heaters can greatly reduce the maximum power requirements and eliminate the need for electrical service upgrades, which is one of the major barriers to electrification. The DHW tank of the MFHP obviates the need for exhaust connections, inlet air flow, or electrical power and has a smaller footprint. Uniquely, air-to-air MFHP systems can also operate in a simultaneous space cooling and DHW heating mode, which utilizes the heat from space cooling to heat DHW. The simultaneous AC-DHW mode usually has higher efficiency and can meet both space cooling and water heating loads flexibly [6].

![Figure 1 Air-to-air MSHP using refrigerant to provide end-use heating and cooling](image)

Previous studies have focused on heat pumps utilizing carbon-dioxide (CO₂) as a refrigerant that can provide high temperature water for both space and water heating [7], [8]. However, these systems did not provide cooling to the household during hot summer months which is a requirement in most climate zones [9]. Heat pumps are best known for their ability to switch between cooling and heating, which is an opportunity to reduce equipment redundancies. Integrated heat pump systems have been available in Europe and a relevant testing standard was made available by International Energy Agency (IEA) through Annex 28 [10]. Although the testing procedure developed by IEA encompassed a multi-function heat pump, the scope was limited to space heating, DHW and ventilation. There has been a lack of understanding of MSHPs in space cooling (AC) with DHW mode and its overall potential to save costs and energy for the typical single-family house in the US. This study attempts to fill that gap by evaluating an air-to-air MSHP in a 2000 sq-ft household in Davis, California. Results from the study about the ease of retrofit installation, performance of the MSHP during summer, and ability of the MSHP to meet space comfort and DHW requirements are presented in this paper. Insights gained from this study will pave the path for further research in MSHP systems for easy electrification while saving energy and costs for existing residential buildings in the US.

2. Site and Installation

MSHP system uses an off-the-shelf standard split system heat pump outdoor unit with refrigerant line set serving an indoor direct expansion (DX) air handler and adds a second refrigerant line set serving a DHW tank (Figure 1). The custom made DHW tank consists of both refrigerant-to-water and water-to-water heat exchangers. City water supply flows separately through the water-to-water heat exchanger and exchanges heat with the thermal storage water from the tank. With this innovative design the DHW tank stays at ambient pressure and does not need to be certified as a pressure vessel with a relief valve. This MFHP product has been certified for capacity and efficiency for water heating by third party tests at Intertek.

As seen in Figure 2, the site before retrofit consisted of a 12.3kW (3.5 ref ton) AC, a 29.3kW (100 MBH/hr) natural gas furnace with a blower, and a 189-liter (50 gallon) tank with natural gas boiler of 11.7 kW (40
MBH/hr) capacity. The house electrical panel was limited to maximum 100 amp with the line to the utility transformer limited to maximum 125 amp. An electrification of the space and water heating would be replacing the AC with HP but would require strip heaters in the 220V air-handler requiring additional 30 amp. Additionally, a unitary hybrid HPWH installation in the closet would require 30 amp more in the electrical panel. This was avoided by electrifying the space conditioning and water heating with an air-to-air MFHP.

The retrofitted air-to-air MFHP consisted of a 14 kW (4 ref ton) cooling capacity outdoor unit (16 SEER) connected to an air-handler in the attic, which circulates 2480 m3/hr (1460 CFM) of air through the house. The innovative refrigerant to water tank was placed in the same closet as the pre-retrofit natural gas DHW tank and did not need any additional air flow paths. Refrigerant (R410A) line sets were connected from the outdoor unit to the AHU and the DHW tank with proper temperature and sound insulation. The main control board of the MFHP is connected to the water tank thermostat and space conditioning thermostat. The main control board decides the mode of the MFHP based on the heating and cooling calls from each thermostat. For the summer monitoring period, the MFHP operated in three modes Space cooling (AC), DHW heating mode, and concurrent AC and DHW heating mode.
3. Methodology

3.1. Instrumentation

To determine the overall performance of the MFHP system, the system was monitored using Frontier Energy’s proprietary data logger. The following were instrumented and logged at 5-second intervals using the data logger:

- Detailed DHW monitoring: An Onicon ultrasonic BTU meter collected temperature, flow, and delivered energy between the hot water storage tank and the heat pump outdoor unit. Three Omega PR-10L RTDs were used to measure water temperature stratification within the DHW tank.

- Detailed HVAC system monitoring: Three ICP M-7059D modules were installed between the inputs and outputs of the MSHP controller to monitor every time the controller activates a new setting, i.e. dehumidification, cooling, heating, heat recycling, etc. Nine thermocouples were installed inside the primary supply duct leaving the supply plenum to create a 3x3 sensor averaging temperature grid to measure supply temperature. A Vaisala HMD62 was installed in the return plenum, and another in the supply plenum to measure temperature and relative humidity. A Wattnode WND-WR-MB1 True-RMS energy meter was installed on both the air handler and the outdoor unit to measure power. Five Omega PR-10L RTDs were mounted around the outdoor unit to monitor the airflow temperature entering and leaving the outdoor unit refrigerant coil.

- Weather monitoring: A Vaisala HMS110 humidity and temperature sensor was mounted outside to collect the local weather data.

In addition to the detailed DHW, HVAC, and weather monitoring, the indoor conditions of the home were monitored using an ecobee thermostat with five remote temperature sensors which provided the following data points in 5-minute intervals:

- Thermostat setpoint
- System mode
- Component operation time
- Current temperature
- Relative humidity at the ecobee
- Occupancy

The specifications for all sensors used are presented in Table 1 and Table 2.
The installation locations of the sensors and monitoring equipment are shown in Figure 4. The data logger was installed with the cell modem, in a lockable NEMA enclosure. Other equipment, such as remote sending units, were installed behind hatches or other removable coverings. The Ecobee thermostat is part of the HVAC system and property of the homeowner.
3.2. Data Analysis

3.2.1. DHW Performance

Detailed domestic hot water (DHW) system data was analyzed to calculate operating efficiencies. The BTU meters performed the necessary calculations for the amount of energy of the water delivered from the hot water tank. The standard heat balance equation follows:

\[ Q_{\text{Water}} = c_{p_{\text{water}}} \rho_{\text{water}} \dot{V}_{\text{water}} \Delta T \]  

(1)

The capacity measured from the BTU meter only accounted for the DHW energy leaving the tank as water was used throughout the home. To determine the capacity delivered to the tank during a water heating cycle, the following equation was used:

\[ Q_{\text{TES}} = m_{\text{TES}} c_{p_{\text{water}}} \frac{\Delta T_{\text{avg,Tank}}}{\Delta t} \]  

(2)

To determine the total capacity during a water heating cycle, the sum of the heat delivered to and leaving the tank was taken shown in the following equation:

\[ Q_{\text{DHW}} = Q_{\text{TES}} + Q_{\text{Water}} \]  

(3)

3.2.2. Heat Pump Performance

The output cooling capacity was calculated in real time using the enthalpies calculated using the Vaisala HMD62 sensors and Type T thermocouples in the supply and return plenums, with the one-time airflow measurement taken when commissioning the system.

\[ Q_{\text{cooling}} = \rho_{\text{air}} \cdot \dot{V}_{\text{air}} \cdot (H_{\text{return}} - H_{\text{supply}}) \]  

(4)
To determine the overall performance of the space cooling mode, the Coefficient of Performance (COP) was calculated:

\[
COP = \frac{Q_{\text{cooling}}}{P_{\text{total}}} \tag{5}
\]

3.2.3. Overall Performance

Due to the design of the tank (an atmospheric storage tank with two coincident coils, one carrying refrigerant and one carrying potable water), it is very difficult to measure the performance of the combined modes. For this reason, overall system efficiency was generalized using the ratio of the total daily delivered cooling and DHW energy to the total electrical energy consumed.

\[
COP_{\text{combined}} = \frac{Q_{\text{DHW}} + Q_{\text{cooling}}}{P_{\text{total}}} \tag{6}
\]

3.2.4. Equation Nomenclature

c\text{p} is the specific heat.
C\text{FM} is the total return airflow in cooling.
COP is Coefficient of Performance at AHRI standard conditions.
P_{\text{total}} is the total HVAC electrical power including AHU.
\eta is the overall system efficiency.
H is supply and return enthalpies.
m_{\text{TES}} is the mass of water within the thermal storage tank.
Q_{\text{cooling}} is the cooling delivery rate.
Q_{\text{DHW}} is the total rate of heat delivered to the tank during a water heating cycle.
Q_{\text{TES}} is the rate of heat added to the thermal storage tank.
Q_{\text{water}} is the rate of heat delivered from the thermal storage tank to the point of use.
\rho is the density.
\Delta t is the time period of the cycle.
\Delta T is the temperature difference between the hot and cold side.
\Delta T_{\text{avg,Tank}} is the change in average tank temperature during a tank heating cycle.
\dot{V} is the volumetric flow rate.

4. Results and Discussion

The significant findings from the summer monitoring period for the MFHP are shown below as results. An hourly average of the indoor, outdoor, and DHW tank temperatures are shown in Figure 4 (top). The modes of the MFHP observed during the summer along with their respective runtimes during that three-day period are shown as bars on the secondary y-axis. It is evident from the indoor temperature that the MFHP is able to hold the indoor temperature steady across fluctuating outdoor conditions. The first 12 hours of the day had cold outdoor conditions and did not have AC runtime, however DHW heating runtimes were triggered by significant water draws. The concurrent AC-DHW mode was also seen to run during times when there is call for both space cooling and water heating. The frequency and run-times of the concurrent mode were low, which provides a scope of improvement for the MFHP with advanced controls. Figure 4 (bottom) shows the performance of the MFHP over the three-day period in terms of cooling capacity, total power consumption, and volumetric flow of hot water. The volumetric flow is represented in liters of hot water provided per minute on the secondary y-axis. The average DHW tank temperature would drop due to water draws but would go up due the MFHP operation in water heating or the concurrent AC and DHW mode. As expected, the cooling capacity was seen to be larger than the total power draw, suggesting a COP higher than unity.
A compressor cycle level analysis was performed to understand the efficiency of each mode of the MFHP. Coefficient of Performance (COP) for compressor cycles above four minutes in the duration between May 21 and October 21 with the outdoor dry-bulb temperature are shown in Figure 5. The cycle level COPs are sorted into three modes: AC mode (top left), DHW mode (top right), and concurrent AC and DHW mode (bottom).
Each blue dot in Figure 5 represents a compressor cycle in the respective mode. As shown, the MFHP ran very frequently in AC mode, followed by the DHW heating mode, and very infrequently in concurrent AC and DHW mode. This is because most of the concurrent mode occurrences throughout the monitoring period usually had lower than 4-minute runtimes, which was taken as the minimum amount of time for a cycle to reach steady state. The AC mode was observed to be drawing a power at 4.1 kW for a COP of 2.8 at 35°C outdoor dry bulb which was lower than the manufacturer published COP data (3.5) for a heat pump without the MFHP modifications. The reason for this difference in COP could be many. Firstly, there is higher refrigerant pressure drop expected from the addition of the three-way valves for changing modes and longer refrigerant line sets compared to the AHRI rated line set length of 25 feet. Secondly, return air conditions and supply air pressure drop in the current installation of the house are probably different than AHRI rating conditions. And lastly, the MFHP refrigerant charge is still being optimized by the manufacturer to accommodate wide range of conditions in the various modes. The DHW mode demonstrated a COP of 2.3 delivering 9.8 kW of thermal power into the water at 19.7°C outdoor dry bulb temperature, several times higher than the regular heat pump water heaters.

The bottom chart shows the measured combined COP of the concurrent mode (blue) and the combined calculated COP of the separate modes (orange), that is, if the MFHP were to run in AC and DHW mode separately to meet the same loads at the same outdoor condition. The calculated combined COP of the separate modes was based on data driven efficiency models of the AC and DHW modes separately. The measured COP of the concurrent AC and DHW mode was 36% better on average than two separate modes and thus, there is potential for energy savings by maximizing the runtime of the concurrent mode.

Figure 6 shows the transient response curve of the temperature in home to a setpoint change. The thick blue line represents the thermostat cooling setpoint which was initially set to 26.7°C as the occupants were away and was dropped to 23.3°C at 16:00 hours. The thick orange line is the temperature as measured by the thermostat and started to drop as the MFHP ran the AC mode. The thin lines with the shading in between are the individual room temperatures and shows the spread in room temperatures across the house. The dotted red line is the outdoor temperature, plotted on the secondary y-axis, stayed relatively constant over the time period. The thermostat temperature was seen to drop by 1.5°C in the first 30 minutes for the 2000 sq-ft house and was able to meet the comfort needs of the occupants. The span temperatures in all the rooms of the house denoted by the shaded region increases as the system operates due to heat gains on the house envelope and unequal distribution of air in rooms.

![Figure 6: Indoor temperature transient response to a cooling call in AC mode](image-url)
Figure 7 shows the water draw temperature over a day measured at the exit of the DHW tank during times of hot water draws, denoted by grey shading. The water temperature data was filtered on this basis to better illustrate the water delivered to point of use since the water at the tank exit cools down and does not heat up until there is flow. At start of every long draw the water temperature was seen to have a lower temperature and quickly increasing in temperature to about 45°C. This is due to the thermal mass in and around the outlet temperature sensor, which takes time to heat up to give a more accurate reading of the water flow temperature. The blue dots denote temperatures at water draws with a duration lasting less than 5 minutes. These points generally have lower temperatures similar reason to the starting measurements of the longer draws. The temperature profiles of the longer draws shows drop in temperature after a peak temperature value is achieved indicating depletion of thermal storage in the DHW tank.

The water temperature distribution shown in Figure 8 was filtered for data when there was a water draw in the 5 minutes prior to the current water draw. This was done to filter out temperature data at the beginning of a draw before the sensor has time to heat up
which was not deemed representative of hot water delivered by MFHP to meet comfort. About 15% of the total water draw occurrences, or 3.2% of the total hot water volume flow, had a hot water delivery temperature of below 45°C, which is the considered the lowest acceptable value for a shower. This shows that the MFHP system reasonably meets the hot water needs of the household during the summer while meeting the space cooling loads.

5. Conclusion

Electrification of space conditioning and hot water heating in homes require installation of separate air source heat pump equipment with each having electrical resistance heaters, which leads to increase in demand and ampacity of the electrical panel. Additional cost and complexity of electrical panel upgrades is one of the main challenges of electrification of older homes in the US. An air-to-air R410A MFHP system, capable of providing DHW and space conditioning, is investigated as a retrofit in a single-family home in Davis, California without electric resistance heaters. The system is monitored over the summer (May 21 to October 21) to analyze efficiencies of the MFHP in each mode and to evaluate its capability in meeting the space cooling and hot water loads. The household was instrumented with several sensors to calculate the metrics necessary for assessing the performance of the MFHP system and the thermal comfort of the occupants. The average COP of the MFHP AC mode was observed to be 2.8 (at 35°C Outdoor dry bulb), lower than heat pump without MFHP modifications. The reasons could be sub-optimal refrigerant charge and higher pressure drop due to longer lineset and refrigerant valving. The measured COP of the concurrent cooling and DHW mode was better than the COP estimated for meeting those loads in separate cycles by an average of 36%. Altering the controls to favor the concurrent mode rather than tackling the space cooling and DHW loads separately, this system can provide major energy and cost savings to the homeowner. Continued monitoring of the operation of MFHP and evaluating the heating performance of the system in the winter is ongoing. The MFHP space heating mode is demonstrated an average COP of 3.25 (at 8.3°C Outdoor dry bulb). Future work will assess the year-round performance and capability of MFHP in providing required household space conditioning and domestic hot water.

Abstract

The importance of industrial heat pumps for decarbonization has gained widespread recognition. Japan has demonstrated preeminence in the realm of industrial heat pump innovation and implementation. This paper overviews the current technology and market status of industrial heat pumps in Japan, demonstrating the maturity of heat-pumping technology to some extent. However, it shows a need to accelerate the introduction. Through a comprehensive questionnaire survey and barrier analysis, this study clarifies the challenges faced in the widespread adoption of industrial heat pumps and proposes measures to address these barriers in the future.

1. Introduction

Industrial heat pumps are recognized as a technology for decarbonizing industries due to their high efficiency and ability to be electrified with low-carbon electricity. According to the net-zero scenario of the International Energy Agency (IEA) by 2050 \cite{1}, industrial heat pumps will play an important role for low- (<100°C) and some medium- (100°C–400°C) temperature heat demand in light industries, accounting for approximately 30% of the total heat demand by 2050. To achieve this scenario, it is estimated that approximately 500 MW of industrial heat pumps must be installed each month over the next 30 years.

In Japan, the “Clean Energy Strategy,” published in May 2022, prioritizes industrial heat pumps as a key decarbonization technology for heat demands below 200°C \cite{2}. This strategy maps out the shift from our current energy system to one with a targeted 46% reduction in emissions by 2030 and an ultimate aim of reaching net-zero emissions by 2050. Industrial heat pumps are considered a practical solution due to their high efficiency and high technology readiness level compared to other alternatives.

The industrial heat pump technologies in Japan are regarded as unparalleled globally, and previous studies have reported on their technologies and application examples \cite{3-5}. However, prior research has focused on specific and individual technologies. Conversely, this study takes a broader perspective, providing a comprehensive overview of the current status of industrial heat pumps in Japan. Moreover, it clarifies the barriers to its widespread adoption through a questionnaire survey and barrier analysis and proposes measures for future development.
2. Current Status

This chapter provides an overview of the technology and market status of industrial heat pumps in Japan.

2.1. Technology status

Various types of industrial heat pumps have been commercialized in Japan, including closed and open systems such as mechanical vapor recompression (MVR). The closed system is further divided into two categories: the air-source type (Fig. 1) and the water-source type (Fig. 2).

The air-source heat pump typically utilizes ambient air as the heat source. Given the latitudinal expanse of Japan, from north to south, the ambient temperature varies across regions and seasons, with an average temperature of approximately 15°C. In the light of the cost-competitive coefficient of performance (COP), the maximum heat supply temperature is limited to approximately 90°C. Some products have a maximum heating capacity of 150 kW–200 kW, whereas many others have a heating capacity of less than 50 kW. It is assumed to be distributed throughout each heating process. This distribution arrangement presents two potential benefits. Firstly, it has the potential to reduce the heat dissipation loss from the long steam pipes of a steam boiler system. Typically, steam boilers have a thermal efficiency of ~ 90%. However, considering the heat dissipation loss from steam pipes, the end-use efficiency was only ~ 50% [6]. Secondly, this distribution arrangement also offers the possibility of utilizing heat dissipation from industrial processes. Many heating processes raise the internal temperature of a factory by dissipating heat, leading to decreased worker comfort or increased air conditioning demand. By placing an air-source heat pump near the heating process within the factory, it is possible to reduce air conditioning demand and improve the heat pump COP by increasing its heat source temperature.

Compared to the aforementioned air-source type heat pumps, water-source type heat pumps exhibit a wider range of heat supply temperature and heating capacity. They have a maximum supply temperature of 175°C, with a maximum heating capacity of ~ 600 kW. This type is primarily employed for waste heat recovery or simultaneous heating and cooling applications. To achieve economic viability for heat supply temperatures exceeding 100°C, relatively high-temperature waste heat is typically utilized as the heat source. At present in Japan, a COP of four is considered optimal for heat pump applications where heating is the sole objective. For combined heating and cooling applications, a total COP of five (with a heating COP of three) is recommended. The integration of a thermal storage tank is often required for simultaneous heating and cooling operations, as
heating and cooling demands may not occur concurrently. However, the addition of this tank can present barriers to the implementation of heat pumps, particularly in terms of capital cost and spatial constraint. Products circled in Fig. 1 are equipped with two evaporators and can switch between water and air heat sources. During periods where both heating and cooling are required, the water heat source is utilized. During periods where cooling is not necessary, the air heat source is employed.

While most of the heat pumps shown in Figures 1 and 2 have been commercially available for over a decade, they are still reliant on hydrofluorocarbon (HFC) refrigerants. Future technical challenges include lowering the global warming potential (GWP) of refrigerants and expanding the product lineup for high-temperature ranges. In national R&D projects led by New Energy and Industrial Technology Development Organization (NEDO), some manufacturers such as Fuji Electric, Mayekawa, and Mitsubishi Heavy Industries Thermal Systems are actively working on developing heat pumps with the capacity to supply heat at temperatures of 150°C or greater. Table 1 provides a comprehensive overview of this technology. The expansion of the product lineup for high-temperature range is expected in the near future.

#### 2.2. Market status

The market status of industrial heat pumps in Japan is reflected in two statistics, as shown in Table 2. The first statistic is an annual publication by the Ministry of Environment (MOE) that tracks progress on the Plan for Global Warming Countermeasures [7], which was established by the Japanese Cabinet in May 2016. This report describes the cumulative heating capacity of installed industrial heat pumps and is based on surveys...
conducted by the Ministry of Economy, Trade, and Industry (METI) and the Japan Refrigeration and Air Conditioning Industry Association (JRAIA). Although the data are limited to products from seven suppliers and do not represent the whole market, they are used as a policy indicator, and it is pertinent to monitor their progress.

The second statistic, published annually by the Japan Electro-Heat Center (JEHC) [8], is used as a basic material for the promotion of industrial heat pumps. This report covers a wider range of suppliers and their products, including MVR systems. In addition to the total heating capacity, the report also provides information on the capacity and number of units in the heat pump category, as well as information on the industries and processes in which heat pumps have been installed.

Figure 3 shows the cumulative heating capacity of industrial heat pumps, as reported by the MOE. The Japanese government expects that the total capacity will reach 1,673 MW in FY2030. However, the actual installation in FY2020 was 168.4 MW, indicating a need to accelerate the installation.

![Cumulative Heating Capacity](image)

Fig. 3. The policy indicator and actual cumulative heating capacity of industrial heat pumps in Japan [7].

Figure 4 shows the entire installation of industrial heat pumps, as documented by the JEHC. As of FY2020, the cumulative capacity of closed-system heat pumps stands at 877 MW, while that of open-type heat pumps (MVRs) is 440 MW, totaling 1,317 MW. The actual installation is approximately 7.8 times greater than the data used in the government’s policy indicator. The cumulative number of installed MVRs was 248, with a total heating capacity of 440 MW and an average unit capacity of 1.8 MW. Conversely, for air-source hot water heating heat pumps, although 981 units are installed, the average unit capacity is 24 kW. The demand for industrial heat pumps with a broad range of capacities remains evident.
For closed-system heat pumps, the breakdown of the installed industries is shown in Fig. 5. The machinery industry, including the automobile and electronics industries, demonstrates the highest installation density. This distribution pattern reflects the prevalent orientation of the Japanese industrial landscape towards machinery development.

3. Barrier Analysis

This chapter presents the results of a questionnaire survey of industries, clarifies why the installation of industrial heat pumps has not progressed, and discusses future measures.

3.1. Questionnaire survey

The authors conducted a questionnaire survey regarding the current status of decarbonization efforts in the manufacturing industry and the adoption of industrial electrification technologies, including heat pumps,
resistance heating, induction heating, dielectric heating, infrared heating and arc furnace. In this paper, we introduce extracts related to industrial heat pumps. This survey was conducted by mail. The response period was from October 15 to November 5, 2021. This survey covered factories in which energy management was specified in the Energy Efficiency Act. Out of the 6,016 mailed questionnaires, there were 690 valid responses, yielding a response rate of 11.5%. This study provides answers to the following questions:

- Q1. Are you currently planning or making progress towards decarbonization in your factory?
- Q2. Are you currently planning or making progress towards electrification?
- Q3. What specific decarbonization efforts are you taking?
- Q4. Have you installed heat pumps in your factory yet?
- Q5. Are you satisfied with your heat pumps?
- Q6. Are you satisfied with your heating equipment?
- Q7. Do you plan to install heat pumps in your factory in the near future?
- Q8. What reasons are making you reluctant to install heat pumps?

Questions one to three are about the status of the efforts towards decarbonization. The survey responses from 671 companies, as depicted in Fig. 6, reveal that 29% of the companies have already initiated efforts towards decarbonization and 47% are in the planning stage. However, 25% of the companies have yet to begin planning for decarbonization. Companies with fewer employees were noted to be less active. The same trend was observed for electrification. Of the companies that have either initiated or are planning for decarbonization, 90% reported that improving energy efficiency was a specific action, as depicted in Fig. 7. Energy efficiency improvement is directly linked to energy cost reduction, which explains its high priority. On the other hand, only 17% of the companies have adopted electrification as a specific action, as it does not guarantee energy cost reduction at present.

A heat pump is a technology that can simultaneously improve energy efficiency and electrification. Figure 8 shows the status of industrial heat pump installations, which encompasses both relatively low-temperature heat pumps, such as air conditioning in clean rooms, as well as high-temperature heat pumps. Of the 476 companies that responded, 38% have already installed heat pumps, while 48% acknowledge their importance but have yet to install them. Moreover, 13% of the companies do not recognize the value of heat pumps.

Of the 155 companies that have already installed heat pumps, 89% reported satisfaction with their performance. Figure 9 shows a comparison of satisfaction with heat pumps and combustion equipment, demonstrating that heat pumps are on par with combustion steam boilers and water heaters in terms of user satisfaction.
satisfaction. Despite any initial concerns that companies may have had prior to the installation of heat pumps, the survey results indicate a high degree of satisfaction post-installation.

Figure 8. Questionnaire for installation of and satisfaction with heat pumps.

Q4. Have you installed heat pumps in your factory yet? (n=476)
- Already installed: 48%
- Recognized but not installed yet: 13%
- Not recognized: 17%
- Unknown: 10%

Q5. Are you satisfied with your heat pumps? (n=155)
- Very satisfied: 38%
- Satisfied: 63%
- Dissatisfied: 10%
- Very dissatisfied: 1%

Figure 9. Questionnaire for satisfaction with heat pumps compared to boilers.

Q6. Are you satisfied with your heating equipment?
- Heat pump (n=155): Very satisfied 26%, Satisfied 63%, Dissatisfied 10%
- Combustion steam boiler (n=356): Very satisfied 26%, Satisfied 63%, Dissatisfied 10%
- Combustion water heater (n=72): Very satisfied 17%, Satisfied 65%, Dissatisfied 14%

Figure 10 shows the responses to the question regarding the future plans for the introduction of heat pumps. Of the 126 companies that have already partially installed heat pumps, 30% are planning new installations, and 32% are contemplating such installations. Conversely, only 4% of the companies that have not yet installed heat pumps are planning to do so. Therefore, it appears that prior experience with heat pump installations may facilitate further adoption.

Q7. Do you plan to install heat pumps in your factory in the near future?
- Already installed (n=126): Planning 30%, Considering 32%, Interested but challenging 28%, Not interested 10%
- Recognized but not installed yet (n=133): Planning 17%, Considering 41%, Interested but challenging 39%

As shown in Fig. 10, many companies, 28% of those that have already partially installed and 41% of those that have recognized the importance of heat pumps but have not yet installed them, answered that they were interested in heat pumps but found the installation process challenging. Figure 11 sheds light on the reasons behind their reluctance to install heat pumps, with most of these companies not being concerned with the technological maturity, energy efficiency, or CO₂ reduction capabilities of heat pumps. Nonetheless, there are technological considerations other than heat pump equipment that may be impediments to the widespread introduction of heat pumps.
The major impediments to the widespread adoption of heat pump technology are primarily of an economic and financial nature. Companies are concerned about large capital investments and extended payback periods. Interestingly, some companies are only concerned about large capital investments; others have complaints about the payback period. These findings suggest that the introduction of more favorable financing arrangements could help to overcome these barriers.

Moreover, site-specific factors, such as the lack of installation space or in-house engineering expertise, were also identified as key challenges by some companies. Some existing factories may not have enough space to install heat pumps, especially when considering the recovery of waste heat from heating processes. In addition, some companies lack in-house engineering capabilities, thereby making it challenging for them to assess the benefits and feasibility of heat pump adoption.

3.2. Barriers and solutions

So far, the support for industrial heat pumps by the Japanese government has mainly focused on technological developments, such as the development of high-temperature heat pumps. These supports have successfully improved the technical potential and maturity of the industrial heat pumps. Nevertheless, it is imperative to continue to support the development of low-GWP refrigerants as well as related lubricants, oils, and compressors. However, for the widespread adoption of industrial heat pumps, it is crucial to extend support beyond heat pump equipment technology in the future.

Table 3 summarizes the main barriers and possible solutions for industrial heat pump applications. As for the solutions, while there may be a number of measures that private entities can undertake voluntarily, this table only considers the solutions that the government can implement.

The installation of a heat pump system requires a thorough analysis of the sources of heat and the areas in which it needs to be supplied. Therefore, it is necessary to establish a process integration methodology and to conduct research on technology deployment as well as technology development.

To provide support in terms of capital expenditure (CapEx), it would be effective to focus on small and medium-sized enterprises (SMEs) and new factories. Additionally, in terms of operating expenses (OpEx), rebalancing the renewable energy levy can be a fair and effective measure.

</tbody>
</table>

4. Conclusions

The integration of industrial heat pumps is deemed crucial for decarbonization. Despite the advancements and commercialization of various types of industrial heat pumps in Japan, their widespread adoption has not materialized as anticipated.

To gain a deeper understanding of the barriers hindering the implementation of industrial heat pumps, a questionnaire survey was conducted. The results highlight four main barriers: high capital investment, a long payback period, spatial restrictions, and a lack of in-house engineering expertise. In addition, we listed the possible solutions that can be provided by the government for each barrier.

These barriers are believed to be common worldwide, and it is our aim to contribute to overcoming these obstacles by sharing our findings and insights with other countries and promoting the utilization of industrial heat pumps globally.

Abstract

The application of an absorption-heat exchangers as transfer sub-station in a district heating grid can use the temperature difference between the primary (up to 145 °C) and secondary supply temperature (ca. 70 °C) of the circuits for subcooling the primary return temperature below the secondary one. This leads to the advantages of increased heat capacity within an existing grid up to 30% at unchanged flow and temperature inlet conditions on the one hand-side, and on the other hand-side, more renewables can be more easily integrated. To proof the required temperature gap between the two supply temperatures to ensure a subcooling of the primary return flow temperature below the secondary one has been experimentally investigated by a small pilot-scaled absorption-heat exchangers (about 10 kW max) at the laboratory of AEE INTEC at different inlet conditions. This analysis has shown that a subcooling up to 20.7 K is achievable between the return temperatures with an AHX at highly primary supply and low secondary return temperatures as long the mass flow of the secondary grid gets increased accordingly to the heat capacity increase.

1. Introduction

In Austria, more than about a quarter of the entire population and numerous companies are currently supplied of thermal energy by means of district heating (DH) \cite{1}, with a forecasted growing rate of 0.8%/anno in average for the next 5 years. This increasing demand is currently being covered by investments in network infrastructure and supply units. At the same time, however, a complete phase out of Gas (about 28% \cite{1}) is limited by the fact that a considerable proportion of renewables and waste heat cannot be integrated in Austrians existing DH-grids based on not fitting temperature levels, which means that the temperature levels, particular in the so-called primary circuit is still too high. A further advantage of a reduction of the used supply temperature in the DH-Grid is the reduction of the distribution heat losses.

But for already existing heating networks - based on already installed pipelines, which means that the diameters of the pipes are also fixed - the maximum possible mass flow ($m$) is limited and thus also the maximum possible heat capacity ($Q$) of the network is limited, according to Eq. (1). The limitation of $m$ in existing pipes is based on cavitation avoidance reasons, where the flow velocity cannot be increased so that the local static pressure in the pipe does not fall below that of the saturation pressure. So, an increase of the heat capacity could be only achieved, if bigger pipes would be installed. But this creates high investment cost and long periods to refurbish the entire grid. To overcome this situation, the (primary) return temperature ($t_{R,P,R}$) has to be lowered by a higher value than the (primary) supply temperature ($t_{S,P,R}$), in order to achieve a bigger temperature-spread and thus ensure an increase of the heat capacity of the existing DH-grid, according to. With a sufficiently high reduction of the return temperature, the supply temperature could also be reduced.

\textsuperscript{*} Gerald Zotter. Tel.: +43 650 891 819 5
\textit{E-mail address: g.zotter@aei.at.}
at a high value, which leads to a reduction of losses and significantly increases the possibility for the integration of renewables, such as deep geothermal or industrial waste heat (compare Figure 1 to Figure 2).

\[ \dot{Q} = \dot{m} \cdot c_p \cdot (t_{S,Pr} - t_{R,Pr}) \]  

(1)

Technologies such as electrically driven heat pumps and thermally absorption heat pumps (AHPs) are widely used to improve the overall efficiency of different energy supply systems in different applications [3-7]. The possibilities to use thermally-driven AHP in district heating and/or cooling grids are wide and cover a broad spectrum for increasing the energy efficiency. According to Hu et al (2020) [8] the absorption heat exchanger (AHX) is one of the most commonly used technologies to improve performance of district heating grids. In comparison to a conventional heat exchanger (HX) an AHX can use the exergetic potential (second law of thermodynamics) based on the temperature difference between the supply temperatures (\( \Delta T_{S,Pr/Se} \)) (see Eq. 2) to sub-cool \( t_{R,Pr} \) below the return temperature of the secondary circuit \( t_{R,SE} \), which is the inlet temperature of the on the secondary side of the TSS. This subcooling \( \Delta T_{Sub-R,Pr/Se} \), according to Eq.3 allows the improvement of the DH-grid, as already mentioned above, and the reason to use an AHX. A detailed explanation of the working principal of an AHX and a comparison to a HX are given in chapter Error! Reference source not found.

\[ \Delta T_{S,Pr/Se} = (t_{S,Pr} - t_{S,Se}) \]  

(2)

\[ \Delta T_{Sub-R,Pr/Se} = (t_{R,Se} - t_{R,PR}) \]  

(3)

| Figure 1: Schematic drawing of an old district heating grid supplied by Gas fired combined heat and power plants (CHP) and biomass fired with a transfer-substation (TSS) with conventional heat exchangers (HX) between primary and secondary grid with different temperature levels (145/56°C at primary circuit and 71/46°C at secondary grid) |

| Figure 2: Schematic drawing of the optimized future district heating grid supplied only by renewables (geothermal, industrial waste & solar thermal heat, etc.), where the primary circuit is operated at lower temperature levels of compared to the schematic in Figure 1 by using absorption heat exchanger (AHX) instead of an HX as transfer-substation (TSS) (125/56°C at primary circuit and 71/46°C at secondary grid) |

So, using an AHX for transfer-subs-stations (TSS) instead of conventional heat exchangers (HX) are key for lowering the temperature levels of already existing DH-grids. Although, AHXs have a high potential for return flow temperature reduction of heating grids [9-10], those applications are still very rare in Austria. To overcome that situation, within this work a small pilot-scaled AHX (of about 10 kW, see Figure 10) has been experimentally investigated in detail at different boundary conditions at the laboratory of AEE INTEC.

2. Optimized transfer-sub-station

When a DH-grid is separated in circuits with different temperature levels (primary and secondary), the circuits are connected via TSS using conventional HX (see Figure 3). Generally, the temperature levels in the DH-grid depend on the ambient temperature. This is based on the fact that grid is operated by a weather-compensating control for the supply temperature, where minima supply temperatures have to be ensured
depending on a floating set value considering the weather conditions. For colder ambient conditions the supply temperature has to be higher than for warmer days. For the design point of about \(-10^°C\) ambient temperature the supply/return temperature in the primary grid is about 145°C/58°C, where else on the secondary grid it is about 70°C/45°C.

2.1. Using heat exchanger as TSS

As mentioned in chapter 1, from an energetical point of view the primary return temperature should be as low as possible. The primary return temperature depends at that case on the arrangement of the HX (parallel- or counter-flow) and the so-called pinch-point temperature difference (Δt_{PP}). Δt_{PP} is influenced by the heat transmission coefficient (U) and the heat transfer area of the HX (A). This means for example that an increase of A of about 40% (see Figure 3 and Figure 5) could lower Δt_{PP} to the half and this raises \(\dot{Q}\) of about 7% at constant inlet conditions, as shown by a comparison of the- two t vs \(\dot{Q}\) - diagram in Figure 4 and Figure 6.

Even if, the heat exchanger efficiency (\(\eta\), see Eq.5) is mostly 100% as long as the heat losses (\(Q_{loss}\)) are negligible, but a change of Δt_{PP} has an influence on the heat exchanger effectiveness (\(\epsilon\), see Eq.4) as well as different inlet conditions concerning \(\dot{m}, c_p\) and temperature. Based on the conditions shown in Figure 4 the HX has an \(\epsilon\) of 0.9, where else the HX with the increased A has an effectiveness of 0.95.

\[
\epsilon = \frac{\text{actual heat transfer}}{\text{maximal possible heat transfer}} = \frac{\dot{m}_{pr}c_{p,pr}(t_{S,pr}-t_{r,pr})}{\min\{\dot{m},c_p\}(t_{S,pr}-t_{r,se})} \tag{4}
\]

\[
\eta = \frac{\dot{Q}_{pr}(-Q_{loss})}{\dot{Q}_{Se}} \tag{5}
\]

2.2. Using absorption heat exchanger as TSS

A (single-stage) AHP is driven by heat and consists of an evaporator, where heat gets absorbed from a cold heat source (cold water). The vaporized refrigerant flow to the absorber, where the solution fluid absorbs the refrigerant by rejecting heat to a mid-temperate heat sink (cooling water). The (refrigerant) rich solution gets pumped over the solution HX (where sensible heat between the hotter poor solution and colder rich solution is transferred) into the generator. The generator gets driven by heat from the hot heat source (hot water) to desorb the refrigerant from the solution. The poor solution flows via a throttle and the solution HX back to the absorber, where else the refrigerant flows to the condenser. The condenser rejects latent heat to the mid-temperate heat source to fully condensate the refrigerant. The condensate gets expanded via another throttle to the evaporator. Evaporator and absorber operate (if pressure losses could be neglected) at the same low-pressure level. Condenser and generator operate (if pressure losses could be neglected) at the same high-pressure level.

The AHX is a combination of an absorption chiller with an HX, as shown Figure 7, which is not used as a chiller or heat pump, but as an energetically optimized HX. As though, the hot water- (external heat transfer fluid-circuit) is short-circuited with the cold water-circuit (external heat transfer fluid-circuit) of the absorption chiller via the heat exchanger; this side represents the primary circuit of the AHX. For the secondary side, the cooling water (external heat transfer fluid-circuit) gets partitioned between the HX and the absorber chiller via the distribution valve (D-valve).

2.3. Analysis of TSS based on the second law of thermodynamics

The AHX is using the exergetical potential (ex_{pot}) of the otherwise unused big temperature gap between the two supply temperatures (Δt_{S,pr/Se}) to drive an AHP for subcooling \(t_{R,pr}\) below \(t_{R,Se}\) in the evaporator of the AHP. At the given boundary conditions, according to Figure 6, the HX offers a theoretical ex_{pot} of ca. 15% (\(T_s = 293.15\) K) which could be used to operate an AHP (according to Eq. 6), but would be irreversible wasted in a conventional HX. That potential is shrinking to zero when Δt_{S,pr/Se} is decreasing to zero: However, this is a theoretical potential not covering the temperature glides, pressure losses, irreversibility in each single heat exchanger etc. is not covered. However, as shown in Figure 8, which is based on a 0D simulation model in EES [13] a subcooling (Δt_{Sub-R,pr/Se}) of 21 K can be achieved by a first principal model, with Δt_{PP} > 3 K in every single heat exchanger of the AHX. According to that, see Figure 8, the heat capacity
could be increased of about 30%, in which the secondary mass flow has to be increased also of the same 30% that the surplus of $Q$ could be transferred without raising $t_{S,Se}$. This is required to avoid that the $\text{ex}_{\text{pot}}$ would not be lowered, which is required to drive the AHX.

Furthermore, a detailed exergy analysis - based on the Gouy-Stodola-Equation, considering the different entropy changes (see Eq. 7) on primary ($m_{Pr} \cdot \Delta s_{Pr}$) and secondary ($m_{Se} \cdot \Delta s_{Se}$) side - shows irreversible exergy losses within the HX and AHX. This analysis shows that up to 30% of the irreversibility can be reduced using an AHX compared to an HX (neglecting the pumps and each single pinch point temperature difference from generator to evaporator). Within this exergetical improvement the AHX could achieve an $\epsilon$ of 1.15. This is only possible due to counter-clockwise rotated cycle is used within the AHX and the driving source comes from the otherwise unused exergetical potential, as already mentioned. However, the exergetical efficiency of the AHX is of course still below 1 and amounts to 0.93 for the boundary conditions listed in table 1.

$$\text{ex}_{\text{pot}} = \frac{\dot{E}_{x}}{Q} = T_a \frac{(T_{S,Pr} - T_{S,Se})}{(T_{S,Pr} + T_{S,Se})} \quad (6)$$

$$- \frac{d\text{ex}_{\text{irr}}}{dT} = T_a \left( \sum m_{Se} \cdot s_{Se} - \sum m_{Pr} \cdot s_{Pr} \right) \quad (7)$$

$$\eta_{ex} = \frac{\dot{E}_{x_{in}} - \dot{E}_{x_{irr}}}{\dot{Q}_{x_{in}}} \quad (8)$$

According to Figure 8, the exergetical benefit of an AHX is that the high temperature level of the supply-side of the primary circuit is used to drive the generator, where that high temperature level is required. All pinch point temperature in the AHX is positive. The directly sub-cooling ($\Delta T_{Sub-R,Pr/Se}$) happens in the evaporator of the AHX. To count the energetical potential of an AHX not only $\Delta T_{Sub-R,Pr/Se}$ should be considered, but also the pinch point temperature difference which is required for a conventional HX. This means that the entire temperature difference between the primary return temperature of a HX and an AHX is in that particular case 27 K (compare Figure 5 to Figure 7).
Figure 3: Principal picture of a conventional heat exchanger (HX) used as transfer sub-station (TSS) in a district heating grid (DH) including temperature levels of external heat transfer fluids of primary and secondary site.

Figure 4: Pinch point temperature difference ($\Delta t_{PP}$) in the temperature vs. heat capacity – diagram ($t$ vs. $\dot{Q}$ – diagram) of a transfer sub-station.

Figure 5: Principal picture of a conventional HX used as TSS in a DH-grid including temperature levels of external heat transfer fluids of primary and secondary site with 40% bigger heat transfer area (A) compared to Figure 3.

Figure 6: $t$ vs. $\dot{Q}$ – diagram of a 40% bigger HX compared to Figure 5 lowering $\Delta t_{PP}$ to the half and increasing $\dot{Q}$ of about 7%; furthermore, also the big temperature difference between the supply temperature of the primary circuit.

Figure 7: Principal picture of an absorption heat exchanger (AHX) consisting of an AHP and a HX and a distribution valve (D-valve).

Figure 8: $t$ vs. $\dot{Q}$ – diagram of all heat exchangers of an AHX and an increased $\dot{Q}$ of about 30%; furthermore,
From a thermodynamical point of view, an AHX can be seen as a combination of a Rankine cycle and compression chiller, as shown in Figure 9. The supply side of the primary circuit is used as heat sink of the Rankine cycle and the supply side of the secondary circuit is used as its heat sink. The electrical power produced by a Rankine cycle is used to drive a Perkins/Evans cycle, where the return-side of the secondary circuit is used as heat sink and the return-side of the primary circuit is used as heat source. So, an AHX is a combination of a HX and a clockwise- and counterclockwise rotating thermodynamical cycles, where exergy fluxes are used regarding its temperature levels.

3. Test bench of the pilot-scaled AHX

Within this work a pilot-scaled AHX was designed and set up as a combination of an AHP (absorption chiller: single-stage chiller with solution HX, available on the market with a nominal cooling capacity of 15 kW, see Figure 9 in orange) and a plate-HX (see Figure 9 in green, with A of 2.46 m²), in a counterflow arrangement. The working pair used in the AHP was water/Lithium-Bromide (H₂O-LiBr). As shown in Figure 10, the AHX been equipped with the required measurement equipment and integrated into the infrastructure of the laboratory of the AEE INTEC (blue-marked) consists of a heat-sink-source system, and analyzed at different operating conditions. For that, the primary inlet (“supply”) and the secondary inlet (“return”) temperature as well as volume flow ratio between primary and secondary site has been varied, as well as the secondary distribution ratio (see table 2). All energy fluxes have been measured at internal AHX cycle as well as on the external primary and secondary circuits. After calibration of the measurement equipment the uncertainties of the temperature sensors amount only ± 0.2 K, of the volume flow meter only about ± 0.5% of the measured value.

At that point it has to be mentioned, that regarding safety reasons thermo-oil was used as heat transfer fluid for the primary side instead of pressurized hot water (up to 20 bar, avoiding cavitation for 145 °C). This had influence on lowering the possible heat capacity of the tested AHX down to max. 10 kW. Particularly, the differences between heat transfer coefficients (HTC) and specific heat capacities (cₚ) of the two fluids must be taken into account. In addition, the energy balance was drawn for stationary points and the corresponding heat losses were analyzed, see. The convective and radiative heat losses were evident (of about 10%) due to the lack of thermal insulation, but could be balanced out for the analysis.

However, to simplify the data collection parameter for the ratios of volume flows, as mentioned above, has been determined. So, the ration of volume flows between primary and...
The secondary circuit is called general volume flow ratio (GVR, see Eq. 9) and the ratio between the secondary volume flow through the HX and the AHP is called secondary volume flow ratio (SVR, see Eq.9)

\[
GVR = \frac{\dot{V}_{SE}}{\dot{V}_{PR}}
\]

\[
SVR = \frac{\dot{V}_{SE,HX}}{\dot{V}_{SE,AHX}}

4. The measurement results

Within this experimental analysis the maximal possible subcooling \((t_{R,se} - t_{R,pr})\) within the pilot-scaled AHX has been investigated in detail, according given boundaries in table 2. Covering all the different variants by changing that parameter as shown in table 2, the measurement matrix consists of 36 different measurement points. Each individual measurement point was recorded dynamically and when the external temperatures and volume flows as well as the internal (high and low) pressure levels settled to a stable asymptote, the steady state was evaluated. In those experimental investigations, the transient behavior of the AHX was also determined, but this is not the subject of this paper.

Figure 12 shows the subcooling of the primary return temperature below the secondary one \((t_{R,se} - t_{R,pr})\) depending on primary supply temperature at different \(t_{R,se}\) and constant \(\dot{V}_{pr}\) of 250 m³/h; GVR of 4.5 and a SVR of 0.2. The highest \((t_{R,se} - t_{R,pr})\) can achieved at high supply temperatures on the primary circuit and low return temperatures of the secondary circuit. However, high \((t_{R,se} - t_{R,pr})\) has been measured also at higher \(t_{R,se}\) up to 56 °C, as long as \(t_{s,pr}\) is high. Furthermore, even at a low \(t_{s,pr}\) of 105 °C a subcooling of about 12 K could be measured as long as \(t_{R,se}\) is not warmer than 44 °C. No subcooling could be achieved at low \(t_{s,pr}\) and high \(t_{R,se}\).

Figure 14 shows the subcooling of the primary return temperature below the secondary one \((t_{R,se} - t_{R,pr})\) depending on GVR at different SVR and constant \(\dot{V}_{pr}\) of 250 m³/h; \(t_{R,se}\) of 44 °C. For higher subcooling the ratio between volume flow rate of the secondary circuit to the one of the primary circuits has to be high. The same is valid for the SVR, as shown in the Figure 13. Figure 13 shows the subcooling of the primary return temperature below the secondary one \((t_{R,se} - t_{R,pr})\) depending on SVR at different \(t_{R,se}\) and constant \(\dot{V}_{pr}\) of 250 m³/h and GVR of 6. As more volume flow rate passes the AHP as higher is the subcooling. There is a limitation based on the required pump power and on the heat which has to be transferred of the HX to cool down the primary circuit coming from the generator and before entering the evaporator. Furthermore, within this investigation room for improvements has been detected regarding thermal insulation of the AHP, the internal control of the solution pump and the throttles, as well as on changes by the cycle of the AHP itself, like connecting the absorber and the condenser not in a serial but in a parallel arrangement.
5. Conclusions

The application of an AHX as a TSS in a DH-grid can use the temperature difference between the primary (up to 145 °C) and secondary supply temperature (ca. 70 °C) of the circuits for subcooling the primary return temperature below the secondary one. This leads to the advantages of increased heat capacity within an existing grid up to 30% at unchanged flow and temperature inlet conditions on the one hand-side, and on the other hand-side, more renewables can be more easily integrated. As shown in this work, this is based on the fact that the exergy losses could be reduced by about 30% compared to a conventional HX and the heat capacity could be extended of about 30%. Furthermore, an AHX offers that the heat exchanger effectiveness could be increased to 115%, but the exergetical efficiency is of course still below 1 (0.94 at the same boundary conditions). However, this exergetical potential for optimization depends on the difference between the supply temperatures of the primary and secondary circuit. If the supply temperature of the primary circuit is close to the one of the secondary side no driving potential for subcooling the return temperature is available.

Considering that, within this work an experimental investigation of an AHX was covered and described in order to analyze its performance as a TSS being considered in DH-grids. The main focus was on the subcooling performance of the return temperature of primary circuit influenced by the difference between the supply temperatures of the primary and secondary circuits. For this research, an AHX at pilot-scale was designed, consist on a H₂O-LiBr - absorption chiller, available on the market (nominal cooling capacity of 15 kW) and the plate heat exchanger with a heat transfer Aera of (2.46 m²) and integrated in the test facility of the laboratory of AEE INTEC. The test rig was driven by various temperature and mass flow inlet parameter variations in order to analyze the optimal operating points, the limitation for subcooling based on the minimal required difference between the supply temperature on steady-state points as well as to investigate the transient behavior of the AHX and explore a fitting control strategy regarding the mass flow distribution. Energy balancing was also carried out to determine the heat losses or inputs from the ambient.

The results of the experimental measurement series show that a high primary supply temperature, a low secondary return temperature and a high secondary-to-primary mass flow rate are required for a high subcooling performance. The partitioning of the secondary mass flow between the absorption chiller and the heat exchanger also had an effective effect, with a high mass flow through the chiller increasing subcooling. At 𝑡_{S,Pr} of 145 °C and 𝑡_{R,Se} of 38 °C, a SVR of 0.2 and GVR of 6 the highest subcooling with 20.7K could be achieved within the pilot scaled AHX. But even under suboptimal conditions, like low primary supply temperatures of 105 °C the AHX subcooled the primary return temperature below the secondary of 12.4K, but for that a low return temperature on the secondary side below 44 °C is required. For 𝑡_{R,Se} higher than 50 °C a minimal 𝑡_{S,Pr} of 125 °C is required.

Furthermore, the measurements have underlined the theoretical considerations about the exergetical driving potential that can be used by the AHX. Namely a big difference between the supply temperatures between primary and secondary circuit is required to sub-cool the return temperature at its most. This means that, for a constant mass flow of the primary circuit, the temperature spread has to increase by raising heat capacity of the AHX. Therefore, the mass flow on the secondary side must also be increased so that the heat capacity can be increased without increasing the supply temperature on the secondary circuit, that the exergetical driving potential stays constant. So at higher GVR a higher sub-cooling (Δ𝑇_{Sub-R,Pr/Se}) could be achieved within the
AHX. In addition, a distribution valve is needed on the secondary side so split the secondary volume flow between a part which flows through the AHP and through the HX (SVR). This experimental investigation shows that if more volume flow rate flows through the AHP part of the AHX the sub-cooling (∆TSUB_R,Pr/Se) raises.

In conclusion, an AHX have high potential avoiding exergetical losses in a transfer-sub-station of a DH-grid and therefore the heat capacity in existing DH-grids could be increased, particular if renewables like deep geothermal heat or solar heat is used for suppling it.

6. Outlook

The experimental investigation of an AHX shows a high potential for reducing the primary return temperature of district heating networks and thus also a high replication potential for other substations, which can thus contribute to the increased use of exclusively renewable energy sources in DH-grids in Austria and Europe. This potential is based on the reduction of the return temperature, as this can also reduce the flow temperature, and thus renewable such as ‘deep geothermal energy, solar thermal energy’ and regenerative such as waste heat can be integrated much more efficiently into the grid. However, a necessary reduction of the flow and return temperatures on the secondary side must also be provided.

However, a necessary reduction of the flow and return temperatures on the secondary side must also be provided. Ergo, suitable measures must also be provided for the end user, such as for example surface heating, building mass activations, sufficiently large house transfer stations, etc.

But before that, from a technical point of view, it is important to convert results that are partly related to thermal-oil, which was used as heat transfer fluid for the primary side should be transferred to pressurized hot water. The measured values have to be transformed considering the higher cp and HTC of water compared to thermo-oil on the primary side. Before the AHX is used in full-scale as a transfer substation, an optimized flow-layout, such as parallel connection of condenser and absorber, use of a multi-chamber machine and a corresponding control strategy for the distribution between secondary mass flow by the absorption machine part and the heat exchanger part has to be investigated in detail.

From an economical point of view, a further dynamic year-round simulation is essential for the economic evaluation in order to determine by how much the primary return can be supercooled. However, the economic consideration also requires a precise analysis of the supply side used. Especially renewables such as geothermal energy are extremely interesting; because by lowering the return temperature at the same flow rate, more heat can be drawn from this regenerative source free of charge. But, also the bigger packing and the issue with the required space of an AHX has to be considered. A planned demonstration of this integration concept of an AHX into a DH-grid shows high replication potential for other TSS, which can therefore contribute to the increased market penetration of these systems in Austria and Europe.

Fields of application of large-scale heat pumps and challenges in planning

Franziska Bockelmann*, Joris Zimmermann

SIZ energieplus, Hamburger Strasse 277, 38114 Braunschweig, Germany

Abstract

Large-scale heat pumps are increasingly used in the heat supply. The challenge in creating a heating concept for the use of large-scale heat pumps is the balance between cost efficiency and CO₂-emissions. Certain criteria such as the innovation of supply concept and technologies, the reduction of CO₂-emission and the acceptance as well as the cost-effectiveness must be taken into account in advance. Heat pump systems and concepts on this scale require appropriate design and pre-planning.

Large-scale heat pumps have the potential to be used in many different ways. In this paper, five examples of heat pump integration will be presented, from neighborhoods, building blocks and the use of waste heat for district supply. These projects show that a significant contribution can be made to increase the share of renewable energy in the heat supply. It can be shown that it is theoretically possible to cover the heat demand up to 100% via the application of heat pumps. Furthermore, enormous ecological potentials can be demonstrated. Compared to gas boilers, CO₂ reductions of 50 - 90% can be achieved.

Keywords: large-scale heat pumps; energy concepts; planning and design; examples

1. Introduction

On average, each person in Germany emits around 7.75 t of CO₂ per year (energy-related – electricity and heat, 2019) [1]. An emission per person of less than 1 t CO₂ per year would be climate compatible [2]. This shows that sustainable consumption requires great efforts and a reduction of around 90 % compared to the current level. A major contribution to achieve climate neutrality can be achieved by reducing emissions in the residential sector. Here, heating offers large potential. Energy consumption must be reduced in the long term, e.g. through thermal insulation of the building envelope. The same time there must be a coupling of the heat and electricity sector, as electricity can more easily be replaced by renewable energy. This coupling can be achieved by using heat pumps.

These positive effects of heat pumps can be scaled up if they are integrated into district heating grids. This can result in modern supply concepts, where smart controllable large-scale heat pumps are integrated for energy-efficient operation. However, these systems face many challenges. Suitable environmental heat sources for the residential energy supply must be dimensioned and developed to the required extent. For resilient and cost-efficient operation, heat pumps may need to be used bivalently in combination with other heat sources of the heating grid. The difference in temperature levels required for new and existing buildings connected to the network needs to be considered.

Such supply concepts should be developed holistically together with the electricity sector. The integration of heat pumps results in a high level of electrification, which should be covered by renewable electricity. Furthermore, the energy concept must enable the energy supply in the neighborhood with the highest possible share of renewable energy at economically justifiable investments and operating costs. In order to consider the costs of the project holistically, land acquisition, grid connection costs and general development costs must be

* Corresponding author. Tel.: +49-531-793893-17; fax: +49-531-793893-98.
E-mail address: franziska.bockelmann@siz-energieplus.de.
taken into account. The transferability of the energy concept to other projects depends strongly on the existing infrastructure and the specific requirements of the residential area, which often results in individual solutions.

To sum up, for designing and choosing an energy supply system for districts, certain criteria have to be met:

- Innovation (using innovative technologies and supply concepts)
- Renewability (including reduction of carbon dioxide emissions)
- Resilience (against internal and external disturbances)
- Potential for servicing the electricity grid
- Transferability (of the system design to other districts / cities)
- Acceptance (among the local population)
- Economic efficiency

The framework conditions and prerequisites for the integration of large-scale heat pumps into supply concepts are given. In addition to the actual concept, the technical components are also available. In addition to the already existing use in the metal processing industry and the food industry, the application area "district heat supply" is seen as a great potential for large-scale heat pumps. For a CO2-neutral heat supply, the transition to large-scale heat pumps is indispensable. The reason why large-scale heat pumps have only been installed sporadically so far is that the price ratio of electricity to gas has been high until now. Therefore, people resorted to a heat supply via gas.

Despite the small number of units installed, the Technology Readiness Level (TRL) of large-scale heat pumps is 6 - 8, and even 9 for large industrial heat pumps.

Large-scale heat pumps are still largely manufactured as individual solutions and are therefore not as inexpensive to purchase as series products. Individual manufacturers offer their systems in a kind of modular system and can thus cover a heat output range of 350 – 3,100 kW. Large-scale heat pumps can cover temperature levels up to 130°C and achieve COPs of 4 to 7. [3]

2. Planning of energy concepts with large-scale heat pumps

The conceptual design is about the intelligent networking of electricity, heat and mobility in everyday life and the sensible integration of renewable energies into existing supply networks. One aspect of this is the use of existing heat sources on site, for example using waste heat from industry to provide heat to neighborhoods.

While smaller heat pumps with lower supply temperatures and low heating capacities have been established for many years in both residential and non-residential buildings, a supply concept with large-scale heat pump makes higher demands. Heat pumps suitable for these operating conditions are not yet standard products but are designed for the specific application. Frequently used air-to-water heat pumps, for example, must be able to raise the temperature of the ambient air to at least 80°C for a neighborhood supply (temperature level for the network if existing buildings are to be supplied and decentralized reheating or decentralized heat generators should not to be used) and may need to provide a thermal output of several megawatts, depending on the size of the heat network and the intended supply share of the heat pump. Many manufacturers of large-scale heat pumps have specialized in high performance and temperatures up to 90°C in the meantime and can offer models with good COPs.

2.1. Evaluation criteria

The conceptualization and elaboration of the supply system include the following points:

1. Demand assessment and load profiles
   For dimensioning the temperature of the supply network to e.g. neighborhoods, where the building-ages varies and usually several decades old, it is necessary to increase the flow temperature due to the associated heat losses.
   In order to consider the dimensioning of the components holistically, several potential expansion and connection stages of the supply network as well as the users must be taken into account. Therefore, variants must be considered with network expansion in the unrefurbished state of the houses and with reduced heating capacity in the refurbished state.

2. Simplicity and multifunctionality
   The biggest challenge in supply existing neighborhoods is to provide heat at a temperature level where residents can decide today whether to replace their old oil or gas boiler with a local heating solution without having to immediately invest in insulation measures for their buildings. The concept
should work both today and in several years, but in the long term the focus should be on reducing
demand.

In terms of reducing complexity, the supply concept should be as simple as possible, while also
maintaining a necessary degree of diversity and redundancy.

In order to implement the concepts, the individual systems, from heating systems to central storage
facilities, must work together in a way that serves the system. For this purpose, the grids for heat,
electricity and e.g. gas as a bivalent heat generator are intelligently connected to the individual
systems in order to optimally use the mutual flexibility potentials.

3. Space requirements and suitability for an energy center

When determining a suitable location for the energy center - building or room in which all
components for heat and power generation are placed, a basic requirement is that the location of the
energy center be close to the key connection users and be accessible by transportation. In order to
keep installation costs and distribution losses low, the distances between the heat storage facility,
energy center and heating network should also be kept as short as possible.

In the conceptual design, attention must be paid to where large open spaces, which also offer space
for redensification, are available in the area under consideration.

Furthermore, the location of the energy center must be compatible with the urban development
plans. Conflicts of use must be avoided. A minimum distance from residential buildings must be
maintained. The necessary redesignations in the land use plan to enable the construction of the heating
center must be verified and clarified in advance.

The resulting space requirement of the energy center is determined by the size of the systems to
be built, the dimensions (installation areas), the space requirement of the inspection areas and the
maintenance of the distance to trees (treetops), neighboring buildings, neighboring properties, etc. In
outdoor area, additional space must be provided for the transport infrastructure or the installation of
the air-to-water heat pumps (incl. distance compliance). The area of the energy center is often largely
determined by the air-to-water heat pumps.

When determining the space requirements, it should also be taken into account that the heating
center can be expanded for future expansion scenarios of the network and the heat demand. Therefore,
there should be potential for the energy center to be supplemented with additional components.

4. Time frame

An important criterion nowadays is the quick realizability of projects.

If the area is owned by the city/municipality or can alternatively be secured quickly, this is
advantageous for the progress of the project. A critical path in the project is the preparation and
amendment of development plans; in Germany, this should be planned for approximately 12 months.
If an area is already earmarked for energy production in the development plan, this significantly
increases the likelihood of implementation within the specified timeframe.

A longer time period of several years or even decades must be seen and planned, if the energetic
refurbishment of the buildings have to be considered.

5. Noise protection

The heat generator, all supply components and especially air heat pumps can generate noise levels
that may exceed the limits of residential areas. Therefore, noise barriers must be integrated into the
installation concept. An evaluation of the noise emissions (sound calculator) is required in order to
plan the necessary measures such as shielding wall / noise barrier or additional protection (cover
damped 1.5 m depth).

A heat supply system or the implementation of a large-scale heat pump in a supply structure requires not
only a suitable concept, but also good communication between different parties to achieve practical
implementation. In addition to the points in above (section 2.1), the corresponding tasks should also include:

- approaching the main potential customers,
- educating local residents about the project.

Acceptance has a great influence on the achievement of the project's goals but it is difficult to assess
regarding to the location of the energy center. An acceptance phenomenon is often described as "not in my
backyard", i.e. general endorsement of a project as opposed to direct and personal influence. If the project is
in an existing neighborhood, it is also complicated by the fact that almost every building has a different owner who has to be convinced of the project and can exert influence.

3. Project examples with large-scale heat pumps

Large-scale heat pumps have the potential to be used in many different ways. Due to their variability, they can cover large capacities as well as high temperatures (up to 130°C). In the following, projects will be presented, in which a large-scale heat pump is to be or has been integrated.

All projects presented are still in the planning stage, which is why only the initial planning results and calculations can be presented.

3.1. Project 1 – District in Heide

The first example shows the integration of heat pumps into a medium-sized district heating system currently planned for the city of Heide in northern Germany. The planned air/water heat pump should produce a supply temperature of at least 80°C and provide a thermal output of 1 to 2 MW. The project aims to design and implement a multimodal and sustainable energy supply system for the existing and future buildings in the district. (Fig. 1)

The selected district with an area of 20 ha is inhabited by approximately 500 people and features a diverse building structure. There are 108 single-family- and 47 multi-family-houses, as well as 27 non-residential buildings that are mostly businesses. Most of the buildings are heated with natural gas, some with oil and electricity. The annual energy demands of the existing buildings in the neighbourhood are approximately 1,683 MWh electricity, 4,932 MWh natural gas and 2,216 MWh oil, equivalent to a total of 3,410 t/a CO₂-emissions.

In the most ambitious planned stage for the district heating network, 125 buildings are connected. This includes 40 new buildings that are planned for the near future, resulting in a connection rate of 56%. Including the additional heat demand of the new buildings, the total heat demand provided by the heating grid adds up to 6,560 MWh/a.

In order to supply this heat and meet all the design criteria of the project, the energy supply system (Fig. 2) consists of various components:

- Photovoltaic installation spread over the roofs of the buildings in the district
- Dedicated electrical grid for collecting the PV electricity in the energy control central (required for regulatory reasons)
- Battery
- High temperature air/water heat pump (up to 90°C)
- Electrolysis (small, for research purposes)
- Combined heat and power plant (CHP), able to use natural gas and hydrogen
- Gas boiler used as back-up heater
- Thermal storage (water tank)
- District heating grid

An air/water heat pump is the primary heat generator, which is powered either by the photovoltaic, the output of a combined heat and power unit (CHP) or the public electricity grid. The latter is an important option for further CO₂-reductions, when electricity from the grid becomes less carbon intensive over time. Electricity can also be used to produce hydrogen in an electrolyser, which is installed for research and demonstration purposes. The use of hydrogen can be tested in the CHP in combination with natural gas, potentially used for hydrogen mobility or fed into the public gas grid. The electrolyser’s waste heat can be used for heating, but only if the temperature is further increased. For this purpose, the waste heat can become a source for the heat pump. However, the available thermal power from the electrolyser is very small compared to the demand of the heat pump. Therefore, the ambient air remains the main source for the heat pump and the system is not dependent on the electrolysis, which makes the concept more easily transferable. The CHP is the secondary heat generator and, finally, a gas boiler is used as a back-up heater. The heat produced can be stored in a large water heat storage of about 500 m³ which can store heat for several days of use. A heating grid is used to transport the heat to the buildings.

Technically, the heat pump is the most challenging component. While smaller heat pumps with lower flow temperatures used in modern buildings have been established for many years, the presented concept has more demanding requirements. The buildings supplied are from different time periods and mostly several decades old. Supplying the heat via a heating grid with its inherent heat losses further raises the required flow.
temperature. Heat storage adds an additional requirement. The available thermal energy is defined by the usable temperature difference. To store the highest possible amount of heat in a given volume of water, a relatively high temperature with up to 90°C must be achieved. For those times when the storage alone is expected to meet the full demand of the grid, it can only do so while its outlet temperature surpasses the set temperature of the grid. The lower coefficients of performance resulting from the high supply temperature can be accepted if the heat pump is powered by local photovoltaic.

As a result, air/water heat pumps of this concept must raise the temperature of the heat source (environmental air) to 80 - 90°C, while providing thermal output power of 1 to 2 MWth, depending on the final size of the heating grid and the targeted share of the heat pump (in relation to the CHP). Heat pumps suitable for these operating conditions are not yet off-the-shelf products, but instead designed for each use case. Due to the large temperature difference between source and load, manufacturers use a two stage process of either screw or piston compressors. The most common refrigerants are R717 (ammoniac) and R1234yf.

The air heat exchangers required to provide sufficient thermal source power need a large installation surface and create a noise level above the limits for residential areas of 60 dB(A) during day and 45 dB(A) at night. Therefore, noise protection barriers must be integrated into the installation concept.

Ground-source heat pumps using geothermal energy have been considered as an alternative, promising higher coefficients of performance and lower noise emissions. However, exploration drilling showed that the area available nearby for boreholes could provide only a fraction of the required annual energy demand, while increasing the investment costs drastically.

![Location plan project 1.](image)
3.2. Project 2 – Building block in Kassel

Project 2 shows the implementation of a large-scale heat pump within a building block with around 150 residential units. The planned air/water heat pump must produce a supply temperature of at least 70 to 80°C and provide a thermal output of 640 kW. The aim of the project and the guiding principle of the building owner is the motto "away from gas": all buildings in the building owner’s portfolio are to be operated with renewable energy in the future. The project is still in the design phase; all boundary conditions are currently being defined and the energy consumption to date is being determined.
3.3. Project 3 – District supply via four heating centers

Project 3 shows the implementation in four single small heating grids. The planned air/water heat pumps are to produce a supply temperature of at least 80 to 90°C and provide a thermal output of 7 MW in total (depending on the final size of the bivalent producer). The aim of the project is to convert four existing heating centers as a first step towards making all of the client's buildings and facilities fit for the future. The desire is to achieve climate neutrality for the properties.

In order to make all of the owner's sites sustainable in terms of construction and renovation activities as well as heat and power supply, the properties shown (Fig. 4) and the development potentials towards climate neutrality have to be assessed first. For the location examined, 90 buildings with about 550 residential units and a heated floor space of about 50,000 m² are assumed. The buildings accommodate different uses such as housing/assisted living or care facilities, workshop/warehouse, administration and social facilities.

Project 3 involves the conversion of four existing heating centers in the owner's entire property, which are currently operated via gas boilers and CHP units. The supply concepts to be developed should have a high share of renewable energy. The goal is to implement a share of 65 - 95% of the heat supply per heating center via air-water heat pumps (Fig. 5).

At present, the tasks are to examine the expandability of the respective heating system and the combination with thermal storage and photovoltaics for the use of self-produced electricity. The different building age classes and varying energy conditions of the buildings as well as the inhomogeneous structure at the site represent a challenge in the concept development and dimensioning. In addition, development scenarios for the site have to be worked out and defined with regard to future expansions and space requirements, as well as requirements for space- and use-specific needs.

The individual heating centers must cover a heat output of 485 kW to 5,145 kW and operate at a temperature level of 80/60°C or 90/70°C.

Fig. 4. Location plan project 3. [energydesign braunschweig GmbH]
The ecological assessment refers to the emissions that are emitted during the generation of heat via the current supply concept with gas boiler compared to the heat pump solution. The balance also includes the yields of the added PV systems and the electricity consumption. (see (1))

\[
\text{\(CO_2\) emission} = \text{\(CO_2\) emission factor} \times \text{final energy (energy source)} - \text{\(CO_2\) emission factor} \times \text{electricity production PV plant} \quad (1)
\]

Based on the examples of the new energy concepts with heat pumps for the heating centers in Area 1 and Area 3, there is an annual \(CO_2\) saving potential of 53 and 78 \% respectively compared to the current supply concept with gas boilers. This would mean a \(CO_2\) reduction of around 515 to 1,210 t\(CO_2\) annually.

- V1: heating center Area 1 – gas boiler
- V2: heating center Area 1 – Air to water heat pump
- V3: heating center Area 3 – gas boiler
- V4: heating center Area 3 – Air to water heat pump

Fig. 6. \(CO_2\)-emission of the different variants of the heating center Area 1 + Area 3 (\(CO_2\) emission factors: natural gas 270 g/kWh, electricity 400 g/kWh, displacement electricity -700 g/kWh) [energydesign braunschweig GmbH]
3.4. Projekt 4 – Data center concept study

Project 4 shows the implementation of a large-scale heat pump with waste heat from a data center in a heating network. The planned water/water heat pump must produce a supply temperature of 80 to 90°C and provide a thermal output of 10 MW. The aim of the project is to use the waste heat from the data center under consideration, which has so far been released into the environment by conventional means via cooling fans, as a source for a new district heating network.

The data center is located between two rural villages with approx. 2,000 to 2,500 inhabitants each, which are currently mainly supplied with individual heating systems and fossil fuels. It is possible to implement waste heat recovery to supply the buildings via local heating networks. Other locations that could also be considered as heat consumers can be included. (Fig. 7)

In connection with the use of waste heat, a climate-neutral supply can be established for the surrounding villages in the building stock. The waste heat from the data center is available throughout the year at a temperature level of 20 - 36°C. (Fig. 8) Currently, a waste heat output of the data center (source) of 7 - 8 MW can be assumed (full expansion of the data center). With an annual performance factor for the heat pumps of 3.3, a theoretical 87,600 MWh/a of heat can be provided to the grid. This would even exceed the total heat demand of the expansion stages to supply the villages (Fig. 7).

Even if the data center could theoretically cover the total energy for the neighborhoods, it is assumed that the heat must be stored - need for a large heat storage tank - and that additional heat generators must be integrated. The following variants are still considered in the study as additional heat generators and heat grid feeders:

- Variant A: Heat pump + electrode boiler (as back-up heating)
- Variant B: Heat pump + electrode boiler + CHP (electricity energy system)
- Variant C: Heat pump + electrode boiler + CHP (electricity energy system) + heat pump for storage (to extract heat from the storage above a certain temperature level)
- Variant D: Heat pump + high voltage electrode boiler [4] + CHP (electricity-fired power plant) + heat pump for storage + wind turbines
- Variant E: Heat pump + electrode boiler (as back-up heating) + wind turbines
- Variant F: Heat pump + electrode boiler + CHP (straw-fired energy plant) + wind turbines

![Fig. 7. Location plan and Expansion scenarios for the heating supply grid.](image)
Fig. 8. Supply concept of the heating grid with integration of the data center as a heating source

The ecological assessment refers to the emissions (see (1)) that are emitted during the generation of heat via the current supply concept using decentralized gas boilers (in Fig 9 the reference) compared to the neighborhood supply with heat pumps (in Fig. 9 Variant A, B, E and F). The balance also includes the yields of the wind turbines.

The concept variants were worked out using level 3 as an example. The results show an enormous ecological savings potential. An annual CO\textsubscript{2} saving potential of about 45 - 97 % (depending on the wind power implementation) compared to the current supply concept is available. This would mean a CO\textsubscript{2} reduction of around 3,185 to 7,122 tCO\textsubscript{2} annually.

Fig. 9. CO\textsubscript{2} emissions of the different variants for heat generation (CO\textsubscript{2} emission factors: natural gas 250 g/kWh, grid electricity 401 g/kWh)

3.5. Projekt 5 – research center for hydrogen technology

Another example is the integration of a large-scale heat pump in a hydrogen technology research facility. The project aims to improve the overall efficiency of the electrolysis by decoupling the waste heat and using it for heating applications. For this purpose, different heat exchangers are to be implemented in combination with a heat pump.
4. Conclusion

Germany is to become greenhouse gas neutral by 2045, to reach this the 65% renewable energy target for heat generation has been introduced. However, this target can only be achieved if the heat supply is restructured in terms of energy and can do without fossil fuels. Large-scale heat pumps will therefore play an important role in the medium and long-term transformation of the heat supply.

In newly built residential buildings (single-family and multi-family buildings) and non-residential buildings (office buildings), the heat pump has already become the standard heating appliance. However, the situation is different in the commercial sector, in existing buildings and at the neighborhood level. Here, the heat pump is still too rarely seen as the ideal technology. The examples given show that this should no longer be a problem in the future at the neighborhood and commercial level, and that municipalities, project developers, public utilities and other energy suppliers in particular see the opportunity to massively advance climate protection when building or modernizing neighborhoods and building blocks - and, quite incidentally, to establish sustainable business models with long-term customer relationships. An individual solution can now be found for every large property/project thanks to the very diverse use of large-scale heat pumps.

However, in order to be able to exploit the potential of this energy supply variant in the best possible way, the design and dimensioning as well as the integration into the overall supply concept are relevant. At present, unfortunately, the large-scale heat pump is still a special design that has to be planned according to the specific application.

The planning and dimensioning of supply concepts with large-scale heat pumps includes in advance an inventory to present the basics and objectives of the concept. In the first step, the demand and load profiles must be determined. If the project involves existing systems / existing buildings, future renovations and changes to the buildings must be taken into account. But also necessary changes to the existing concept, like the adjustment of the supply temperatures, have to be considered. Existing systems require increased attention during replanning so that all individual systems, from the heating system to the central storage tank, are coordinated and work together in the future.

Other factors, albeit secondary locations, should not be neglected. For example, the new location of the energy center, if required, or in general the space requirements of the new supply system must be examined and defined. Existing technical rooms could become too small if additional components such as storage tanks or the heat pump itself have to be installed.

In the entire planning process, attention must be paid to early coordination and clarification of goals and target values, as well as communication with all stakeholders and their involvement in the processing and concept development.

The projects shown relate primarily to the replacement and exchange of gas boilers and the implementation of large-scale heat pumps in the existing supply. The supply concepts are increasingly changing from a decentralized to a centralized supply. All concepts have the goal of saving as much CO₂ as possible in order to meet climate protection targets. It can be clearly seen that just by exchanging the old heat generators (fossil fuels, gas) to a heat pump (regenerative energy source) the CO₂ emissions can be reduced more than 50%. Furthermore, a high share of the heat supply should be covered by the heat pump and thus renewable. Depending on the concept, “>50% “up to 100% (total exchange) can be achieved as coverage share.

Abstract

This study is to evaluate ionic liquid as absorbents for absorption refrigeration system using Hydrofluoro-olefin (HFO) refrigerant. By examining properties of absorbent/refrigerant mixture, we found the most efficient absorbent/refrigerant pair for the absorption refrigeration system. First, we analyzed characteristics of ionic liquid as absorbent in absorption refrigeration system. Imidazolium ionic liquids have relatively low viscosity of about 10 mPa.s at 70 °C and high stability to water and air, so that we decided to apply imidazolium ionic liquid as absorbent. Then, we examined proper HFO refrigerant for the system. Among the refrigerants, R1336mzz(Z) and R1234ze(Z) are applicable for the absorption refrigeration system because both have low inflammabiliy, and high critical points over 150 °C. Next, we analyzed characteristics of absorbent/refrigerant pair. When [OMIM][BF4] is used as absorbent, R1336mzz(Z) and R1234ze(Z) have the highest solubility of 0.05848 and 0.66149 at absorber, respectively. Lastly, we analyzed performance of the refrigeration system. Since difference of solubility of [OMIM][BF4]/R1234ze(Z) is large between absorber and generator, it shows the highest COP than other pairs.

Keywords: Absorption refrigeration system; Absorbent/refrigerant pair; Ionic liquid; Hydrofluoro-olefin; Non-Random two liquid model

1. Introduction

To maintain indoor thermal comfort in summer days, the use of refrigerator is rapidly increasing. Among various refrigeration system, absorption refrigeration system is promising due to its low operating cost and low heat source temperature. The absorption refrigeration system usually used H2O/LiBr or NH3/H2O as refrigerant/absorbent pair. Those refrigerant/absorbent pairs, however, have fatal problems, such as crystallization of absorbent and corrosion [1-2]. Therefore, it is necessary to find proper refrigerant/absorbent pairs that can be used in absorption refrigeration system.

Ionic liquid has gained attraction as absorbent in absorption refrigeration system, because asymmetric structure between cation and anion of ionic liquid can help dissolve polar refrigerant, and it has good stability in air and water. Therefore, many studies are trying to apply ionic liquid in absorption refrigeration system. Firstly, research on finding substitute of LiBr in H2O/LiBr absorption refrigeration system is conducted. Some researchers examined absorption refrigeration system using H2O/[EMIM][DMP] pair. The COP of refrigeration system using ionic liquid as absorbent is about 7% lower than that of H2O/LiBr system, but it still showed relatively high COP over 0.7 [3]. Other researchers tried to increase COP of absorption refrigeration system using H2O/[DMIM][DMP] pair [4]. They insisted that COP of the refrigeration system using H2O/[DMIM][DMP] pair can provide higher COP of 0.78 compared to the system using H2O/LiBr pair by proper system optimization. Others analyzed pair of water and various imidazolium-type ionic liquids for
absorption refrigeration system, and showed that H2O/[EMIM][(CH3)3PO4] showed the highest COP of 0.69 [5]. Others tried to apply EMISE to absorb water in absorption refrigeration system [6]. Although COP of absorption refrigeration system with H2O/EMISE pair showed relatively high value of 0.66, the COP is lower than the refrigeration system with H2O/LiBr pair. Although many previous studies analyzed application of ILs as absorbent to use water as refrigerant, water is frozen below zero temperature, so that operating range of the refrigeration system using water as refrigerant is limited. Therefore, research on various refrigerant for absorption refrigeration system is needed.

Due to environmental issue, research of low global warming point (GWP) refrigerant has been actively conducted, so that researchers tried to apply ionic liquid as absorbent with low GWP refrigerant. Some researchers analyzed application of [HMIM][PF6] and [HMIM][Tf2N] as absorbent for R134a refrigerant [7]. When [HMIM][Tf2N] is used as absorbent, about 0.1 higher COP is obtained compared to the absorption refrigeration system using [HMIM][PF6] as absorbent. Other researchers analyzed performance of absorption refrigeration system with HFO/refrigerant pairs [8]. Since high solubility of R32 to [C3MIM][Tf2N], the COP of the system with R32/[C3MIM][Tf2N] pair showed the highest value of 0.734 among various working pairs. Others examined six imidazolium-type ionic liquids as absorbent for using R1234yf as refrigerant [9]. Among the ionic liquids, [HMIM][Tf2N] showed the highest COP of 0.35 among IL absorbents. The R1234yf/[HMIM][Tf2N] pair, however, showed lower COP than conventional working fluids due to low specific volume of R1234yf. Although various studies have been conducted to find proper ionic liquid for absorption refrigeration system, studies on finding proper ionic liquid for absorbing hydrofluoroolefin refrigerant is insufficient.

2. Methods

The purpose of this study is to find proper working fluid/absorbent mixture for double effect absorption refrigeration system. Therefore, we have to develop the refrigeration system model and express behavior of the mixture. The double effect absorption refrigeration system model is developed using MATLAB. Properties of HFO refrigerants are obtained by REFPROP 10.0, and that of the mixture is calculated using COSMO-RS.

The absorption cooling system is largely composed of a generator, a condenser, an evaporator, and an absorber. The double-effect absorption system is a device that aims to improve performance by adding a regenerator and a condenser, respectively, to the existing system. The working pressure of the double-effect absorption cooling system is divided into three levels, and the concentration is also divided into three levels. The schematic diagram is shown in fig 1. For the study of this system, it is necessary to assume the understanding of the phenomena of each component. The whole system is calculated assuming a steady state. At the outlet point of the low-pressure condenser, the refrigerant from the low-temperature condenser is assumed to condense to saturation, where the pressure determines the operating pressure at the mid-level. The refrigerant vaporized in the evaporator is also assumed to be saturated, where the pressure determines the low level operating pressures in the evaporator and absorber. In the absorber, the gaseous refrigerant is absorbed by the working fluid with a low concentration to become a saturated working fluid with a high concentration that satisfies the phase equilibrium state under the operating conditions. In the high-pressure regenerator and the low-pressure regenerator, the refrigerant is separated due to the difference in boiling point between the two liquids constituting the working fluid. Since only the refrigerant is separated in the regenerator, the concentration of the outlet is calculated using the same amount of absorbent. Concentration calculation and thermal equilibrium are calculated through the following equations.

\[ \sum m_i = \sum m_o \]  
\[ \sum m_i h_i = \sum m_o h_o \]  
\[ m_i x_i = m_o x_o \]

When calculating the coefficient of performance of the cycle, the energy consumed by the pump is very small and is therefore neglected.

\[ COP = \frac{Q_{\text{Evaporator}}}{Q_{\text{High Pressure Generator}} + W_{\text{Pump}}} \approx \frac{Q_{\text{Evaporator}}}{Q_{\text{High Pressure Generator}}} \]
Fig. 1. Schematic of double effect absorption refrigerator.

The pressure at vapor-liquid phase equilibrium in the absorber and the two regenerators of the double-effect absorption chiller is calculated using Raoult's law, which introduces the activity coefficient.

\[ y_i P = x_i y_i^{P, sat} \]  \tag{5}

\( x_i \) denotes the mole fraction in the liquid phase, and \( y_i \) denotes the mole fraction in the vapor state. The activity coefficient is introduced in consideration of the fact that the gas has not great non-ideality with respect to the actual gas, but the liquid phase has large non-ideality. The enthalpy of various working fluids used in a double-effect absorption chiller is calculated as follows.

\[ h = h_{Ref} x_{Ref} + h_{IL} x_{IL} + h_{mix} \]  \tag{6}

\[ h_{IL} = h_o + \int_{T_o}^T C_{p, IL} dT \]  \tag{7}

\[ h_{mix} = -RT^2 \left[ \frac{\partial (G/E)}{\partial T} \right]_P \]  \tag{8}

3. Results and discussion

3.1. HFO refrigerants and ionic liquid absorbents

In this study, we examined HFO refrigerants that are usually used in refrigeration system. Most of GWPs of HFO refrigerants and flammability are also low, so most HFO refrigerants are applicable to the refrigeration system. Moreover, these refrigerants have lower freezing point than water, so we can generate more cold heat source with refrigeration system using HFO refrigerants than that using water. Next, we examined possibility of application of HFO refrigerants to double effect absorption refrigeration system. The desirable operating ranges of HFO refrigerants are listed in Fig. 2. Here, we assumed that the desirable operating range is between triple point and critical point. Heat source temperature of double effect absorption refrigeration system is usually over 120 °C. Therefore, when refrigerants which has low critical point than heat source temperature, the thermodynamic cycle will be operated in super critical state. Unfortunately, the studies on super critical state of HFO refrigerant are insufficient. Therefore, the refrigerant which has higher critical point than heat source temperature is recommended, such as, R1336mzz(Z) and R1234ze(Z).
Next, proper ionic liquids are examined. Ionic liquids consist of large cation and small anion. This asymmetry leads to weak attractive force, so that ionic liquids have low melting point. Characteristics of ionic liquids are determined by combination of cation and anion. Especially, flow characteristics of ionic liquids are mainly determined by structure of cation. The characteristics of various cation are listed in Table 1.

Among the flow characteristics, viscosity is one of important factors that affects performance of the refrigeration system. Therefore, we examined viscosities of ionic liquids based on cations shown in Fig. 3. In this study, we examined viscosity of ionic liquids with 1-ethyl-3-methylimidazolium (EMIM), N-methyl-N-propylpyrrolidinium (P13), trimethyl propylammonium (TMPA), and 1-ethyl-2,3,5-trimethylpyrazolium (ETMP) comparing with H2O/LiBr solution of 59.9 wt%. Most ionic liquids have higher viscosity than that of H2O/LiBr solution. Among the ionic liquids, however, imidazolium type ionic liquid has relatively low viscosity. Over 50 °C, viscosity of EMIM is lower than 20 mPa.s. Therefore, we concluded that EMIM ionic liquids are promising for absorption refrigeration system.

3.2. Examination of HFO refrigerants/ionic liquid absorbents solution

In this section, we analyzed application of HFO refrigerant/ionic liquid mixture for double absorption refrigeration system. Here, heat source temperature of the refrigeration system is 140 °C, and temperatures of pressure generator and absorber are 37 °C and 80 °C, respectively. Candidate of HFO refrigerants are R1336mzz(Z) and R1234ze(Z) and that of ionic liquids are imidazolium type ionic liquids. Results of the mixture are compared to water/ionic liquid pair.

Solubility of R1234ze(Z) with various ionic liquids are shown in Fig. 4. Here, solubility of refrigerant is expressed using concentration that is defined by mass fraction of refrigerant weight and solution weight. Since the highest concentration is observed absorber and the lowest concentration is observed in low-pressure generator. Therefore, we compared concentration in low-pressure generator and absorber. The Concentration of R1234ze(Z) is increased according to saturation pressure. For example, the solubility of R1234ze(Z)/[OMIM][BF_4] mixture increased from 0.15 to 0.32 when saturation pressure increased from 30 kPa to 90 kPa. The concentration of the mixtures, however, inversely proportional to temperature. For example, the solubility of R1234ze(Z)/[OMIM][BF_4] mixture at 100 kPa decreased from 0.37 to 0.14 when the temperature increased from 37 °C to 80 °C.

Among the refrigerant/absorbent mixtures, R1234ze(Z)/[OMIM][BF_4] pair is the only promising pair for the double absorption refrigeration system. Because the concentration at absorber is lower than that in low-pressure generator when other refrigerant/absorbent mixtures except R1234ze(Z)/[OMIM][BF_4] pair. When we use [OMIM][BF_4] as absorbent, the concentration of refrigerant at absorber is 0.01 higher than that at low-

![Fig. 3. Changes in viscosity of ionic liquids depending on various cation with Tf 3N anion [10].](image)

![Fig. 4. Comparison of solubility of R1234ze(Z) with various ionic liquids in double effect absorption refrigeration system.](image)
pressure generator shown in Fig. 5. Therefore, R1234ze(Z)/[OMIM][BF₄] is good for double effect absorption refrigeration system.

Fig. 5. Concentration of R1234ze(Z) at absorber and low-pressure generator with various ionic liquids.

Next, solubility of R1336mzz(Z) examined with various ionic liquids shown in Fig. 6. Similar to R1234ze(Z), solubility of R1336mzz(Z) is proportional to pressure, and inversely proportional to temperature. In case of R1336mzz(Z) with [HMIM][TfO], concentration is increase from 0.22 to 0.58 when saturation pressure increased from 150 kPa to 300 kPa. Concentration decreased from 0.8 to 0.15 when the temperature increased from 37 °C to 80 °C at saturation pressure of 100 kPa. Among the mixtures, R1336mzz(Z)/[HMIM][Tf2N] pair showed the highest solubility. At 600 kPa, concentration of R1336mzz(Z) with [HMIM][Tf2N] is about 0.42.

Fig. 6. Comparison of solubility of R1336mzz(Z) with various ionic liquids in double effect absorption refrigeration system.

In case of R1336mzz(Z), however, the concentration of refrigerant at absorber is lower than that at generators. To operate absorption refrigeration system, the concentration of refrigerant at absorber should be higher than that at generator. Because refrigerants are absorbed to absorbent at absorber. Therefore, R1336mzz(Z) is inappropriate refrigerant for absorption refrigeration system in given condition.

Solubility of water with various ionic liquids also analyzed shown in Fig. 7. Changes in solubility of water with ionic liquids are similar to other refrigerants. The higher the saturation pressure, the higher the solubility, and the higher the temperature, the lower the solubility. Among the mixture, H₂O/[EMIM][Ac] pair shows the largest solubility. In low-pressure generator, the concentration is about 0.65 at 5 kPa.
However, concentration difference between at absorber and low pressure generator is the largest for H₂O/[DMIM][DMP] mixture shown in Fig. 8. Therefore, H₂O/[DMIM][DMP] is suitable for the absorption refrigeration system.

![Fig. 7 Comparison of solubility of water with various ionic liquids in double effect absorption refrigeration system.](image)

![Fig. 8. Operating range of high pressure generator for the absorption refrigeration system using water with various ionic liquids.](image)

### 4. Conclusion

In this study, proper HFO refrigerant/ionic liquid pairs for double effect refrigeration system are examined. We analyzed properties of various mixtures for the double effect absorption refrigeration system depending on working fluid/ionic liquid.

1. Among HFO refrigerants, R1234ze(Z) and R1336mzz(Z) are promising refrigerants for double effect absorption refrigeration system. Because heat source temperature of double effect absorption refrigeration system is higher than the critical point of rest of HFO refrigerants. Therefore, only R1234ze(Z) and R1336mzz(Z) can be exited in stable condition under operating condition of double effect refrigeration system. In case of ionic liquid, imidazolium type ionic liquids are suitable for the refrigeration system. Because viscosity of imidazolium ionic liquid has relatively low value compared to other ionic liquids.

2. The solubility of HFO refrigerant/ionic liquids are examined to find promising mixture for the absorption refrigeration system. For R1234ze(Z), [OMIM][BF₄] is promising due to high solubility of 0.28 in low pressure generator at 300 kPa. It also has high concentration difference between absorber and generator, so that large amount of refrigerant can be supplied to evaporator. In case of R1336mzz(Z), however, concentration of refrigerant at absorber is lower than that at generators, it is not suitable refrigerant for the absorption refrigeration system. We also analyzed solubility of water to ionic liquid absorbent. Although the highest solubility can be found for H₂O/[EMIM][Ac] mixture, concentration difference between absorber and generator is relatively small. Therefore, we recommended that H₂O/[DMIM][DMP] is promising absorbent for water.

Abstract

This study demonstrates the feasibility of a near-isothermal compressor for the transcritical CO$_2$ compression cycle. A copper tube-based compression chamber was designed, built, and installed in the open-loop liquid piston compression system. The oil compressed the CO$_2$ in the chamber from 40°C, 4,000 kPa to 10,000 kPa by an external gear pump. A 59% isothermal compression efficiency was measured at 900 RPM motor speed. To increase the efficiency, we tried the following two options: (1) lower the operation speed and (2) enhance the heat transfer rate. Evaporative cooling was applied by installing a mist generator in front of the chamber to improve the outer heat transfer performance. According to the experimental results, simply slowing down the operation to 270 RPM increases the efficiency to 80%, and combining evaporative cooling and slower operation delivers 93.8% of isothermal efficiency. Under this enhancement, the compression power can be 30% less than the isentropic compression. Several suggestions have been proposed to improve the current prototype’s performance.

Keywords: Isothermal compression; Trans-critical CO$_2$; Efficiency; Heat pump; Refrigeration

1. Introduction

The transcritical CO$_2$ application has been getting much attention recently, considering it has numerous advantages over traditional HFC refrigerants. First, CO$_2$ refrigerant is much cheaper than the HFC or HFO system. Second, CO$_2$ is a natural refrigerant with a global warming potential of 1, which will not be regulated. Hence, many researchers in academia and industry have considered CO$_2$ as a long-term solution for approaching carbon neutrality. Many applications are being studied and investigated, including vehicle heat pumps, residential heat pumps, heat pump water heaters, heat pump dryers, and commercial refrigeration [1].

Many methods can improve the efficiency of the transcritical CO$_2$ system, such as optimizing the gas cooler design, improving the control logic through artificial intelligence, or recovering the expansion work by using an expander, ejector, vortex tube, and so on. One of the intriguing approaches is reducing the compression work through isothermal compression. It can be commonly seen in Compressed Air Energy Storage (CAES) for isothermal compression technology to reduce the work required for compression, increasing the charge-discharge efficiency for CAES [2]. Unlike these conventional approaches, we proposed an integrated gas cooler compression system combining the gas cooler and compression chamber. In the typical transcritical CO$_2$ system, refrigerants are compressed isentropically, carrying the compression work to the gas cooler. Then the compression work and inherent internal energy are discharged into the environment. So the refrigerant enthalpy can reach the designed conditions. This study integrates these two processes into a single isothermal compression process, compressing the refrigerant and discharging the heat simultaneously and isothermally to

E-mail address: yhhwang@umd.edu.
improve the system's efficiency. This work demonstrates the suggested idea's feasibility and proposes future design improvement suggestions.

2. Isothermal and Isentropic Compression in Transcritical CO₂

The transcritical CO₂ near-isothermal compression demonstrated excellent potential for compression work reduction and is compared with the isentropic compression process using the property chart in EES (Engineering Equation Solver). In Figure 1, the red square symboled curve illustrates the CO₂ refrigerant being isentropically compressed from 40°C and 4,000 kPa inlet to 10,000 kPa outlet. It should be noted that this suction condition is after considering the suction line heat exchanger to be employed. For isentropic compression, the compression work is the enthalpy difference between the initial and final state, which follows the isentropic line in the P-h diagram. On the contrary, the compression work of isothermal compression includes heat discharged out of the compression chamber to keep the constant compression temperature. Hence, the isothermal compression work could not be shown in the P-h diagram but can be evaluated in another way as follows. First, the isothermal compression process is divided into many finite segments. As an example, 100 segments are shown in Figure 1. Each segment comprises an isentropic compression and an isobaric cooling along the isothermal line. Then the isothermal compression work was derived by integrating the tiny consecutive compression and cooling operation for 100 segments. The other way is to integrate the pressure and volume variation during the compression process, as shown in Eq. (1).

\[
W = \int_{V_i}^{V_f} PdV = \int_{V_i}^{V_f} \frac{ZnRT}{V} dV = ZnRT \ln \frac{V_f}{V_i}
\] (1)

where \(Z\) is the compressibility factor.

By comparing the finite segments approach with the ideal gas law approach, the calculated work difference is only 0.2%. Since pressure and temperature sensors are installed in the system, the refrigerant status can be calculated immediately and reflected in the P-h diagram. Therefore, the finite segments method would be applied to the following calculation to facilitate the compression work estimation.

Table 1 illustrates the work input requirement to compress the CO₂ refrigerant from 40°C, 4,000 kPa to 10,000 kPa isothermally or isentropically. The isothermal compression work is 32.9 kJ/kg, and the isentropic compression work is 48.5 kJ/kg. Therefore, if the isothermal compression process replaces the isentropic compression in transcritical CO₂, the overall potential work reduction can achieve 32.1%, which benefits the refrigeration industry by cutting off the carbon footprint. The following chapter explains how this study experimentally approaches the near-isothermal process and demonstrates the possible work reduction using this technology.

Fig. 1. CO₂ Compression Processes in P-h Diagram
3. Experimental Facility

3.1. Isothermal Compression Process Mechanism

A simple figure illustrating the fluids’ movement was created to give the readers a better understanding of how we approach near-isothermal compression. In Figure 2, the CO₂ refrigerant stored in the compression chamber was compressed by pressurized oil, and the CO₂ pressure increased when the oil level elevated. Meanwhile, forced air cooling discharged the CO₂ compression work and its internal energy from the compression chamber, maintaining the isothermal process. Once the CO₂ pressure reached the designed pressure, the pressure regulator opened, and the compressed CO₂ was delivered downstream. The compression process finished when the upper optical sensor detected the oil level.

3.2. Experimental Facility

The first open-loop liquid piston isothermal compressor prototype has been designed for CO₂ and built to demonstrate the near-isothermal compression process, as shown in Figure 3 and the actual picture in Figure 4. The dimensions of the experimental facility, including integrated gas cooler compression chamber, tube diameters, and gear pump capacities, were developed based on delivering 1.75 kW of cooling capacity. Therefore, the self-built compression chamber utilized 17 of 6.2 mm inner diameter copper tubes with an outer diameter of 9.5 mm. The 1.65 mm wall thickness was designed to have a working pressure of 16,500 kPa and a burst pressure of 25,000 kPa with a safety factor of 1.5. The overall dimensions of the chamber are 0.61 m wide and 0.55 m height. And the overall heat transfer area is 0.279 m². The detailed chamber design parameters are listed in Table 2.

In Figure 3, the experimental facility is categorized into three major sections: (1) The left-hand side liquid oil circulation section. (2) The integrated gas cooler compression chamber. (3) The right-hand side compressed CO₂ storage and release section. At the beginning of the compression process, the mineral oil was fed into the 9.5 c.c gear pump at a given driven speed from the open oil tank. The atmosphere pressure oil was compressed
to 11,000 kPa limited by a back pressure regulator to ensure the liquid piston pressure was large enough to compress CO$_2$ to 10,000 kPa. In parallel, there is a relief valve set to 12,000 kPa for its bypass back to the oil tank in case of any unexpected situation. Since the gear pump operated continuously, even not in the compression process, the friction loss would increase the oil temperature. Before entering the compression chamber, an oil heat exchanger was placed to prevent heat accumulation and maintain the constant oil temperature. Two solenoid valves break down the liquid piston cycle into compression and suction process. If the compression solenoid valve opens and the suction solenoid closes, the oil flows into the compression chamber and starts compressing, and if the compression solenoid closes and the suction solenoid opens, the oil flows back to the oil tank. The compression speed depends on the driving speed of the motor. On the other hand, the suction speed depends on the opening of the needle valves. The longer the suction time, the more accurate the replenishment mass flow rate would be, but it reduced the cycle frequency or cooling capacity.

Fig. 3. Experimental Facility Schematic Diagram

The aforementioned integrated gas cooler compression chamber is located in the middle of the facility. The system’s criteria for deciding when to compress and release depends on two optical leveling sensors. When the dyed mineral oil passes through the bottom-level sensors during the suction process, the detected sensor signal change makes the compression solenoid open, the suction solenoid close, and the compression process starts. When the oil reaches the top of the level sensor, the system responds vice versa.

Upon reaching 10,000 kPa for the CO$_2$ refrigerant compression, the compressed CO$_2$ passes the upper back pressure regulator and enters the receiver. During the suction process, a certain amount of CO$_2$ was degassed from the mineral oil because of the solubility difference between 10,000 kPa and atmosphere pressure. Hence, the CO$_2$ from the supply tank would compensate for this loss and be mixed with CO$_2$ from the receiver. Altogether, the mixed CO$_2$ was conditioned to 40°C and recorded by the mass flow meter before flowing back into the compression chamber.

3.3. Instruments and Uncertainties

Table 3 lists the experimental facility’s instruments and their systematic error. All the instruments were calibrated before being installed in the facility. The data were acquired when the system operated for at least half an hour and reached a steady state.

3.4 Test Matrix

The experimental facility was built inside the environmental chamber, which was set at 35°C and 20% humidity. The initial chamber's temperature and pressure were set to 40 °C and 4000 kPa, respectively. And the final chamber pressure is 10,000 kPa. Two pump speeds, 270 RPM and 900 RPM have been chosen. In addition to the fan cooling, the room-temperature water mist was sprayed on the compression chamber surface as a heat transfer enhancement method in test #3, and an additional fan was installed to facilitate the water evaporation.

4. Results and Discussion

4.1. 900 RPM Operation with Axial Fan Cooling: Test #1

The motor operation speed of 900 RPM has been chosen to observe the compression chamber’s temperature and pressure variation under the isothermal compression process. In Figure 4, the upper graph displays the pressure variation in each measuring section. When the compression process starts, the pump elevates the liquid piston and compresses the refrigerant in the chamber, increasing the pump and chamber pressure simultaneously. Once the chamber pressure reaches 10,000 kPa, the upper back pressure regulator opens, and the compressed CO\textsubscript{2} flows into the receiver, which causes the suction pressure to increase. After the oil level reaches the upper-level sensors, the solenoid valves are switched, and the suction process is started. Consequently, the pump pressure built up because the compression solenoid valve closed, and the chamber started to decompress to the initial conditions (40°C, 4,000 kPa) and then started the compression process over again.

Compared with the isentropic compression, which would result in a 117°C chamber temperature under the same given conditions, the current temperature increased to 55°C with a 15 K lift, demonstrating a 62 K temperature suppression. The chamber temperature in Figure 4 describes this temperature suppression for the test #1 condition. One thing worth noting is that the temperature curve has a noticeable slope change at around 7,000 kPa. It can be attributed to heat transfer area reduction and the reaching of the local CO\textsubscript{2} pseudocritical point. First, the heat transfer area between the compressed CO\textsubscript{2} and the environment becomes less as the liquid oil level upraises during compression. Second, Figure 5 shows that CO\textsubscript{2} density and specific heat increased dramatically from 4,000 kPa to 10,000 kPa, which means the internal energy is significantly different. The same thing can be observed in the P-h diagram, shown in Figure 1. A significant enthalpy drop can be found along the 40°C isothermal line. These factors make the chamber temperature inevitably deviate from the isothermal process.
The compression power curve and the mass flow rate of replenished CO₂ are depicted in Figure 6. Due to the open-loop design, the gear pump has to consume energy to hold the pump pressure to 4,000 kPa from atmospheric pressure, corresponding to the power consumption below the black line, which is about 1 kW. The motor power can be derived by integrating along the power line above the black line. According to the given product specification, the gear pump and motor have a combined efficiency of 0.72, and the actual work input for compressing the CO₂ must consider this factor. At the bottom of Figure 6, refrigerant replenishment can be derived by integrating the mass flow rate curve, and the integrated value stands for the initial CO₂ mass stored in the chamber for the next compression cycle.
4.2. 270 RPM Operation and Evaporative Cooling Heat Transfer Enhancement: Tests #2 and 3

Based on the experimental results from the 900 RPM operation, which has 59.7% of isothermal efficiency, the current chamber design was too small to approach the near-isothermal operation for 1.75 kW cooling capacity. Nevertheless, the near-isothermal operation is still achievable by manipulating the control operation and heat transfer enhancement.

First, the motor compression speed is decreased to 270 RPM, the minimum allowable operating speed for the installed gear pump (Test #2). By slowing down the compression process, the extended heat transfer time helps discharge the accumulated heat inside the compression chamber. In contrast to Figures 5 and 6, Figure 7 only focuses on the single compression stroke. As shown in the upper left of Figure 7, the temperature lift is reduced to 10.6 K compared to 15 K in 900 RPM operation. For evaluating how the entire process is close to the isothermal compression, isothermal efficiency is defined as the ideal isothermal compression work divided by the actual compression work, which can be found in Eq. (2). And the motor plus pump efficiency was defined as actual compression work divided by the integrated work from the measurement, as shown in Eq. (3).

\[
\eta_{\text{iso}} = \frac{W_{\text{isothermal}}}{W_{\text{actual}}} = \frac{\text{Mass}_{\text{chamber}} \cdot W_{\text{isothermal}}}{W_{\text{integrated}}} \eta_{\text{motor+pump}} \tag{2}
\]

\[
\eta_{\text{motor+pump}} = \frac{W_{\text{actual}}}{W_{\text{integrated}}} \tag{3}
\]

In Eq. (2), the \( W_{\text{isothermal}} \) represents the ideal compression work for the amount of CO\(_2\) in the compression chamber, which was the product of CO\(_2\) mass and the specific ideal isothermal work. The CO\(_2\) mass can be derived from the initial CO\(_2\) density and chamber volume. And \( W_{\text{isothermal}} \) is the specific ideal isothermal work calculated from the second section, 32.9 kJ/kg. The actual work is calculated from the integrated work multiplied by the efficiency of the motor and pump. A 59.7 % isothermal efficiency can be found for operating the system at 900 RPM. As a comparison, a significant improvement to 80% isothermal efficiency can be achieved by slowing down the pump speed to 270 RPM.

Fig. 7. Compression Behaviour Comparison at 270 RPM
Except for slowing down the rotation speed, additional heat transfer enhancement can be applied to the integrated gas cooler compression chamber (Test #3). While the current chamber’s configuration limited the improvement method, evaporative cooling was chosen to help further enhance the heat transfer. According to Heyns and Kroger (2010), the water film heat transfer coefficient ranges from 1,500 to 3,000 W/m²·K, which is the function of the deluge water mass flow rate, air mass flow rate, and deluge water temperature. The enhancement can significantly reduce the thermal resistance at the outer surface. Hence, a water mist generator was placed in front of the compression chamber. We made sure all the tubes were sufficiently wet during the compression chamber. In addition, one more axial fan was installed to improve the air volumetric flow rate, helping the water evaporate from the tube surface. By doing so, the temperature curve in Figure 7 shows further temperature suppression and maintains a relatively low-temperature increase compared to test #2. In the upper right of Figure 7, the pressure shows an evident suppression from 7,000 to 9,000 kPa, which has the most heat needed to be removed in the entire process.

However, a rapid increase in temperature and pressure occurred around 9,000 to 10,000 kPa because the heat transfer area was still too small to discharge heat. Evaporative cooling effectively improves the heat transfer rate and isothermal efficiency, which results in a 93.8% achievement. A detailed comparison can be found in Table 5. However, the lower motor RPM results in a decrease in cooling capacity. Assuming a gas cooler and a suction line heat exchanger were installed in the system, the cooling capacity in each test would be 1719, 674, and 743 W, respectively.

Although the demonstrated prototype achieved high isothermal efficiency, many future design opportunities can improve furthermore. First, water has become scarce as climate change exacerbates yearly, and using it as a heat transfer enhancement is not the ideal option. Instead, different geometries or fins would be applied to the outer compression chamber to increase the heat transfer area and coefficient. Second, the preliminary thermal resistance analysis shows that the CO₂ side was the dominant contributor to the overall thermal resistance compared with the conduction resistance and external resistance. Therefore, the heat transfer enhancement technique should also be applied to the internal chamber to lower the thermal resistance. Third, due to the lower operation speed, the average CO₂ mass flow rate was much lower than the design capacity. The number of tubes for the compression chamber should be increased accordingly to increase the heat transfer area and cooling capacity.

### 5. Conclusions

The prototype of a near-isothermal compressor for transcritical CO₂ has been built and demonstrated the capability of achieving high isothermal efficiency. In this study, a 0.61 m by 0.55 m integrated gas cooler compression chamber was self-built, utilizing 17 tubes in 9.5 mm diameter. The compression process was set to compress 40°C, 4,000 kPa CO₂ to 10,000 kPa. Three different operation conditions were performed and compared: (1) 900 RPM compression with fan cooling, (2) 270 RPM compression with fan cooling, and (3) 270 RPM compression with evaporative cooling. The demonstrated isothermal efficiency was 59.7%, 80%, and 93.8%, respectively. Based on the current experimental results, three main improvement options were suggested: (1) enhance the outer heat transfer area and geometry of the compression chamber, (2) improve the inner heat transfer rate by applying turbulators or internal fins, and (3) increase the number of such tubes to enable a faster compression speed for higher system capacity. This study demonstrated that the near-isothermal compression process could be achieved. The 93.8% isothermal efficiency contributes 30% of the compression power input savings compared to traditional isentropic compression, which may facilitate the world and industry to achieve net-zero emissions.

Abstract

The US heat pump market has been affected by the socioeconomic impacts of the COVID-19 pandemic. However, the Biden administration’s goal of net-zero greenhouse gas emissions by 2050 through electrification and clean energy technologies is accelerating the research, development, and deployment of heat pumps in the United States for improved energy performance, reduced greenhouse gas emissions, and wider adoption. The US heat pump market has experienced steady growth since 2010. In 2020, heat pumps surpassed gas furnace shipments for the first time, and the trend maintains through 2022. The current priority is to improve the affordability of energy and equitable access to heat pump technologies through cost reductions and further accelerate this trend. In addition, current R&D includes emphases on alternative refrigeration technology and lower–global warming potential refrigerants to reduce direct emissions. Heat pump market share is expected to grow as regulatory policies and financial incentives steer the building sector toward decarbonization. This paper reviews policies and market trends, discusses the challenges and opportunities in the current policy landscape, and reviews current research in the United States.

1. Introduction

The halt in manufacturing and construction activities due to partial or complete lockdown during the COVID-19 pandemic severely impacted the global economy, including the heat pump market, in 2020 [1]. In 2021, global economy recovery began. However, the growth has been fragile because of the continued pandemic and geopolitical and economic uncertainties [2]. According to the United Nations [3], the economic impacts of the war in Ukraine has had both positive and negative effects on climate action. In particular, countries have an opportunity to address high prices and resource availability concerns by accelerating the adoption of clean energy, which also strengthens the fight against climate change [3]. Specifically, heat pump technologies are receiving unprecedented priority to reduce the use of fossil fuels and vulnerability to supply disruptions in response to the global energy crisis [4].
2. US Policies and Programs

The Biden administration’s affirmative response to international climate change agreements, including Paris Climate Accord to limit and resist climate change [5], and the Kigali Amendment to Montreal Protocol to phase down the consumption and production of hydrofluorocarbons [6], confirms a commitment toward global clean energy economy. The United States has set forth the goals to reduce greenhouse gas (GHG) emissions by 50%–52% from 2005 levels in 2030, decarbonize the US power sector by 2035, and achieve a net-zero emissions economy by 2050 [7]. Minimizing the emissions from buildings has been a priority to accomplish these goals [8]. Federal investments have been allocated to modernizing and upgrading buildings to be affordable, resilient, accessible, energy-efficient, and electrified [9]. A number of policies have been implemented, and targeted actions are taken to support heat pump technology research, expand deployment, and address supply chain vulnerabilities. Figure 1 shows a timeline of policies since 2020 that have supported the development and adoption of heat pump–related technologies.

Fig. 1. Heat pump–related policies since 2020.

2.1. Policies and programs to support heat pump research, development, and deployment

In May 2021, the US Department of Energy (DOE) launched the E3 Initiative for improved energy, emissions, and equity to advance the research and adoption of clean energy technologies, including heat pumps. Initial actions under the E3 initiative included a nationwide Advanced Water Heating Initiative to increase market adoption of high-efficiency, grid-connected heat pump water heaters in residential and commercial buildings; the Residential Cold Climate Heat Pump Technology Challenge to accelerate the performance of cold climate heat pump technologies; and new collaborative research, development, and deployment efforts partnering national laboratories and manufacturers to accelerate the development of low–to no–global warming potential (GWP) refrigerants [10]. The focus of the E3 Initiative expanded to workforce solutions that ensure proper installation and maintenance through the Residential HVAC Smart Diagnostic Tools Campaign; and understanding implementation challenges through the Better Buildings Low Carbon Pilot [11].

2.2. Policies and programs to support heat pump supply chain

The United States has implemented international and domestic policies to respond to supply chain vulnerabilities and build up domestic manufacturing capacity. In May 2021, Japan and the United States collaborated under the Japan–US Clean Energy Partnership to accelerate the deployment of heat pumps in their respective domestic and global markets through support for manufacturing, training, and promotion [12]. On May 22, 2021, two bills—the ICEE HOT Act and HEATR Act—were introduced, which provide incentives for manufacturers and distributors of heat pumps [13]. In June 2022, the Defense Production Act was invoked to rapidly expand US manufacturing of five critical clean energy technologies, including heat pumps [14].
2.3. Policies and programs to increase affordability for heat pump technologies

To improve the affordability of energy and equitable access to heat pump technologies, the United States launched the Justice40 Initiative in January 2021, with the aim to direct 40% of the overall benefits of certain federal investments, including clean energy and energy efficiency, toward disadvantaged communities [15],[16]. These include R&D investments in the development of low-cost heat pump technology solutions and financial incentives for consumers. In August 2022, the Inflation Reduction Act was introduced, which offers tax credits and rebates for families to buy heat pumps and other energy-efficient home appliances, and rebates to low- to moderate-income households to electrify their homes [17].

3. Heat Pump Market

A review of the US heat pump market is presented in terms of prevalent heat pump technologies, market growth compared with competing heating and cooling technologies, and share in existing and new residential and commercial building sectors. Potential factors such as climate, energy price, efficiency standards, and financial incentives that impact the heat pump market are discussed.

3.1. Shipment

As shown in Figure 2, US heat pump market shipments predominantly comprises air source heat pumps. Heat pump water heaters, water loop heat pumps, and ground source heat pump comprised a little over 7% of heat pump sales in 2022 [18]. More than 96% of air source heat pumps have a capacity of 19 kW or less [19].

Figure 3 shows the annual shipments of air source heat pumps (green) compared with gas and oil furnaces (orange and yellow, respectively) and central air conditioners (blue) since 2001. Despite the sharp drop in the shipments of all heating and cooling equipment during the 2006–2007 housing market collapse, the share of heat pumps (black dotted) has shown a relatively consistent increasing trend. In 2020, heat pumps surpassed gas furnace shipments for the first time and the trend maintains through 2022, reaching 52.6%. Meanwhile, the heat pump share in cooling equipment market reached 41.7% in 2022 [19].

Fig. 2. 2022 market distribution of heat pump technologies.

Fig. 3. Air source heat pump shipments compared with furnaces (left) and central air conditioners (right).
Figure 4 shows the sales of water loop heat pumps and heat pump water heaters since 2006 [18]. Water loop heat pumps are typically installed in multifamily buildings, hotels, dormitories, and so on, which may require simultaneous heating and cooling. Water loop heat pump shipments also saw a drop since 2007 due to the housing market collapse, and again, since 2019 as construction activities slowed down due to COVID-19 pandemic [18]. Heat pump water heaters have experienced a dramatic increase in sales due to the National Appliance Energy Conservation Act 2015 that requires higher energy factor ratings on all residential and some light-duty commercial products, and requires all electric water heaters of over 55 gal to use heat pump water heating technology [18].

Figure 5 shows the annual shipments of ground source heat pumps (GSHP) in the last 20 years [18]. It shows a steady increase from 2003 to 2011, first, due to increasing natural gas price, and since 2009, when the federal government started offering tax rebates for GSHP installation. GSHP shipments were apparently affected when tax credits expired in 2016, but jumped back in 2019 when tax credits were reinstated. The GSHP shipment dropped again in 2020 due to the COVID-19 pandemic and the resulting halt in construction activities and supply chain issues [18]. The low natural gas price during the pandemic may also have contributed to the staggering growth of GSHP applications in the United States.

3.2. Market share

The US Energy Information Administration’s (EIA’s) 2020 Residential Energy Consumption Survey estimates that approximately 15% of existing US homes use electric heat pumps as their primary heating source. The heat pump market share is higher in the South, where heat pumps serve one-third of existing homes [20]. The heat pump market share is smaller in the commercial building sector. According to EIA’s 2018 Commercial Building Energy Consumption Survey, only 4.5% of existing US commercial building floorspace is served by electric heat pumps [21].

Based on the US Census Bureau’s housing data [22], the market share of heat pumps in new single-family construction has stayed relatively constant since 2012. More than 39% of single-family homes completed in the United States in 2021 used a heat pump as their primary heating source (Figure 6, left). An estimated 59% of single-family homes completed in the South in 2021 used a heat pump for heating. The share has remained at 60% or more since 2011 (Figure 6, right). In the West, the installation of heat pumps has been ramping up, reaching 17% in 2021—the highest share since 1986. The housing construction, as well as the heat pump share, has declined in the Midwest. The heat pump market share has fluctuated in the Northeast, but stayed at a share of less than 10% [18].
3.3. Energy price

Figure 7 shows the historical and projected prices of electricity and natural gas for residential sector in the United States [23],[24]. Both nominal and real prices\(^1\) are shown to allow for a more accurate comparison between the past and predicted values. Over the 2007–2018 period, natural gas prices have decreased, and electricity prices gradually risen (or remained relatively level in terms of real price). Under nominal conditions\(^2\), the prices are predicted to change with a 2022–2050 growth rate of 2.2% for electricity (-0.2%, considering real price) and 1.8% for natural gas (-0.5%, considering real price) [24].

\[\text{Electricity: Real Price (2022$)}\]
\[\text{Natural Gas: Real Price (2022$)}\]

\[\text{Electricity: Nominal Price}\]
\[\text{Natural Gas: Nominal Price}\]

Fig. 7. US average historical and projected residential electricity and natural gas prices.

Figure 8 shows the 2021 natural gas and electricity prices by state [25],[26]. The regional differences in the heat pump market share, as noted in Figure 6 (right), can be attributed to the mild winter combined with lower electricity and higher natural gas prices in the southern states.

\[\text{Electricity:} \quad 22.89 \text{ cents/kWh}\]
\[\text{Natural Gas:} \quad 22.9 \text{$/1000 cu ft}\]

\[\text{Electricity:} \quad 10.11 \text{ cents/kWh}\]
\[\text{Natural Gas:} \quad 7 \text{$/1000 cu ft}\]

Fig. 8. 2021 residential energy prices by US state: (left) electricity and (right) natural gas.

\(^1\) Nominal price is the price paid for a product or service at the time of the transaction. Real price is a price that has been adjusted to remove the effect of changes in the purchasing power of the dollar, expressed in constant dollars relative to a base year.

\(^2\) The EIA’s Annual Energy Outlook modeled projections include cases with different assumptions about macroeconomic growth, world oil prices, and technological progress. The Reference Case represents projections under nominal conditions, which presumes no new policy or laws over the modeled time horizon.
3.4. Financial incentives

Heat pump installations in the United States have been in part driven by an array of tax credits. As part of the Inflation Reduction Act of 2022, federal tax credits have been extended through 2032 [27]. Equipment tax credits of $300 is available for installing air source heat pumps and heat pump water heaters in existing homes that meet specified efficiency criteria. Renewable energy tax credits are available for geothermal heat pump installation in existing homes and new construction, with a gradual step down in the credit value (i.e., 22%–30% of system cost) based on the year the system is placed in service. In addition, most states offer rebate programs for air source and geothermal heat pump installation [28]. Other common financial incentive mechanisms are available as loan programs, grant programs, and Property-Assessed Clean Energy financing [28]. The recent high natural gas prices and the uncertainties in natural gas supplies make the investment in GSHP systems more economically viable than during the pandemic. For example, New York and Massachusetts have invested in several pilot projects for district-scale GSHP systems [29].

Furthermore, under the High-Efficiency Electric Home Rebate Act, a part of the Inflation Reduction Act of 2022, point-of-sale consumer rebates are available for low- and moderate-income households to electrify their homes. The rebate covers 50%–100% of purchase and installation costs up to $14,000 on electrification measures, including heat pumps, heat pump water heaters, panel/service upgrades, electric stoves, clothes dryers, and insulation/air sealing measures [30].

These financial incentives help reduce the cost burden on consumers of heat pump technologies and support electrification.

3.5. Efficiency Standards

In the United States, the cooling and heating efficiency of central heat pumps is measured by seasonal energy efficiency ratio (SEER)³ and heating seasonal performance factor (HSPF)⁴. The minimum efficiency standards for heat pumps were established in 1992 and were updated in 2006 and 2015 [31]. In 2017, DOE announced changes to the testing procedure and rating descriptor for central air conditioners and air source heat pumps. Effective January 2023, they will be rated by SEER2 and HSPF2 (as opposed to the current SEER and HSPF rating descriptors) following a more stringent testing procedure. The new testing procedure increases the systems’ external static pressure by a factor of five to better reflect field conditions of installed equipment in a typical ducted system and results in a lower numerical rating value for the same product [32]. Thus, beginning in 2023, all new residential air source heat pump systems sold in the United States are required to meet or exceed 14.3 SEER2 and 7.5 HSPF2 (equivalent to 15 SEER and 8.8 HSPF) compared with 14 SEER and 8.2 HSPF required by the current standard that went into effect in 2015 [33]. The efficiency standards for other heat pump technologies are unchanged and are summarized in Joe et al. [34].

4. Challenges and Opportunities

The US government’s decarbonization goal and the supporting policies and programs have presented an unprecedented opportunity for advancing the research, development, and deployment of heat pump technologies. Electrification of buildings and large-scale deployment of heat pumps are key to accomplishing this goal. A review of the heat pump market indicated areas and sectors that need dedicated solutions to encourage heat pump adoption. Solutions for increasing the supply chain capacity; workforce expansion, training, and education; affordability and accessibility for heat pump technologies; and a supporting grid infrastructure are needed. Key technological challenges include lack of regional solutions for cold climates, high upfront cost, complicated design and control of the components and system for hybrid heat pumps with multiple heat sources, compromised energy benefits due to installation challenges, and space constraints that potentially limit the installation of heat pumps.

Specific research topics to address these challenges include the following:

1. Improve efficiency and capacity of heat pumps for cold climates, and efficiency of systems for warm climates
2. Reduce installed cost and improve reliability of high-efficiency systems

³ The total heat removed from the conditioned space during the annual cooling season, expressed in Btu's, divided by the total electrical energy consumed by the central air conditioner or heat pump during the same season, expressed in watt-hours.
⁴ The total space heating required during the heating season, expressed in Btu, divided by the total electrical energy consumed by the heat pump system during the same season, expressed in watt-hours.
3. Develop solutions for problematic heat pump installations, such as space and electrical panels, particularly for retrofit and renovation applications.
4. Develop alternative refrigeration technologies and lower-GWP refrigerants to reduce direct emissions.

Tackling these challenges requires technological, economic, social, and political innovations from all stakeholders by developing efficient systems with efficient components, smart monitoring, optimal control, innovative system integration, aggregation, and servicing.

5. Current R&D Focus

This section reviews recent research and developments in heat pump systems in the United States. The goals of R&D efforts are to increase the energy efficiency, reduce system cost, expand single-function equipment to be multi-function systems, and reduce environmental impacts. The focuses of these developments are depicted in Figure 9.

**Fig. 9. Research and development focus for heat pump systems.**

**Advances in heat exchangers:** The evolving simulation and manufacturing capabilities have given engineers new opportunities to pursue high-performance, cost-efficient heat exchanger designs. Figure 10 shows a topology optimized heat exchanger fabricated by additive manufacturing [35]. There has always been a great emphasis on understanding the underlying physics and improving the performance of these heat exchangers. Recently, researchers have been investigating the use of small hydraulic diameter flow channels and novel heat transfer surfaces based on topology optimization. The designs include shape-optimized tubes, as well as tube bundles with varying tube and fin geometries and refrigerant flow paths. The research interests for heat exchangers include mitigating the impact of airflow and refrigerant maldistribution, developing methods to reduce material/cost, developing advanced manufacturing techniques, and using technologies such as desiccant-coated, water-sorbing heat exchangers to reduce energy for dehumidification [36].

**Fig. 10. Topology optimized heat exchanger fabricated by additive manufacturing [35].**

**Advances in compressors:** The goal for new compressors is to reduce the power consumption, and one effective way is to keep compression temperature low. Most recently, several teams in US universities and national labs invest efforts to develop isothermal compressors that transfer heat out of the chamber during the compression process [37].

**Low-GWP refrigerants:** Natural refrigerants, HFO (hydrofluorooolefins), and HFO mixtures have significantly lower GWP than traditional HFC (hydrofluorocarbons) refrigerants. Researchers have selected HFO refrigerants via drop-in testing and optimized heat pump components to achieve optimal solutions considering the trade-offs among low GWP, low flammability, and high system performance. Air-Conditioning, Heating, and Refrigeration Institute (AHRI) has established this industry-wide cooperative research program to identify and evaluate promising alternative refrigerants for major product categories. The
AHRI Low-GWP Alternative Refrigerants Evaluation Program (AREP) includes compressor calorimeter testing, system drop-in testing, soft-optimized system testing, and heat transfer testing [38]. For component soft optimization with goal of improving system performance with low-GWP refrigerants, the major efforts are on heat exchanger and compressor designs [39]. The IEA Annex 53 on advanced cooling/refrigeration technology development is exploring two directions on low-GWP refrigerants application: advanced vapor compression with low- or ultralow-GWP refrigerants, and nontraditional technologies such as zero-GWP refrigerants. McLinden et al. [40] identified 138 low-GWP refrigerants by screening more than 60 million chemical formulas. They filtered out the refrigerants according to several criteria. For instance, only molecules that consist of eight chemical elements were chosen, and the maximum number of atoms in a molecule was limited to 18. In addition, the critical temperature was limited to between 320K and 420 K. After filtering out highly toxic and unstable fluids, the screening identified 23 fluids with GWP values below 1000.

Frosting and defrosting improvements: Problems of frosting and defrosting are one of the biggest obstacles restricting the promotion of air source heat pumps. Research includes understanding the frosting and defrosting mechanism; comparing different defrosting technologies, including hot gas bypass, reverse cycle defrosting, electric heater, and dual hot gas bypass; thermal energy storage-based new reverse cycle defrosting to mitigate the indoor thermal discomfort during defrosting cycle; using frost-free air source heat pumps by different latent heat removal technologies to dehumidify the outdoor coil; and optimizing heat exchanger circuitry for uniform frost formation [41].

GSHPs: To enable wider adoption of GSHP systems, several recent projects have tried to reduce the cost of ground heat exchanger by developing shallow bore ground heat exchanger [42],[43] and advanced design tool for borehole field to minimize needed drilling [44],[45]. In addition, a web based GSHP screening tool has also been developed and released to public [46],[47]. This tool allows potential consumers of GSHP system to quickly evaluate the costs and benefits of retrofitting almost any existing commercial and residential buildings in the United States. To enable quick retrofit/replacement of existing conventional HVAC equipment, a dual-source heat pump (DSHP) has been prototyped and tested in an experimental house. DSHP can use the ambient air or the ground as heat sink or heat sources. It can switch between the two sources based on the available temperature of each. Therefore, it has potential to solve the performance degradation problem of ASHP in cold climate and cost less than conventional GSHP system by using a smaller ground heat exchanger. The DSHP system can also be integrated with thermal energy storage to shift electric demand from peak hours to off-peak hours or provide active demand side response according to control signals of electric grid operators [48]. DOE’s Geothermal Technologies Office released its roadmap for developing geothermal energy, including geothermal heat pump, in its GeoVision study [49]. One of the goals of Multi-Year Program Plan of the Geothermal Technologies Office is to implement geothermal heat pumps in 28 million homes by 2050.

Dual-fuel heat pumps (DFHPs): DFHPs, consisting of an electric heat pump and a natural gas furnace, are a promising compromise between economic and environmental impacts in the transition period toward zero emissions and eliminating the use of fossil fuels. Dual fuel heat pumps allow customers to adapt to changing temperatures and fuel prices, since they can easily alternate power or fuel sources. Plus, like other advanced electric technologies, many dual fuel heat pumps can be programmed to optimize economic or environmental impacts according to utility goals. Current research focuses on smart control of DFHPs to optimize their switching/mode of operation between furnace and heat pump modes in response to the outdoor temperature, gas and electricity prices, desired indoor temperature, and renewable energy generation to improve energy efficiency, minimize energy cost, and minimize carbon footprint [50].

Thermal energy storage (TES)-integrated heat pumps: Integrating heat pumps with a TES component to shift most of the electricity used for space cooling and heating from peak to off-peak periods is a popular research topic [51]. Commonly used phase change materials (PCMs) include paraffin wax, ice, and salt hydrates. Taking advantage of the thermal energy storage ability, several feasible PCM application schemes have been proposed. One of the recent research focuses is to develop a model-predictive control strategy to regulate the PCM tank charging and discharging mode switching based on weather, utility, and grid emission signals. Simulation based research have demonstrated the efficacy of TES-integrated heat pumps for electrification of space cooling and heating devices without overtaxing the grid [52]. Most recently, under the auspices of IEA Annex 55, the project “Comfort and Climate Box” develops nearly market-ready TES-integrated heat pump systems for cooling-dominated climate regions for 11 countries including the United States [53].

Heat pump water heaters: Potential research areas to improve heat pump water heater performance include incorporating defrost strategies to boost performance under low or extreme ambient conditions; considering suitable refrigerants for heat pump water heater applications; applying advanced materials and
components to increase storage capacity; developing smart control strategies to optimize energy use, reduce operation cost, and reduce CO₂ emission; developing products with multi-function applications; and developing plug-in 120 V heat pump water heater units [54].

**Cold-climate heat pumps (CCHPs):** Driven by the building sector electrification policy in the United States, CCHPs are a popular research focus. For CCHPs, research challenges include the following: First, the maximum COP of the advanced system under low ambient temperature condition is relatively small in terms of primary energy ratio. Second, the heating capacity needs to be further enhanced to satisfy the building load, especially under extreme conditions. In addition, low-temperature start-up technology and year-round control strategy have potential to improve the reliability of CCHP systems. CCHPs can be classified into three categories: single-stage, dual-stage, and multi-stage compression systems [55]. For single-stage compression systems, employing an ejector and new refrigerant can improve the heating performance but cannot reduce the discharge temperature of the compressor. For dual-stage compression systems, various intermediate configurations, such as flash tank, sub-cooler, and ejector, are employed to enhance the heating performance to the maximum extent. For multi-stage compression systems, the theoretical COP increases with the number of compression stages. In general, CCHP technologies includes innovations on compressor technology, new system configuration, new cycle types such as vapor injection, defrosting technology and expansion loss recovery [56]. Long-term research, development, and deployment efforts have made heat pumps a viable option even in cold climates. DOE recently launched the Residential Cold Climate Heat Pump Technology Challenge to accelerate the deployment of technologies in very cold climates. Optimized heat pump solutions differentiated by climate needs could lower equipment costs.

**Non-vapor compression technologies,** as listed in Figure 11 [57], have also been developed to eliminate high GWP refrigerants, improve source energy efficiency, or expand operating conditions. Long-term R&D is still needed to improve performance, reliability, and cost effectiveness.

![Non-vapor compression heat pump technologies](image)

**Fig. 11. Summary of non-vapor compression heat pump technologies**

DOE’s Building Technologies Office (BTO) characterized the non-vapor compression technologies based on their technical energy savings potential and development status as shown in Figure 12 [58]. The top favored technologies are thermoelastic, membrane heat pumps, evaporative liquid desiccant, magnetocaloric, and vuilleumier heat pump.

![Energy saving potential for different non-vapor compression technologies](image)

**Fig. 12. Energy saving potential for different non-vapor compression technologies reorganized based on [58].**
6. Summary and Outlook

This paper presents a review of the US policies, heat pump market potentials, identifies challenges and barriers facing large-scale deployment of heat pumps, and provides a brief review of recent developments in heat pump technologies.

The US government’s decarbonization goal and the supporting policies and programs have presented an unprecedented opportunity for advancing the research, development, and deployment of heat pump technologies [59]. A large increase in heat pump policies and incentives, notably in the US Inflation Reduction Act, is set to accelerate their deployment [4]. Governmental actions, along with public and private sector incentive programs for heat pump and building electrification, promote deploying more efficient heat pump systems.

The US heat pump market has shown steady growth since 2010—faster relative to competing space heating technologies. However, the market growth is uneven geographically, with a very small market share in cold climates. The heat pump market share is also very small in the commercial sector. GSHP market trends show a direct and immediate influence of tax credits.

There are several hurdles to expanding heat pump deployment, including the relatively high cost of installation; high operational costs in cold climates; various supply chain constraints such as limited manufacturing capacity and shortages of skilled workers; and existing building stock with fossil fuel systems and constraints for fuel-switching.

DOE is investing heavily in heat pump technology. Research efforts have significantly improved the energy efficiency of heat pumps, as evidenced by the evolving efficiency standards. The development of component technologies effectively reduces the energy consumption, and the expansion of multi-functional equipment has enabled heat pumps to perform efficiently with wider applications. To further expand the usage of heat pumps, continuous efforts are needed to improve performance and reliability while discovering novel applications.

As the share of renewables in the energy mix increases, heat pumps can play an important role in electrifying the building sector. Heat pump technology is mature, and production and installation can, in principle, be scaled up quickly. Long-term solutions, including policy consistency, targeted action to strengthen supply chains, building the grid capacity, and expanding renewables, thermal storage, and smart technology (such as smart thermostats, zoning control, and auxiliary heat control) at lower costs, are needed to encourage further investment [4]. The future of heat pump technologies will be highly influenced by the evolving minimum standards, R&D, tax credits, and incentive programs.

Abstract

Air Source Heat Pumps (ASHPs) are the most common heat pump type in Europe's residential buildings. To increase the energy efficiency of ASHPs, a main research field focuses on defrosting management. Currently, researchers showed that optimal defrosting initiation time (ODT) exists, which exhibits great potential to improve operational efficiency. However, ODT depends on multiple factors such as ASHP operation (e.g., compressor RPM) and ambient conditions (e.g., relative humidity). While mapping all correlations between ODT and all relevant factors can be accomplished with artificial neural networks (ANN), gaining sufficient test-bench data is time-consuming. When combining ANNs with reinforcement learning (RL) the data can be automatically generated on-site. A key aspect for the successful realization of RL is the determination of necessary sensors to detect frost under dynamic ASHP operation and varying ambient conditions. This work studies the applicability of different sensor sets to predict frost. Therefore, we use a heat pump model with valid frosting and defrosting behavior. The model is calibrated with test bench data. The results indicate that commonly available sensors in heat pumps are suitable for robust frost detection. Using only the ambient and evaporation temperature, the RL agent can separate frosting behavior from heat pump control and improves energy efficiency by up to 9.4 % compared to conventional time-controlled defrosting.

Keywords: defrost initiation; self-optimizing control; artificial neural network; reinforcement learning; simulation

1. Introduction

The federal government of Germany has set itself ambitious and legally binding climate protection goals: Greenhouse gas emissions must be reduced by 65% until 2030 and by 88% until 2040, relative to 1990 levels. [1]. Since heat pumps are an resource-efficient option to convert electricity from renewable energy sources to heat, the Federal Environmental Agency attributes a key role to heat pumps in achieving the goals [2]. Currently, Air-Source Heat Pumps (ASHPs) make up 82% of heat pumps installed in Germany’s building sector (2021), and their market share rises continuously [3] as they are easier to install and retrofit. Thereby ASHP are more cost-effective while performing only marginally worse than Ground Source Heat Pumps (GSHPs) [4].

During the heating operation of ASHPs, frost may form on the evaporator's fins due to the temperature difference between the heat-transferring surface and the ambient air, depending on the ambient conditions. The frost deteriorates the evaporator capacity and, thus, the heat pump efficiency. To maintain safe and efficient operation, defrosting operations are performed. Wang et al. experimentally show that optimal defrosting initiation time (ODT) exists [5]. Further, they conclude that ODT varies significantly depending on ambient conditions and ASHP operation. However, simple defrosting strategies such as time-based defrosting (TBD) are widely used in commercial applications [6] because of their ease of implementation. In TBD, a defrosting

\textsuperscript{*} Corresponding author.

E-mail address: jonas.klingebiel@eonerc.rwth-aachen.de
operation is performed at a fixed time interval, ranging typically between 60 to 90 minutes [7]. TBD inevitably leads to sub-optimal defrost initiations, so-called "mal-defrost phenomena" [8], which comprise either too early or too late defrost initiations.

To limit the inherent mal-defrost losses of TBD, several attempts have been made to develop demand-based defrosting (DBD) strategies. DBD strategies aim to enhance the defrost initiation by determining correlations between measurable operational parameters and the current state of frosting on the ASHP. Recent works study the application of artificial neural networks (ANNs) [9], [10]. ANNs seem promising for the complex control task due to their capability of capturing complex system relations [11]. Wang et al. [9] propose a supervised learning approach using convolutional neural networks (CNNs). The researcher use samples from a time-based defrosting approach as labeled data for the supervised learning task. The data was manually filtered for mal-defrost operations leading to a data set without apparent mal-defrost phenomena. The trained CNN reached a root mean squared error (RMSE) of 7.2 % and avoided mal-defrosting for most of the investigated test cases. However, the authors constituted that the quality of the labeled data limits the quality of the CNN defrosting strategy. Generating labeled data in sufficient quantities is often a core limitation in ANN applications.

To support this research, we considered the application of Reinforcement Learning (RL) algorithms for DBD in a previous simulation study [12]. In difference from pure ANN approaches, RL allows for learning independent of labeled data since it autonomously discovers the inherent patterns in a dataset. Thus, an RL agent does not impose the limitation of high-quality data but gradually evolves by learning from previous experiences. The investigated Deep-Q-Network (DQN) Agent achieved an average improvement of 5.6% over TBD for a 24h dynamic interval and avoided mal-defrosting operation. However, we used the air-side pressure drop as a frost indicator, among other sensor data, which might not be available in real-world application. In this context, this parameter represents a comparatively direct correlation to frost mass but is difficult to determine experimentally.

Therefore, this paper studies the applicability of different sensor sets to predict frost formation. The paper is organized as follows: In the 2. section we present the basics of RL, and the algorithms used to analyze the results. In the 3. section we describe the case study system, our implementation approaches, and the experiment design. In the 4. section we present the results, which are discussed in the 5. section in more detail. In the 6. section we give a concluding summary as well as inspirations for future work.

2. Methodology

2.1. Reinforcement Learning

RL is a model-free, self-optimizing control algorithm in which an agent interacts with an environment without providing it with instructions on how to act correctly. However, the agent receives feedback on the quality of its actions in the form of a reward $r$. The goal of the agent is to maximize its immediate and future rewards. Therefore, actions leading to higher rewards are reinforced during the learning process. Based on experience, the agent derives a policy $\pi$ which maps an action $a$ to each environment state $s$. The state $s$ is a set of features/sensors representing the environment and includes all information upon which the agent chooses the action. With increasing training, the agent's policy converges toward the optimal policy. Figure 1 illustrates the agents' interactions with the environment.

In Q-Learning, a standard reinforcement learning algorithm, the values of state-action pairs $(s,a)$ with respect to the reward signal are established. In basic Q-Learning the relation between $(s,a)$ and value is stored in a table. While this works well for simple systems with limited states and actions [13], complex problems make use of function approximators. Deep Q-Networks (DQN), a state-of-the-art RL algorithm, use artificial neural networks (ANN) as function approximators [14].

Many design principles have been published over the years, enabling stable ANN training in dynamic environments and improving training data efficiency. As part of our last study, we used two principles: a target network and a replay buffer. The target network is a second ANN, which is used to calculate the Q-values. Its trainable parameters are frozen for a fixed number of interactions. Unlike the main Q-network, the target network's parameters are not trained but periodically synchronized with them. Using a target network prevents instabilities (or even divergence) during training that may arise from rapidly changing policies. The second principle is the use of a replay buffer for experience replay. This overcomes two issues when combining RL with ANNs. First, the data set of RL is non-stationary since the RL algorithm constantly learns new behaviors, but ANNs need stationary data sets. Second, classical ANNs see training samples independent from each other but the training data of RL is sampled from a sequence of correlated states. The replay buffer serves as a growing but stationary data set, breaking the correlation between data samples during training. When RL is
applied to slow-responding thermal systems, including past observations is important because an important design principle (the Markov property) requires that future states depend only on the current state [20].

![Schematic illustration of reinforcement learning.](image)

**2.2. Feature Importance**

Machine learning models can be interpreted by assessing feature importance. To quantify a feature's importance, the model's prediction error is calculated after it has been permuted. As a result of this procedure, the relationship between the feature and the target is broken, thus causing the model score to drop, indicating the model's dependence on it. The feature is considered "important" if randomizing its values increases model error since the model relies on the feature to make predictions. A feature is "unimportant" if shuffling its values leaves the model error unchanged. [15], [16]

**3. Experimental design**

In this section, we describe the case study system, our implementations in Python and Modelica, and the different configurations of our experiment.

**3.1. The Case Study**

In the conducted case study, a DQN agent is implemented as a defrost controller and applied to a dynamic heat pump simulation model. The simulation model and the RL agent are described below.

**3.1.1. Simulation Model**

The dynamic simulation model of the ASHP is implemented in Modelica [17] using Dymola [18] and TIL Library [19], [20]. A detailed description of the calibrated simulation model can be derived from [12]. In the following, the essential principles of the model are outlined.

At the core of the ASHP model is a finite-volume model of the evaporator. The control volume is discretized into several small volumes (cells), and the conservation equations for energy, mass, and impulse are solved for each cell. To model the effect of frost on the heating capacity, the two dominant loss mechanisms are incorporated into the evaporator model:

- **Thermal Resistance**: Frost acts as a thermal insulation layer between the air and the fin. The thermal resistance is a function of frost density and frost layer thickness.

- **Hydraulic Resistance**: Frost reduces the air-side cross-sectional area. For a constant fan power, the air volume flow decreases with increasing frost layer thickness.

To determine the described mechanisms, the frost density and the frost thickness must be modelled sufficiently accurately. For this purpose, the convective water mass flow from the moist air to the frost is divided into frost densification and frost thickening by applying literature correlations. The evaporator model is embedded in a model of the refrigerant cycle with lower complexity to preserve high simulation speeds. The complete refrigerant cycle model is calibrated using measurement data from an ASHP test bench. To enable the dynamic operation of the heat pump model a compressor control is implemented, which adjusts compressor
power to match a set value for supply temperature. Further, a superheating controller regulates a constant superheat at the evaporator outlet.

The resulting heat pump model takes the ambient temperature, the relative humidity, the condenser capacity, and the supply temperature of the heat sink as model inputs as illustrated in Figure 2. Dynamic profiles are generated with AixLib library [21] to simulate real-world scenarios with varying ambient conditions and heat demands. This study uses a building model of a 120 m² single dwelling in Berlin as a case study.

Fig. 2. Inputs of dynamic heat pump simulation model.

3.1.2. Reinforcement Learning Agent

In the following, the design of the control problem is formulated. We use a DQN Agent with the extensions outlined in section 2. The agent interacts with the ASHP model every 100 seconds (simulation time). Every interaction step consists of taking an action, observing the environment, and receiving a reward. The agent decides whether defrosting should be initiated (action $a$). Thereby the agent’s action space is discrete:

$$ a = \begin{cases} 
1: \text{initiate defrost operation} \\
0: \text{stay in heating operation} 
\end{cases} \quad (1) $$

While defrost initiation is controlled by the RL agent, defrost termination is not part of the agent’s control domain. The defrosting operation is terminated by a threshold value with regard to the frost mass. The agents’ state $s$, which is composed of several features, is varied in this study. The selection of suitable state spaces is described in section 3.3. The $COP$ of the system can serve as a reward function, but its value is strongly dependent on ambient conditions. Therefore, selecting COP as reward would penalize the agent for thermodynamic demanding ambient conditions. To eliminate this deficiency, we use the Carnot efficiency as a reward function:

$$ r = \frac{\text{COP}}{\text{COP}_{\text{Carnot}}} \quad (2) $$

The Carnot efficiency normalizes the $COP$ to the physical optimum. As a result, ambient conditions do not directly affect the reward signal. The described interaction approach exhibits temporarily delayed rewards: The agent has to learn that occasional defrosting operations positively impact the future reward trajectory even though it receives a penalty in the short term.

3.2. Implementation

Figure 3 shows the overall framework in which the agent and the environment (heat pump simulation model) interact. The simulation model written in Modelica is exported as Functional Mock-up Unit (FMU).
FMI is an open-source standard for the simulation of dynamic models generated in Dymola or Simulink in other frameworks such as Python. The FMU is embedded in Python with the Python library FmPy [22]. In order to develop reinforcement learning agents, the FMU is embedded into an OpenAI Gym environment [23]. These provide standardized interfaces in the field of RL research to test and compare algorithms efficiently. The algorithms used are provided by the Pytorch-based stable-baselines library [24]. The library provides tested state-of-the-art RL algorithms, a comparatively user-friendly API, and many recurring needed evaluation and backup methods.

3.3. State space variations

In this study, we investigate the influence of different state spaces on the performance of an RL-based defrosting controller. In many cases, the environment is not fully observable, preventing the agent from developing an accurate picture of its environment. The features must contain sufficient information about frost accumulation and its impact on the operation. To develop a reasonable strategy, the agent must separate between phenomena caused by frost formation and other unrelated influences. For this purpose, sensors which directly measure the existence of frost while having few external influences are advantageous. However, these sensors are usually not installed in conventional heat pumps and may be expensive and unreliable.

For example, frost mass or air-side static pressure difference over evaporator are good frost indicators, but they represent an additional asset in terms of cost and reliability. On the contrary, the evaporating temperature is robust and inexpensive to measure but contains only an indirect link to frost mass. Other parameters, such as fan or compressor speed, influence the evaporation temperature, complicating the control problem. In general, a small state with high-quality information leads to faster convergence. Considering the abovementioned limitations, we selected the following features:

- Ambient temperature $T_{\text{Air}}$
- Prior action $a_{t-1}$
- Evaporating temperature $T_{\text{Evaporator}}$
- Evaporator outlet temperature $T_{\text{Evaporator,out}}$
- Condensing temperature $T_{\text{Condenser}}$
- Air-side static pressure difference over evaporator $\Delta p_{\text{Air}}$
- Electrical power consumption of the compressor $P_{\text{el,compressor}}$

Section 4.1 describes the influence of frost and external disturbances on each parameter. The features were grouped into state spaces based on expert knowledge. Tab. 1 displays five state spaces that were investigated in this study. The state spaces are increasingly difficult (from #1 to #5) since number and information quality are reduced successively. While the first state space (#1) contains variables that exhibit a direct link to frost mass (air-side pressure difference $\Delta p_{\text{Air}}$), the last one (#5) only includes the ambient temperature and the prior action, which significantly complicates the control problem. All state spaces contain the air temperature $T_{\text{Air}}$ and the last performed action $a_{t-1}$ since they are easy to determine and have proven to be relevant parameters for the agent’s decision. Additionally, except for #5, each state space contains the evaporating temperature.
Since the air-side pressure difference $\Delta p_{\text{Air}}$ has to be determined by additional sensors, it is only utilized for state space #1. From #3 on, the compressor power $P_{\text{El,compressor}}$ is also discarded since measuring this parameter is costly. As a result, only standard sensory is used from #3 - #5.

Besides the sensor values listed above, historical sensor values are also included in the state space. In addition to the current sensor value at time $t$, the last 39 historical sensor values are provided as input to the agent.

### 3.4. Training

The training is divided into two phases. The goals of the training stages are explained in the following:

- **Pre-training:** Pre-training aims to train the agent to cope with constant ambient conditions. After pre-training, the agent should recognize patterns between ambient conditions and frost growth rate. Therefore, the agent should be capable of adjusting the time point of defrost initiation concerning the ambient conditions in a static case. The agent is required to generalize as the ambient conditions are random and nonrepetitive. Pre-Training is terminated when a certain reward threshold is reached.

- **Main training:** Main training aims to train the agent in a dynamic environment. After the main training, the agent exhibits a reasonable defrosting strategy for dynamic ambient conditions and heat loads. The agent is also required to identify conditions in which no frost formation occurs and not to initiate defrosting when these conditions are present. The agent is trained for 150,000 steps, corresponding to 170 days of simulation time.

### 4. Results

In this section, we present the results obtained with our experiment design.

#### 4.1. System dynamics

In the following, the state spaces' features and their influence on frost are analyzed. Figure 4 displays selected features for a frosting-defrosting cycle. Two scenarios were simulated for constant ambient conditions and heat demands to highlight the influence of frost growth velocity on the corresponding features. The first represents severe frosting conditions, and the second mild frosting conditions. Table 2 summarizes the simulation set values for both scenarios. The frost growth rate is high in the severe frosting scenario due to high absolute humidity. In contrast, the frost growth rate is lower in the "mild frosting" scenario.

The frost growth is reflected in the accumulated frost mass. The gradient is higher for severe frosting than for mild frosting. This relationship can be extracted directly from the signal for the air-side pressure drop: The pressure drop increases faster in the severe frosting scenario. Faster growth of frost causes the air-side cross-sectional area to decrease rapidly so that the pressure drop increases and the volume flow decreases. In the severe frosting scenario, the air-side pressure drop at $t = 2000$ converges to a limit at 100 Pa. Here, the air-side cross-sectional area is completely blocked. The increase in frost mass is only due to frost densification.

The compressor's electrical power shows similar characteristics: As the frost mass increases, the transferred heat at the evaporator decreases. To maintain a constant condenser capacity, compressor power is increased by the heat pump controller to compensate for the reduction in evaporator capacity. If heat demand, ambient temperature, and supply temperature are constant during the heating phase (frosting), the electrical power is a valid frosting indicator. Under frost-free conditions, the air-side pressure drop is identical for both scenarios and is thus independent of external influences (see figure 4, $t=0$). In contrast, the compressor's electrical power depends on the heat demand and the supply temperature and thus differs under frost-free conditions.

Figure 4 also displays the evaporating temperature. The evaporating temperature decreases with increasing frost mass due to the expansion valve control, which regulates a constant superheat. The evaporating temperature shows a qualitatively similar curve to the compressor's electrical power consumption. While the evaporating temperature decreases significantly in the severe frosting scenario, only a slight decrease can be seen in the “mild frosting” scenario. The evaporating temperature differs under frost-free conditions due to the varying ambient temperatures.
In addition to the quantities shown in figure 4, additional features were selected for frost detection. The temperature at the output of the evaporator differs from the evaporation temperature by a constant value (superheat). The condensation temperature correlates with the ambient temperature according to the heating curve and thus has an indirect influence on frost growth.

4.2. State space variations

The agents with the state spaces defined in Table 1 were trained according to the description in section 3.4. After training, the performance of the agents was evaluated for ten randomly selected test periods with varying environmental conditions and heat demands with a length of 72 h. The average reward per step for each test period was calculated to compare the agent’s performance. The reward corresponds to the Carnot efficiency (see equation 2). The value was then averaged over the ten episodes.

Additionally, a time-based defrost controller that initiates a defrosting operation every 60 minutes was evaluated. The 60 minutes correspond to a typical value from the literature [7]. Figure 5 displays the average reward per step over the ten test periods for RL and TBD. Additionally, minimum and maximum deviation is displayed.

![Fig.5. Results of state space variation.](image)

RL with state space #1 (RL#1) achieves the highest reward per step. However, RL#3 and RL#4 achieve comparable scores. While the performance of RL#4 is marginally worse compared to RL#3, this may be due to the randomness of the selected test conditions. The similar performance between RL#3 and RL#4 implies that the evaporator output temperature and condensing temperature do not add beneficial information. Based on the results, we conclude that demand-based defrosting can be accomplished with just the air temperature, the evaporation temperature, and the last action.

RL#2 performs significantly worse compared to RL#3. At first, this seems counterintuitive since RL#2 contains all features of RL#3. The difference between RL#2 and RL#3 is in the electrical compressor power signal, which was classified as a reasonable frost indicator in the previous section. The weaker performance can be attributed to the higher number of features. The additional information provided by the sensor is not valuable enough for the agent to achieve higher performance. Conversely, the additional feature increases the
complexity of frost detection. As a result, the RL#2 agent requires more training time to achieve similar results as RL#3.

RL#5 shows significantly worse performance compared to all other RL agents. The included features do not exhibit sufficient information to perform demand-based defrosting operations. The agent has to develop a defrosting control based on the ambient temperature. However, since frost growth is, among others, dependent on relative humidity and condenser power, the agent cannot establish a reasonable defrosting strategy.

Compared to TBD, the RL agents #1 - #4 achieved significant efficiency improvements. The increase in efficiency between TBD and RL#1 is 9.4%. The efficiency improvement between TBD and RL#4 is 8.9%.

4.3. Feature importance

We performed permutation tests in order to measure feature importance. Therefore, each feature was randomly permuted, while the remaining features were kept untouched. After a permutation was performed, the loss of the model prediction was calculated. This was repeated 100 times (for each feature), and the average prediction loss was evaluated.

Figure 6 displays the model loss due to feature permutation for different state spaces. Across the three state spaces presented, there is no dominant feature. While the absolute value of the model error has a low information value, the relative differences within a state space can be interpreted.

In state space #1 the air-side pressure difference and the compressor power show the most significant influence on the agent's actions. The remaining features have a minor impact on the agent's decisions. Consequently, the agent has discovered that the two dominant features provide sufficient information to learn a reasonable defrosting strategy.

Ambient temperature and evaporator outlet temperature have the most decisive influence on the agent in state space #3. The feature importance of the evaporating temperature is negligible. The agent has detected that the difference between both features consists of a constant offset (superheating). Thus, the features share identical information as long as the superheat is kept constant by expansion valve control. In state space #5 the
evaporation temperature is the dominant feature since evaporator outlet temperature is not part of the state space. The decisive influence of the ambient temperature is significantly smaller.

5. Discussion

The results show that RL can serve as a demand-controlled defrost algorithm using only standard temperature sensors of the refrigerant cycle as frost indicators. The state space variation and the feature importance evaluation demonstrate that the agent successfully recognizes the sensor values with the highest information quality and assigns the greatest influence to these values in the decision process. Furthermore, we observed that a larger state space leads to a lower performance for the same training time. For this reason, the number of features should be kept reasonably small.

In the calibrated simulation model, the evaporation temperature shows a characteristic drop due to frost. The absolute value of the evaporation temperature is dependent on the ambient temperature. Thus, the agent needs both features to predict defrosting necessity. An improvement could be achieved by applying feature engineering. Here, multiple features are combined into a single value to decrease state space dimension and accelerate convergence speed. With regard to the results of section 4.2, it seems promising to pass the temperature difference between ambient and evaporation temperature to the agent as a single value.

Although the results of this simulation study are promising, the simulation did not take into account several effects that arise in heat pumps in the field and might complicate the control problem significantly. In this study, the fan speed was assumed constant. Since fan speed affects the evaporating temperature, its set value should be implemented as a feature when applying RL to real heat pumps. Furthermore, we did not investigate the effect of controller-related oscillations on the agents' performance. In real-world applications, the frosting influences the controlled system of the expansion valve because system dynamics differ from no-frost conditions. Altered system dynamics can result in an oscillation of the superheat and, thus, of the evaporating temperature. Smoothing the features with respect to time may resolve the issue.

Furthermore, we defined the reward using Carnot efficiency. While this is an excellent quantity to optimize, the computation of the value is subject to variances due to measurement uncertainties. In addition, many frost-unrelated factors influence the Carnot efficiency, e.g., isentropic compressor efficiency. Contrary to the assumption implied in this study, the isentropic efficiency is not constant. Consequently, the reward function will fluctuate in absolute value over the operating range, which is a disturbance factor for the agent. Hence, alternative reward functions that directly relate to frost growth should be investigated.

6. Conclusion and future work

In this paper, we apply a State-of-the-Art RL algorithm to perform demand-controlled defrosting for a calibrated dynamic ASHP simulation model. The results indicate that RL can serve as a demand-controlled defrost algorithm while using only standard sensors of the refrigerant cycle as frost indicators. The agent extracts all necessary information and outperforms conventional time-controlled defrosting by 9.2% by only using two temperature sensors in the state space (ambient temperature and evaporation temperature). We conclude that the selected state space significantly impacts the agent's convergence speed and final energy efficiency. Further, we apply a feature importance analysis to quantify the impact of individual features on the agent's decision.

However, some aspects must be addressed to exploit the full potential for real-world applications. Future work should focus on accelerating convergence speed (e.g., feature engineering) and implementing more on-site effects (e.g., measurement uncertainty) into the simulation model. Additionally, research that investigates the reusability of already trained algorithms to heat pumps with different evaporator geometries could accelerate the deployment of RL algorithms to commercial heat pumps.

Interconnected heat pumps in Austria: A technology implementation survey

Veronika Wilk*, Reinhard Jentsch*, Tilman Barz*

* AIT Austrian Institute of Technology GmbH, Giefinggasse 2, 1210 Vienna, Austria

Abstract

Heat pumps become increasingly connected devices enabled to participate in the Internet of Things (IoT). Such heat pumps, both in domestic and industrial applications, allow for operation optimization to reduce energy consumption, to reduce the carbon footprint, to realize economic benefits or to increase comfort. They also enable grid services, which is of increasing importance due to the rising share of renewable energy. This contribution presents results of a survey among companies of the Austrian heat pump industry which was conducted to gather and evaluate the general sentiment on the relevance of interconnected heat pumps, state-of-the-art use cases, market availability and selected technology trends. The collected feedback clearly indicates significant progress in technology implementation. All participating companies offer both, IoT products (e.g. heat pumps with connectivity or intelligent components such as compressors or sensors), and related services (e.g. marketing of flexibility, remote service, monitoring, etc.). While two thirds of these products are already available either in the product portfolio of the companies, or in a large number in use, another third is currently under evaluation, under development or in a pilot phase. IoT technology is expected to bring significant changes in product development, business models and maintenance. For IoT enabled heat pumps this means that instead of being an autonomous smart component, they will be increasingly integrated and will be part of connected energy systems in the future.

Keywords: products; services; data transmission protocols; communication interfaces; trends

1. Introduction

Ambitious climate, energy and environmental goals require the transformation of the energy system into an efficient and renewable system with low CO₂ emissions. Digitalization is one of the important factors for this transformation. According to the IEA, digitalization is the increasing interaction and convergence between the digital and physical worlds. The digital world comprises data (digital information), analytics (the use of data to produce useful information and insights) and connectivity (exchange of data between humans, devices and machines) through digital communication networks. Digitalization is driven by increasing volume of data due to the declining costs of sensors and data storage, rapid progress in advanced analytics and computing capabilities, and greater connectivity with faster and cheaper data transmission. [1] Intelligent, digital solutions are increasingly in demand to efficiently use various flexibility options such as power-based heat generation, the use of storage facilities or e-mobility as well as to safely control the electricity grid. The EU has high expectations for digital technologies in the energy transition, as they should unlock the full potential of flexible energy generation and consumption. Digital technologies enable system optimization, operational savings and savings in network infrastructure, as they should provide the necessary data to match supply and demand both locally and system wide. Therefore, the EU Commission has adopted an action plan in October 2022 that aims to contribute to the EU energy policy objectives by the development of a sustainable, cyber-secure and competitive market for digital energy services and digital energy infrastructure. Main pillars are the

E-mail address: veronika.wilk@ait.ac.at
establishment of a common European energy data space for sharing and using energy data, a code of conduct for interoperability, enhanced participation in demand-response schemes for energy-smart appliances and strengthening cyber security and resilience of the energy system. [2]

Heat pumps are a versatile technology for the provision of domestic hot water and process heat, and for cooling of buildings and processes. According to the IEA’s Net Zero by 2050 report, a total of 1800 million heat pumps have to be installed in buildings world-wide to provide more than half of the heating needs. It is a tenfold increase compared to the level of 2020 [3]. The EU aims at doubling the current deployment rate of individual heat pumps, resulting in a cumulative 10 million units over the next 5 years to be installed. [4]

As digitalization progresses, heat pumps increasingly become connected devices that participate in the Internet of Things (IoT). They can be designed to intelligently meet demand, enabling real-time energy efficiency, flexible use of electricity, optimized load profiles and an optimized compromise in terms of comfort and operating costs. IEA’s Net Zero by 2050 report also elaborates on the impact of digitalization on emission reduction. Advances in technology, e.g. smart thermostats or other smart appliances lower carbon emissions, as they reduce the necessity for people to play an active role in energy savings. It is expected that emissions from the building sector will be reduced by 350 Mt CO\textsubscript{2} by 2050 due to digitalization and smart controls. [3]

Recently, the impact of digitalization was assessed for Austria and Germany. The Austrian study analyzed the potential for reducing energy consumption and GHG emissions through applications of digitalization by 2040. It was found that, taking into account the increased energy consumption of the necessary ICT infrastructure, effective savings of 4 – 9% of energy consumption can be reached by 2040. This is equivalent to a 2-10% reduction of greenhouse gas emissions and reductions of up to 2.3 million t CO\textsubscript{2eq}. The highest net effect on energy consumption can be realized by process automation in industry, smart homes, simulation and digital twins in industry and building automation in the service sector. [5] Similar high potential was identified for Germany, where digitalization could contribute up to 34% of the CO\textsubscript{2} emission reduction that is required according to the climate targets for 2030 (up to 126 Mt CO\textsubscript{2eq}). The highest reductions can be achieved in industrial production, mobility, energy, and buildings. Important technologies in buildings are intelligent energy management and intelligent HVAC components. [6]

In the Technology Collaboration Programme on Heat Pumping Technologies of the IEA, the IoT Annex project was launched in 2020. In this collaborative project, researchers from Germany, France, Sweden, Norway, Denmark, Switzerland and Austria explore the opportunities and challenges of connected heat pumps. Both, typically mass-produced heat pumps for household applications, and heat pumps with large capacities for industrial and district heating are included. The Annex project has a broad scope looking at different aspects of digitalization and aims to create a knowledge base on connected heat pumps to provide information for heat pump manufacturers, component manufacturers, system integrators and other actors involved in IoT. This contribution presents the results of a survey among companies of the Austrian heat pump industry to assess the relevance of interconnected heat pumps, state-of-the-art use cases, market availability and selected technology trends.

2. Manufacturer Survey in Austria

2.1. Methodology

The purpose of the survey was to collect feedback from companies in the heat pump market segment to gather and evaluate the general sentiment on the importance of IoT. The survey had more than 50 questions, which were single and multiple choice, rating and ranking as well as free text questions. The average time for completing the survey was about 20 min. The survey was divided in two different parts. The first part was equal for all participants. The second part was different for participants active either on the residential, commercial and office buildings market, or on the industrial heat pump market, with specific questions relevant for each group.

The questionnaire was designed after conduction of interviews and focus groups with domain experts in residential and industrial heat pump technology, buildings automation, data security and electricity market from the IEA HPC Annex 56 expert group. Companies were contacted by the Austrian Heat Pump Association “Wärmepumpe Austria” (WPA) and asked for their participation in the survey. WPA covers the entire value chain of the heat pump industry in Austria and includes heat pump manufacturers, as well as all electricity supply companies, component suppliers and drilling companies as well as planners, installers and engineering companies. Answers were collected from May to June 2022.
2.2. Survey participants

A total of 16 companies participated in the survey. 13 participants answered all questions in the survey, 3 participants only answered a part of them (76%, 84% and 91% completion). All company sizes, from small SME to large companies are covered by the survey: 6 companies have less than 50 employees, 5 companies 50 – 250 employees, and 5 companies have more than 250 employees.

Most companies identified themselves as heat pump manufacturers and heat pump vendors (8), three are heat pump installers (thereof 2 also vendors) and 3 component manufacturers (thereof 1 also heat pump manufacturer and vendor), see Fig. 1. Among the current members of WPA, there are 44 companies that manufacture or import heat pumps, thereof 17 that manufacture a part or all of their products in Austria and 12 component manufacturers. From the numbers of participating companies, it can be concluded that 53% of the heat pump manufacturers, 37% of the vendors and 17% of the component manufacturers were reached.

Fig. 1: Participants in the Austrian IoT survey

Activities in market segments: All 16 companies are active on the residential heat pump market including commercial and office buildings. From these 16 companies only 6 have indicated that they are also active in the industrial and district heating market segment (Fig. 2). However, because this second market segment is smaller, and because it is likely that not all companies address this second market segment, no direct conclusions can be drawn about different relevance of IoT in the two different market segments.

Fig. 2: Market segment covered by the participating companies

2.3. Availability of products and services

The feedback clearly indicates that participating companies have IoT products and services. 66 % are available, which means either in their product portfolio (in implementation), or in a large number in use (extensive implementation). 33% are currently under evaluation, under development or in a pilot phase. All companies offer both IoT products (e.g. heat pumps with connectivity or intelligent components such as compressors or sensors) and services based on IoT products (e.g. marketing of flexibility, remote service, monitoring, etc.). In 56% of the companies, the product and service portfolio have the same maturity level, in 31% the services are further developed than the products and in 13% the products are more advanced and the services still under development.
2.4. Relevance and implementation of IoT related products and services

A self-assessment and comparison to international competitors revealed that 2 companies identify themselves as a pioneer in offering IoT products. The remaining answers from manufacturers are more conservative, 8 regard their products as state of the art, 6 companies see development needs. With regard to the use of IoT services, the feedback is very similar, 1 company regards itself as a pioneer, 7 regard services as state of the art, 8 see development needs.

The feedback on the question who deals with IoT in the company is expectedly diverse, considering the different company sizes among the participants. It ranges from external developers and individual employees, as found in small companies to dedicated IoT departments and company-wide digitalization strategies in medium and large companies. Most commonly, project teams or a part of the development department deals with IoT.

![Fig. 3: IoT development by company size](image)

As asked about the motivation for adopting IoT products, the top three selected answers were customer loyalty, service improvement and new business models, see Fig. 4. Cost reduction has been ranked higher than environment awareness. For most companies, IoT products are not seen as a unique selling proposition.

![Fig. 4: Motivation to introduce IoT products](image)

2.4.1. IoT in residential, commercial and office buildings

Operation data is collected locally at the heat pump or in a cloud service. For residential, commercial and office buildings, 50% of the companies use both, local storage and the cloud, 31% use the cloud and 13% only local storage. All these companies offer data-based features for the customers, such as operation monitoring and control, visualization of operation data and historic data and integration in a home automation system. To access these features, 93% of the companies provide an app for the customers, 73% have a control panel on the heat pump, 73% provide access to a website and 67% allow for integration in a home automation system. 47% of the companies offer all four ways of access.

The most common interface to collect operation and field data is LAN (81% of the companies), followed by WLAN (63%). 31% offer all interfaces that were mentioned: LAN, WLAN, local wireless, local wired, GSM, interfaces for smart grid ready. The most common transmission protocol is Modbus (75%), followed by
KNX (50%). Data security, transmission security and availability are most frequent reasons to choose the transmission protocol.

On the one side, certain IoT features are explicitly requested by customers. The participants confirmed that the following features are important for their customers: monitoring; interfaces for home automation; interfaces for smart tariffs and marketing of flexibility; coordinated operation with local PV and storage; and optimized maintenance intervals. On the other side, the companies confirm that the following IoT features are of great and almost equal importance for themselves: efficiency improvement; anomaly detection and operational monitoring; installation error detection; improved service offering (e.g. PV or price optimization); and product improvement and development. Interestingly, those IoT features which are seen as important by the companies are also those features which are already in use. A total of 88% of the companies apply data analytics for the following applications: installation error detection; efficiency improvement; anomaly detection and operational monitoring; product improvement and development.

2.4.2. IoT in industrial and district heating applications

For industrial and district heating applications, heat pump data is collected in the cloud and locally, most of the companies have both types. All of them offer integration of the data in the process control system and provide access to features in the cloud. The features comprise visualization of operation and historic data, monitoring and control and integration in the process control system. This is in good agreement with the IoT features requested by the customers. Unlike residential applications, smart tariffs are of less importance in industry.

The most common interface to collect operation and field data is LAN, which is used by all companies, (100%), followed by WLAN (67%). The most common transmission protocol is Modbus (83%), followed by OPC-UA and BACNET (each used by 50% of the companies). The reason to choose the transmission protocol are similar to the residential applications (data security, transmission security and availability).

2.5. Trends and future developments

Generally, most participants agree that IoT technology brings significant changes. These changes are especially expected in product development, business models, maintenance and partially in sales. Less or insignificant impact is anticipated in the customer segment, production, installation, and supply. Most companies (except one) explicitly foresee the option to add or change IoT features through software updates after heat pump installation. This can be accomplished mainly via internet or manually by service personal. Three participants state that customers can also manually do software updates.

Clearly, IoT enabled heat pumps are expected to be rather a part of a connected system in the future than an autonomous smart component. As shown in Fig. 5, this was found for both residential and industrial heat pumps. The most important barriers for IoT technologies are the availability of qualified personnel, data protection and legal requirements as well as lack of standards. There is less concern about communication protocols and interfaces and the availability of suitable hardware.

It should be noted that IoT technology is seen as one of several digital transformation technologies to which a high importance is attached for the future. According to Fig. 6, equal or similar importance is attached to machine learning, predictive maintenance and building information modelling. Privacy requirements are ranked neutrally. In contrast, asset administration shell, semantic modeling and digital twin are considered as less important.
3. Conclusions and outlook

A survey on the importance of IoT was carried out among companies of the Austrian heat pump industry. The participants represent 53% of the Austrian heat pump manufacturers and 27% of the heat pump vendors allowing for meaningful results. All companies offer both, IoT products (e.g. heat pumps with connectivity or intelligent components such as compressors or sensors), and services based on IoT products (e.g. marketing of flexibility, remote service, monitoring, etc.). Two thirds of the evaluated products are available, which means either in their product portfolio (in implementation), or already in a large number in use (extensive implementation). Another third is currently under evaluation, under development or in a pilot phase.

Most commonly, IoT products and services are developed by project teams or by a part of the development department. The main drivers for these products and services are customer loyalty, service improvement and new business models. The most important barriers for IoT technologies are the availability of qualified personnel, data protection and legal requirements, as well as lack of standards. There is less concern about communication protocols and interfaces and the availability of suitable hardware. The general expectation shared by all participants is that IoT technology will bring significant changes in product development, business models and maintenance. Moreover, IoT enabled heat pumps are expected to be a part of connected systems, and IoT technology is seen as one of several important digital transformation technologies for the future.

Digitalization is an important factor in the transformation of the energy system. It is expected to facilitate matching of supply and demand with increasing volatile energy production and to significantly contribute to end energy savings and CO₂ emission reductions. Connected heat pumps will play a vital role in the future energy system. Important fields of action are the establishment of common standards and interoperability of the appliances in the energy system. This is now also addressed in the latest EU action plan aiming at a common European energy data space for sharing and using energy data, a code of conduct for interoperability, enhanced participation in demand-response schemes for energy-smart appliances and strengthening cyber security and resilience of the energy system.

Numerical study of the part load operation for a reverse Brayton high-temperature heat pump

Enrico Jende*, Nancy Kabat, Panagiotis Stathopoulos

* Institute of Low-Carbon Industrial Processes, German Aerospace Center, 03046 Cottbus, Germany

Abstract

Electrification of industrial process heat from renewable sources can contribute to the reduction of energy-related CO2 emissions. High-temperature heat pumps are one of the most important technologies to realize this electrification while reducing the electrical energy required for it. The Institute of Low-Carbon Industrial Processes of the German Aerospace Center (DLR) is developing high-temperature heat pumps (HTHP) based on reverse Brayton and Rankine cycles for heat transfer temperatures above 150 °C. The development and integration process of HTHPs for industrial processes often starts with their sizing at nominal operating conditions. Once the operational boundary conditions are defined, the individual components are sized. A large proportion of industrial heat pumps operate at a fixed point and are not optimized or designed for frequent part-load operation. This is expected to change, especially when heat pumps are required for industrial processes with part load operation. The current work presents an analysis of the part load operation of a reverse Brayton HTHP built in the laboratory of DLR and investigates its operational limits.

Keywords: high temperature heat pumps; reverse Brayton cycle; process heat; stationary process simulation

1. Introduction

1.1. Motivation

Reducing greenhouse gas (GHG) emissions by 2050 is one of the most important steps to achieve the European Union’s (EU) climate goals [1]. An interim target for 2030 is to reduce GHG emissions by at least 55% compared to 1990 levels [2]. Industrial heating and cooling demand in the EU accounts for over 25% of these emissions [3]. More than 30% of the cumulative energy demand for heating and cooling is used for industrial processes. This heating and cooling demand is mainly met by fossil fuels and a transformation to a GHG-free energy system is required to achieve the EU climate goals [4]. Several studies have been carried out in the past to estimate the heat demand for different process temperatures and industrial sectors in the EU. Naegler et al. [5] and Rehfeldt et al. [6] analysed several industrial processes and concluded that there is a large demand for heat at temperature levels from 100 °C to 500 °C mainly in industrial sectors such as chemical, paper and food industry. It is shown that the total final energy demand for heat in the EU-28 Member States in 2012 was 8518 PJ. The resulting total energy demand for heat at process heat temperature levels of 100 - 400 °C is 2214 PJ and above 400 °C 3859 PJ [5]. Marina et al. [7] highlighted that a total of 641 PJ/year of process waste heat could be covered by industrial heat pumps. Wolf [8] investigated the application potential for heat use in German industry. He found a technical potential of 611 PJ using heat pumps with a maximum heat sink temperature of 140 °C. Kosmadakis [9] analyzed the possibilities of waste heat recovery using industrial heat pumps. He concluded that industrial heat pumps in the EU have a total potential of 28.37 TWh/year (102.132 PJ).

All authors also emphasized that high-temperature heat pumps (HTHP) driven by renewable energy can make a significant contribution to the decarbonization of industrial heat supply in Europe and also significantly reduce the necessary primary energy demand for industrial heating [10], [11].

1.2. Short overview of the state of the art on HTHPs

The literature provides a first overview of the state of the art. For example, Wolf et al. [12] compared available types and technologies of heat pumps (HP), focusing on compression, absorption and hybrid HPs with a temperature delivery limit of 120 °C. Schlosser [13] investigated the decarbonization of industrial heat supply through the integration of heat pumps and presents methods for techno-economic detailed planning. Arpagaus et al. [14] give an overview of HPs already available on the market and the state of the art.

The IEA HPT Annex 58 project is currently underway to provide an overview of the state of the art and ongoing developments for HTHP systems and components [15]. This overview of the development of supplier technologies for HTHP shows that maximum supply heat sink temperatures between 115 °C and 280 °C with heating capacities up to 70 MW are available at the highest Technology Readiness Level (TRL) of 9 [15]. In addition, the demonstration cases of different technologies for HTHP have heat sink temperatures up to 211 °C, heating capacities up to 12 MW, and a coefficient of performance (COP) of 5.3 maximum [15].

In addition, published work with a simulative background has focused on the on-design operation of HTHPs and their techno-economic evaluation. For example, Zühlendorf et al. [11] presented possible solutions for a HTHP with sink temperatures around 250 °C and recommended a closed-loop reverse Brayton or Rankine cycle. Oehler et al. [16] investigated the part load capability of a HTHP based on a closed loop reverse Brayton cycle. They presented a combined method to operate such heat pumps at part load either by changing the speed of their compressor or by actively controlling the working fluid mass in the closed loop of the heat pump. As part of investigations on the load strategy of a gas turbine using the Brayton cycle, the benefits of fluid inventory control were also investigated by Pradeep Kumar et al. [17]. Both studies have shown that a Brayton cycle based HP can achieve high efficiencies and provide good flexibility by using an appropriate part load strategy [16], [17].

1.3. Motivation and contributions of this study

Potential applications for Brayton heat pumps are drying processes, e.g. in the food industry with temperature requirements up to 280 °C [11], [18]. Another application is preheating processes, for example in the metal industry [11]. In some cases, variations in production conditions (temporary production line shutdowns, etc.) often lead to variations in the mass flow rate of the heating medium, even though the same product is being processed. To accomplish this task, it is necessary to understand the operating behavior, especially at partial load.

The DLR Institute of Low-Carbon Industrial Processes is developing a HTHP pilot plant based on the Reverse Brayton Cycle to analyze the feasibility of heat sink temperatures up to 300 °C. The aim of the present work is to analyze the steady-state part-load performance of this Reverse Brayton Cycle pilot plant under different boundary conditions. The ability and limitations of part load operation play an important role in the integration of HTHP into existing industrial processes with different operating conditions. The conclusions of this work are expected to pave the way for further investigations on the part load operation of HTHP.
2. Research object

This work focuses on the part load operation for reverse Brayton high-temperature heat pumps in the context of industrial process integration. The following subsections outline the research object of this considerations. First, the reverse Brayton process and the main evaluation parameters are described. The technical basis for the simulations and a detailed description of a prototype are then presented.

2.1. Brayton process and coefficient of performance

The reverse Brayton process considered in this study is shown in Figure 1. By absorbing mechanical power from the compressor shaft (P_C), the compressor (C) raises pressure and temperature of the working fluid (1 → 2). After that, the high-temperature heat exchanger (HTHX) transfers sensible heat (Q_out) to the heat sink and cools down the working fluid (2 → 3'). If the cycle uses recuperation, heat is transferred (Q_int) over an internal heat exchanger (IHX) to further reduce the temperature of the working fluid (3' → 3) before it expands through a turbine. The output mechanical power of the latter (P_T) is used directly to partially drive the compressor. In the DLR design, the turbine and the compressor are mechanically decoupled and the exchange of energy takes place through a power electronics system. After expansion the working fluid pressure drops to the initial level while its temperature decreases significantly (3 → 4). Finally, the working fluid absorbs heat (Q_in, 4 → 1') first from the environment in the low-temperature heat exchanger (LTHX) and subsequently from the fluid exiting the HTHX in the internal heat transfer of the IHX (3' → 1) to close the cycle.

Figure 1. Scheme of the recuperated Brayton process (left) and sketched T-s-diagram of the simulation model of the CoBra

With regard to the following investigations, process parameters of heat sink, heat source, heat flow, temperature, and drive power outside the system boundaries of the Brayton process - see Figure 1- are mainly evaluated. In addition, the investigations on the heat pump system also need a main indicator to evaluate the results of the different part load operations. Arpagaus et al. [19] described the key efficiency indicator of a heat pump as the coefficient of performance (COP). The COP is defined as the ratio between the output heat power and the applied drive power. Considering the application of the Brayton process shown in Figure 1, the COP (Equation 1) is defined in these considerations as the ratio between the transferred heat flow \( \dot{Q}_{out} \) and the difference between the drive power at the compressor shaft \( P_C \) and output power of the turbine \( P_T \).

\[
COP = \frac{\dot{Q}_{out}}{P_C - P_T}
\]
Arpagaus et al. [19] and Marina et al. [7] described that operating between process and waste heat streams with constant heat capacities and varying temperatures (temperature glides), the maximum theoretical COP is known as the Lorenz COP. Considering the application of the Brayton process shown in Figure 1, the Lorenz COP (Equation 2) is defined as the ratio between the logarithmic mean temperatures $T_m$ at the HTHX (Equation 3) and the LTHX (Equation 4). The Lorenz efficiency will not be reached in practice due to all kinds of losses. To determine the real COP, a system efficiency must be considered [19]. An efficiency term, which relates the actual COP to the maximum Lorenz COP is given in Equation 5.

\[
\text{COP}_{\text{Lorenz}} = \frac{T_{m,\text{HTHX}}}{(T_{m,\text{HTHX}} - T_{m,\text{LTHX}})} \tag{2}
\]

\[
T_{m,\text{HTHX}} = \frac{T_I - T_H}{\ln(T_I/T_H)} \tag{3}
\]

\[
T_{m,\text{LTHX}} = \frac{T_{III} - T_{IV}}{\ln(T_{III}/T_{IV})} \tag{4}
\]

\[
\eta_{\text{Lorenz}} = \frac{\text{COP}}{\text{COP}_{\text{Lorenz}}} \tag{5}
\]

2.2. DLR-HTHP Prototype CoBra

At the DLR Institute of Low-Carbon Industrial Processes, a prototype of a high-temperature heat pump based on the reverse, closed-loop and recuperated Brayton cycle was developed and built. The prototype is called CoBra (Cottbus Brayton). The main components are the two turbo machines and three shell-and-tube heat exchangers. To accommodate a large number of possible experimental investigations, the following design features are included:

- Designed for two working fluids - air and argon
- Compressor and turbine with own shafts and coupled to their electric machines through gearboxes
- Three-way-valve (3WV) to vary the mass flow of the hot fluid entering the recuperator
- Electrical heater upstream of the compressor to simulate an additional waste heat application
- Fluid inventory control by actively controlling the working fluid mass in the cycle
- Simultaneous supply of process heating and cooling
- Flexible secondary heat sink circuit to experimentally simulate various industrial processes / customers
- Flexible secondary heat source circuit with controllable fan and electrical heater as heat source to simulate an industrial cooling process with waste heat recovery

In addition to the design features of the prototype CoBra, the plant has been equipped with a comprehensive range of instrumentation to monitor the operation of all components in detail. Each circuit - the Brayton primary and the two secondary circuits - has a mass flow meter (MFM) and the necessary temperature and pressure measurements to evaluate the performance of the system under all operating conditions.

3. Methodology

A simulation model of the Brayton HTHP based on the CoBra has been developed in order to study the part-load operation in the context of industrial process integration and as a function of different process conditions. Furthermore, it is necessary to consider the possible industrial process integration of the Brayton HTHP. The following subsections outline the simulation model used for the numerical study and set up different Scenarios for the integration of the Brayton HTHP.
3.1. Simulation model of the Brayton HTHP

The first part of the development process of an industrial heat pump requires a design of the system based on defined boundary conditions. A simplified thermodynamic model of a reverse, recuperated Brayton cycle has been implemented in the software tool EBSILON® Professional [20]. This model considers the detailed operating maps of each component and is capable of simulating part-load operation of the entire cycle for steady-state operating conditions. The additional features of the off-design model can be summarized as follows:

- The compressor operation has been modelled with its operational maps
- The reduced mass flow rate in the turbine is considered constant. In other words, it is assumed that the turbine is always operating in the choked region of its operational map.
- Heat exchanger with exchange surfaces and a standard map for off-design in EBSILON®
- Pipes with geometric based pressure losses and heat losses
- 3WV, electrical heater and MFM (based on CoBra) with constant pressure losses

The simulation model derived by the Brayton HTHP is based on parameters and maps of the main components and design features of the CoBra (see subsection 2.2). Environment conditions used for the first approach of the design was dry air as working fluid, the inlet temperatures of the HTHX and LTHX is set equal to 15 °C and the heat sink outlet temperature equal or higher than 250 °C. Based on this boundary conditions, Figure 2 shows the process design parameter of the fully recuperated CoBra at the maximum compressor speed of 105 000 min⁻¹. In general, the allowable range of tests is based on the operating limits of the plant. (see Table 1). The resulting model is conditionally switchable, allowing investigations of the Brayton heat pump in the context of industrial process integration and as a function of different process conditions.

3.2. Industrial process integration of the Brayton HTHP

In order to investigate the integration of the Brayton HTHP into an industrial process, it is necessary to define an appropriate integration Scenario. In the current work, a generic industrial process is assumed that requires a flow of hot air with a fixed temperature of 250°C and a mass flow of 0.5 kg/s (heat flow of 120 kW). In addition, it is assumed that this industrial process returns an exhaust air heat flow with a temperature of 50 °C at a mass flow of 1 kg/s (based on the heat mass flow rate of the CoBra). In general, the output temperature of the heat source is considered as a free parameter. Depending on its temperature, this flow can be made available for a cooling process or can be discharged to the environment. Finally, Figure 3 shows the two integration Scenarios. The first considers a Brayton HTHP with CoBra boundary conditions. The second introduces a recirculation of the exhaust air heat flow for the heat source of the Brayton HTHP.

Figure 3. Schemes of process integrations Scenarios of a Brayton HTHP into an industrial process
4. Results and discussion

Table 2 shows the operating range that used to study the off-design operation of the HTHP. It should be noted that, based on the compressor map, the minimum possible load is equal to approximately 60% due to the compressor surge limit. In general, the heat sink outlet temperature is specified fixed at 250 °C. The heat source outlet temperature is considered as a free parameter that can potentially be made available for a cooling process.

</tbody>
</table>

For the described integration Scenarios (see Figure 3), the results are presented in the following subsection. The HTHP load has been varied between 60 – 100 % (fan 1 as control parameter, mass flows see in Table 2) and the operating modes with and without recuperation have been studied. The degree of recuperation (3WV as control parameter, 0 % is non-recuperated, 100 % is recuperated) and the speed of the compressor (free parameter between 80 000 and 105 000 rpm) are the only variable control parameters. The other control parameters are fixed (fan 2 is 1 kg/s, heaters 1 and 2 with no heat input, control valves 1 and 2 are deactivated for no fluid inventory control).

4.1. Results of the Scenario 1

Figure 4 shows the compressor efficiency for the part load operations of Scenario 1. The comparison shows that the recuperated HTHP generally has a higher COP and Lorenz efficiency in all part load modes. The reason for the higher HTHP efficiency can be explained by the compressor and turbine mechanical powers conditions, inlet temperatures and compressor pressure ratio (Figure 5).

![Figure 4. Process parameter of the Brayton HTHP (Part 1) - Scenario 1](image-url)
Figure 5 shows that the recuperated operation mode has a significantly lower compressor power at all part load conditions, which is not compensated by the lower turbine power. Relative to the constant heat flow through the heat sink, this effect results in a higher COP (see equation 1 in subsection 2.1). The lower compressor and turbine power is due to the internal heat transfer through the IHX, which generally results in higher compressor inlet temperatures and lower turbine inlet temperatures. This is due to the fact that the only controllable parameter to run at part load is the compressor speed, which is controlled for an appropriate pressure ratio, which in turn provides the 250°C. When the compressor shaft speed is reduced, the Brayton mass flow and the compressor pressure ratio in the primary circuit are also reduced. This effect shifts the compressor operating condition to points on its map with higher isentropic efficiencies compared to non-recuperated operation (Figure 4).

In addition, Figure 5 shows that the consistently low turbine inlet temperatures and the generally lower Brayton mass flow in the recuperated mode in turn ensure consistently very low heat sink outlet temperatures and a higher heat source heat flow. With increasing part load, the outlet temperatures increase in both operating modes, which in turn leads to higher theoretical maximum efficiencies in the form of the Lorenz COP (Figure 4).
4.2. Results of the Scenario 2

Figure 6 shows the complete process parameters of Scenario 2 and the difference between the Brayton HTHP for the part load operation of Scenario 2 compared to Scenario 1. In general, it can be seen that the higher inlet temperature at the heat source results in a higher COP and, at full load, nullifies the effects and benefits of recuperation described above. This can also be seen where the turbomachinery capacities are almost the same at full load. This effect is cancelled as the partial load increases, as the internal heat transfer increases and the conditions become more similar to those in Scenario 1. In general, the inlet temperatures at the turbomachinery are higher, which leads to better conditions (e.g. compressor pressure ratio and Brayton mass flow) and ultimately to better but more similar efficiencies - compared between operating modes - as well as higher heat source flows and outlet temperatures in Figure 6.

Figure 6. Process parameter of the Brayton HTHP - Scenario 2
4.3. Comparison of the two Scenarios of industrial process integration of the Brayton HTHP

Firstly, the graphs of the key efficiency indicator COP show the typical increase in COP for heat pumps as the heat source inlet temperature rises. Scenario 2 has a significantly higher efficiency than Scenario 1 at all load conditions.

In relation to the influence of recuperation, both Scenarios show that the recuperated mode has a higher COP than the non-recuperated mode in part load operation. However, Scenario 2 shows that recuperation has no effect on the heat sink and heat source conditions and the COP of the Brayton HTHP as the heat source inlet temperatures increase. From this effect it can be concluded that as the available temperature increases, the decision of whether a recuperated process is required becomes obsolete.

A consideration of the heat sink conditions indicates that the type of process integration is critical to the intended application. This is because the outlet temperatures drop significantly at lower temperatures (see Scenario 1) and the use of the Brayton HTHP only makes sense if the cold temperatures are used in a cooling process.

Finally, a look at the controllable parameter of the compressor shaft speed of the two Scenarios in Figure 7 reflects the behavior of the heat pump in both Scenarios, where at low heat source inlet temperatures (Scenario 1) a higher demand is placed on the compressor than at increasing heat source inlet temperatures (Scenario 2), up to the approximate balance at full load due to cancellation of the positive recuperation effect.

![Figure 7. Compressor shaft speed of Scenario 1 (left) and compressor shaft speed of Scenario 2](image)

5. Conclusion and outlook

High temperature heat pumps based on the reverse Brayton process can contribute to the decarbonisation of industrial drying processes. For process integration into existing industrial processes with variable conditions, the ability and limitations to operate at part load play an important role. A simulation model based on a DLR-HTHP prototype was developed in these investigations and integrated into the simulation environment of EBSILON® Professional for off-design simulation considerations. An industrial process was then assumed and described which provided two investigation Scenarios for the Brayton HTHP integration and the part load study. These investigations were initially carried out with the two controllable components, the compressor to vary the compressor shaft speed and the 3-way valve to vary the recuperation rate.

The part load studies show that the conditions of the heat source and ultimately the nature of the industrial process are critical. If efficiencies increase as expected at low inlet temperatures and increasing recuperation, the advantage of recuperation is cancelled out as inlet temperatures increase.

Based on the controllable components presented in the methodology of this research, further studies on partial load operation can be carried out with DLR-HTHP prototype CoBra. Examples include fluid inventory control, or investigating further process architectures with the electric heater upstream of the compressor to simulate an additional waste heat application.

Furthermore, in the context of process integration, it should be noted that an experimentally designed HTHP has been studied in the context of these considerations. Although this will allow future experimental verification of the results with the DLR-HTHP prototype CoBra test facility, a potential Brayton HTHP integrated into an industrial process must be optimized for the industrial process with variable part-load conditions already in the design phase. The above considerations can serve as a basis for this.

Abstract

Traditional district heating systems face disadvantages such as low utilization of renewable energy and high system heat loss, while ultra-low temperature district heating (ULTDH) systems can make full use of low-temperature waste heat or renewable heat sources while reducing the heat loss of the pipe network. To deeply recover the low-temperature waste heat from the flue gas of a gas boiler in a heating project in Beijing, this paper designs a dual-loop booster heat pump system and uses it in the ULTDH system. The coefficient of performance (COP) and annual power consumption of the designed booster heat pump operating in the ULTDH system is simulated and analyzed using DeST software and actual compressor specifications. The results show that the average COP of the dual-loop booster heat pump is 0.92 higher than that of the conventional heat pump, which can save about 0.034 million kW·h of electrical energy during the heating period, and has a large energy-saving potential and broad market prospect.

Keywords: Booster heat pump; ultra-low temperature district heating; deep flue gas heat recovery.

1. Background

Current energy systems worldwide consume vast amounts of energy, even triggering global climate change. To achieve sustainable development strategies, there is a need to reduce primary energy consumption and gradually transition to sustainable energy. Among all energy consumption, building energy consumption account for a huge proportion of energy consumption, so improving building energy consumption is an effective way to achieve efficient energy use\cite{1-3}. Currently, the district heating of buildings in China is still dominated by coal-fired and gas-fired boilers, which pollutes the atmospheric environment and brings the problem of excessive energy utilization. Therefore, the effective recovery of low-grade waste heat or using renewable energy for building heating and hot water is an effective way to reduce energy consumption and achieve sustainable development\cite{4-6}.

In recent years, researchers have proposed an ultra-low temperature district heating system (ULTDH) that can fully use low-temperature heat sources or renewable energy, also known as the fifth generation district heating system. ULTDH improves the problems of significant heat loss, high energy consumption and less available heat sources in traditional district heating networks. The water temperature flowing from the heating network of the ULTDH is lower than 50 °C, even as low as 25 °C\cite{7,8}. Since the hot water temperature of the ultra-low temperature district heating system is relatively low, the hot water should be heated by the heat pump (booster heat pump) before passing through the terminal equipment to meet the requirements of the user or terminal equipment. In this case, the heat loss can be minimized to the extent that no pipe insulation is required because the hot water is close to the ambient temperature as it flows through the pipe network\cite{9-14}.

The high-temperature flue gas emitted from conventional district heating boilers can be recovered and utilized by heat exchangers or absorption heat pumps. But in the low-temperature flue gas still contains a large amount of waste heat that can be used. The compression heat pump can deeply recover the low-temperature...
flue gas waste heat between 30~60℃[15-18]. Mu et al.[19] applied heat pumps to flue gas recovery and conducted an experimental analysis of the performance of heat pumps. Compared with the energy consumption of gas boilers, exhaust-source heat pumps can save 55% of standard coal. The comprehensive energy efficiency ratio of heat pumps can reach more than 4.0. However, because two sets of units are needed to supply heat and domestic hot water separately, there are problems with occupying large space and large installation and operation and maintenance costs. Wu et al.[20] analyzed the engineering application of exhaust-source heat pumps. The results show that although the traditional heat pump has greater advantages in waste heat utilization, the large-scale implementation of the application is more difficult due to the large number of equipment and complex system operation. Huang et al.[21] address the problem of low utilization of waste heat from flue gas boilers, combined with air source heat pump technology for low-level flue gas waste heat for gradient depth recovery and utilization. Results show that by recycling flue gas waste heat, with low valley electricity prices, the heating cost of domestic hot water can be reduced more significantly, with energy saving, emission reduction, water saving and other economic benefits. However, the initial investment cost of the system is large. In the face of large temperature differences, there are still problems of relatively low energy efficiency and poor system heat transfer efficiency.

Due to the problems of high initial investment cost, large floor space and low heat transfer efficiency of the system under large temperature difference conditions, this paper designs a dual-loop heat pump system for boiler flue gas deep recovery. Integrating two independent heat pump loops into one device improves the uniformity of the heat transfer process and the coefficient of performance (COP) of the heat pump. The dual-loop booster heat pump is applied to the deep recovery of boiler flue gas waste heat in a district heating project in Beijing. Based on the performance of the actual compressor, the operating performance of this dual-loop booster heat pump was simulated and analyzed using DeST software.

2. System design and application scheme

2.1. Dual-loop booster heat pump system

The flue gas waste heat recovery device integrated with the heat pump is shown in Fig. 1. Firstly, the boiler flue gas and part of the heating return water for heat exchange, then the flue gas is discharged to the flue gas heat exchanger, in the flue gas heat exchanger for intermediate water heating, flue gas reduced to a certain temperature and then discharged to the heat exchanger, the heated intermediate water as a low-temperature heat source into the heat pump, the heat pump will be the remaining heat network return water heated to the heating temperature.

![Fig. 1. Combined utilization of flue gas waste heat recovery device and booster heat pump.](image)

Fig. 2(a) shows the designed new dual-loop heat pump system. After absorbing the flue gas waste heat, the hot intermediate water enters the evaporator of the heat pump to exchange heat with the refrigerant, the booster heat pump absorbs heat from the intermediate water and raises the refrigerant to a higher temperature with the input of electrical energy to heat the heating return water in the condenser. The designed dual-loop system contains two compressors, two expansion valves, an evaporator and a condenser. The return water enters from the inlet of the condenser and carries out counter-current heat exchange with the refrigerant in the low-temperature loop and the high-temperature loop successively, and then discharges from the outlet of the condenser after reaching the required temperature of the user and flows to the user side for heating; the heat
source water enters from the inlet of the evaporator and carries out counter-current heat exchange with the refrigerant in the high-temperature loop and the low-temperature loop successively. The pressure-enthalpy diagram of the dual-loop heat pump system is shown in Fig. 2(b), where cycle 1-2-3-4-1 represents the low-temperature loop and cycle 5-6-7-8-5 for the high-temperature loop.

![Diagram of dual-loop system](source.png)

Fig. 2. (a) Schematic of the dual-loop system; (b) P-h diagram of dual-loop heat pump system.

### 2.2. Application scheme

This paper designs a traditional single-loop and a new dual-loop booster heat pump for flue gas waste heat recovery in a heating boiler room in Beijing, and the heat recovered by the booster heat pump heat some commercial buildings in the area, and this boiler room is divided into two rooms in the North and South, covering 188,848 m² and 353,603 m², respectively, the design indexes are shown in Table 1.

<table>
<thead>
<tr>
<th>Building location</th>

<td>957.83</td>
<td>16869.99</td>
<td>843.5</td>
</tr>
</tbody>
</table>

The main heating form of the project is gas boiler heating, and the flue gas is the main waste heat source of the project itself. The waste heat recovery index is 5% of the total heat load, the total installed capacity of the South area is 9392kW, and the total installed capacity of the North area is 16870kW. The waste heat recovery index of the heat pump in the South area is 470kW, and the waste heat recovery index of the heat pump in the North area is 843.5kW. The heat recovered from the heat pump will be used to meet the heat demand of some buildings in the area, the main load of this part of the building is commercial heat load, mainly concentrated during the daytime, with insulation running at night.

For the traditional single-loop booster heat pump systems, each unit is set to have a rated heat capacity of 150kW. For the new dual-loop booster heat pump systems, each unit is set to have a rated heat capacity of 240kW, and the heat production is made to meet the heat load requirements by connecting multiple units in parallel. For the South area, the index of waste heat recovery is 470kW, so the single-loop heat pump in the South area is set to 4 units in parallel, and the dual-loop heat pump is set to 2 units in parallel. In the North area, the waste heat recovery index is 843.5kW, so the single-loop system in the North area is set to 6 units in parallel, and the dual-loop heat pump is set to 4 units in parallel.

Due to the large amount of low-temperature flue gas discharged from the district heating boiler, it is necessary to select a large-capacity compressor that can operate at low-temperature conditions. According to the compressor's applicable temperature range and heat capacity, the working fluid's safety and economy. Danfoss DSH381–4 scroll compressor and R410A are selected, and the curve of COP with temperature is shown in Fig. 3.
2.3. The curve of the heating load

In this case, the heat recovered from waste heat is used for heating some buildings in this area. To meet the real-time heat demand of users, this paper has used DeST software to conduct modeling and simulation and obtains the hourly heating load curve of the whole heating period of some buildings in this area. As shown in Fig. 4(a), the heating period is from November 15 to March 15 of the following year, totaling 2904 hours. In Fig. 4, the horizontal coordinate represents the time and the vertical coordinate represents the heating load, the blue curve is the heating load of some buildings in the North area and the red curve is the heating load of some buildings in the South area. The average hourly heating load of the buildings in the North area is 261.76 kW, and the maximum heating load can be 710.75 kW, while the average hourly heating load of the buildings in the South area is 145.75 kW, and the maximum heating load is 395.74 kW, the waste heat recovery index can fully meet the heating load demand of this part of the buildings. From the perspective of the whole heating period, the overall trend of hourly heating load in both the South and North areas is first increased and then decreased, which is consistent with the actual local climate change. It is shown in Fig. 4(a) that the heating load fluctuates greatly in a short time interval, this is because the buildings are mainly commercial buildings, and there are many people in the daytime, so they need high thermal comfort and high heating load. However, there are few people in commercial buildings at night, and the thermal comfort is low. Therefore, the heating load of the buildings at night is low.

Instantaneous heating load on the customer side is variable, so heating regulation is required during operation. In this paper, temperature regulation is utilized as a centralized regulation method for the hot water heating system, that is, the mass flow rate of heating water is unchanged, and only the temperature of the supply water is changed. Fig. 4(b) shows the variation in the temperature of the supply and return water in the heating system regarding the number of days. At the beginning of the heating period, the required heating load on the customer side is low, the temperature of the supply water is slightly lower, the temperature of the return water is high, and the temperature difference between supply and return water is small; at this stage, the average temperature of the supply water is 45.29 °C, the average temperature of the return water is 34.43 °C, and the average temperature difference between supply and return water is 10.86 °C. As time passes, the ambient temperature gradually decreases, the heating demand on the customer side becomes higher, the temperature of the supply water rises continuously up to 48.45 °C, the temperature of the return water gradually decreases, down to 32.92 °C, and the maximum temperature difference between supply and return water is up to 15.53 °C. At the later stage of the heating period, the ambient temperature gradually rises, the heating load of the customers is lower, the temperature of the supply water gradually decreases, the temperature of the return water gradually increases, and the temperature difference between the supply and return water becomes smaller, at this stage the average temperature of the supply water is 45.63 °C, the average temperature of the return water is 35.86 °C, and the average temperature difference between supply and return water is 9.77 °C.
2.4. Control strategy of heat pump

Based on the hourly heating load curve and the temperature variation curve of the supply and return water obtained from the above simulation throughout the heating period, this paper carries out the analysis of the year-round control strategy of the booster heat pump system, which controls the heat production by controlling the compressor on and off, and the higher the heating load, the more the number of compressors on. When the heating load is lower than the rated heat capacity of one unit, only one heat pump unit is turned on. It is important to note that two compressors need to be started for the dual-loop heat pumps for each unit.

On the day with the highest heating load during the whole heating period, the number of started compressors hour by hour for the North and South areas are shown in Fig. 5(a) and 5(b), respectively. It can be seen that the number of started compressors is higher in the North area than in the South area due to the difference in heating load. Since the dual-loop systems contain two compressors in one unit, the number of started compressors is greater than or equal to that of the single-loop systems. At night, there are few people in the commercial buildings, the heating load is low, and the number of started compressors is small; during the daytime, the number of people in the commercial buildings increases, the heating load rises, and the number of started compressors increases and reaches the highest from 7:00 a.m to 9:00 a.m. After 9:00 a.m., solar heat radiation gradually becomes more robust, the heating load decreases, and the number of started compressors decreases. From 11:00 a.m to 3:00 p.m, the heating load is lowest and the compressor is turned on the least.

During the heating period, solar radiation, ambient temperature, as well as the number of people in the building, vary almost cyclically, which means that the trend of the number of compressors starting and stopping each day is the same, and there will only be quantitative differences, so the day with the highest heating load is chosen for the control strategy analysis to be more representative.
3. Calculation and result analysis of booster heat pump system

3.1. Thermal cycle calculation process of the heat pump unit

The temperature of the supply and return water and heating load obtained in section 2.3 are used as input to calculate the parameters of the thermal process for the conventional single-loop system and the new dual-loop system based on the control strategy of compressors, and the calculated parameters include the condensation and evaporation temperature temperatures, condensation and evaporation pressures, water-side mass flow rate, refrigerant mass flow rate, the heating capacity, heat taking and power consumption.

For the whole dual-loop system, the heating capacity, power consumption and COP of the system can be calculated by equations (1), (2) and (3). The heating capacity and power consumption of the whole system are the sum of the two loops. Equations (4) and (5) are the power consumption calculation process of the low-temperature loop, and the calculation process of the high-temperature loop is similar to that of the low-temperature loop.

\[ Q_e = cm_1(t_{w,1,i} - t_{w,1,o}) \]  
\[ Q_c = cm_2(t_{w,2,o} - t_{w,2,i}) \]  
\[ COP = \frac{Q_c}{W} \]  
\[ m_{r1} = \frac{Q_{c1}}{(h_2 - h_3)} \]  
\[ W_1 = m_{r1}(h_2 - h_1) \]

Where, \( Q_e \) is the heating capacity of the whole system, kW; \( Q_e \) is the quantity of heat taken from the low-temperature heat source side, kW; \( c \) is the specific heat capacity of water, J/(kg·°C); \( m_1 \) is the mass flow rate of the heat source water, m³/h; \( m_2 \) is the mass flow rate of the supply water, m³/h; \( m_{r} \) is the mass flow rate of refrigerant, kg/s; \( W \) is the power consumption of the compressors, kW; \( COP \) is the coefficient of performance; \( t_{w,1,i} \) is the inlet temperature of low-temperature heat source water, °C; \( t_{w,1,o} \) is the outlet temperature of low-temperature heat source water, °C; \( t_{w,2,o} \) is the temperature of the supply water, °C.

3.2. Flowchart for calculating dual-loop booster heat pump

Since a dual-loop heat pump system has two loops and the two loops interact, the calculation process differs from that of a single-loop heat pump. Using the heat balance equation of the water side and the refrigerant side, input the known temperatures of the supply water and the return water, the inlet and outlet temperatures of the heat source water side, the average temperature of the inlet and outlet temperatures of the hot water side and the average temperature of the inlet and outlet temperatures of the heat source water side can be selected as the assumed temperature of the middle point respectively, and after repeated iterations to reach equilibrium, simulations are performed to calculate the low-temperature loop, high-temperature loop and the overall unit performance parameters. The flowchart of the calculation of the dual-loop heat pump is shown in Fig. 6 below.
3.3. Verification of calculation results

In order to verify the accuracy of the calculation results in this paper, the working condition of supply/return water temperature of 60/50 °C and heat source water inlet/outlet temperature of 30/25 °C are calculated and compared with the results in Ref. [22]. The results are shown in Table 2. From Table 2, the deviation of COP is 4.36%, the deviation of power consumption is 4.82% and the deviation of heat capacity is 9.06% compared with the data in the literature, which are less than 10%, which can indicate the reliability and accuracy of the calculation results.

3.4. Calculation results

Calculations are performed according to the calculation procedure shown in Fig. 7, keeping the inlet temperature of heat source water at 28 °C and outlet temperature at 18 °C, heat transfer temperature difference of the heat exchanger at 3 °C. The inlet and outlet temperatures of heating water vary according to the curves shown in Fig. 4(b).
Fig. 7 shows the dynamic variation of the COP of the conventional single-loop booster heat pump and the new dual-loop booster heat pump in terms of days. Under the same conditions, the COP of the dual-loop heat pump is significantly higher than that of the conventional single-loop heat pump. The COP of the single-loop heat pump and the dual-loop system has roughly the same trend over time, both decrease first and then increase, mainly because the temperatures of the supply and return water are different at different times, as shown in section 2.3, the temperature of the supply water increases first and then decreases over time during the heating period. When the temperature of the supply water increases, the system needs to reach a higher condensation temperature. The compressor’s compression ratio increases, the refrigerant mass flow rate decreases, and the system performance decreases. The average COP of the single-loop heat pump was 5.42 and the average COP of the dual-loop system was 6.34, with a difference of 0.92. The highest COP of the single-loop heat pump was 6.28 and the lowest was 5.03, with a variation of 1.25, and the highest COP of the dual-loop heat pump was 7.12 and the lowest was 6.01, with a variation of 1.11.

3.5. Energy saving effect

Fig. 8 shows the daily power consumption of the traditional single-loop booster heat pump and the dual-loop booster heat pump in the North area. The horizontal coordinate is time and the vertical coordinate is the power consumption of the heat pump. The red curve represents the dual-loop heat pumps and the blue curve represents the single-loop heat pumps. It can be seen that in the middle of the heating period, the power consumption is higher than that at the beginning and end of the heating period, which is the same as the trend of the heating load. The power consumption of the dual-loop heat pumps is generally lower than that of the single-loop heat pumps, which is more obvious when the heating load is high.

After calculation, this ultra-low temperature district heating system can produce 4260 GJ of heat per year during the heating period, of which the single-loop heat pumps need to consume 0.217 million kW·h of electric energy and the dual-loop heat pumps need to consume 0.183 million kW·h of electric energy. In the whole heating period, compared with the single-loop heat pump system, the dual-loop heat pump system saves 0.034 million kW·h of electric energy, and the electricity saving rate is up to 15.6%.
4. Conclusions

In this paper, a new dual-loop booster heat pump for ultra-low temperature district heating is designed and applied to a gas boiler flue gas deep recovery project in Beijing. Simulations were performed using DeST software to obtain the hourly heating load for the entire heating period, and then the annual energy consumption and COP of the dual-loop booster heat pump system were calculated and analyzed, with the following conclusions:

The heating load of the building is affected by the ambient temperature more obviously, from the beginning to the end of the heating period, the heating load of the buildings rises first and then decreases, in the middle of the heating period when the weather is cold, the heating load is larger, at the beginning and the end of the heating period the heating load of the buildings is smaller, among which the maximum heating load of the buildings in the North area can reach up to 710.75 kW, and the highest heating load of the buildings in the South area is 395.74 kW. The waste heat recovery capacity of the booster heat pump designed in this paper can fully meet the heating demand of this part of the building.

Compared with the traditional single-loop heat pump, the dual-loop heat pump has a significant energy-saving effect, with an average COP increase of 0.92. The traditional single-loop heat pumps need to consume 0.217 million kW·h of electric energy in the whole heating period. In comparison, the dual-loop heat pumps consume 0.183 million kW·h, saving 0.034 million kW·h of electric energy, with an electricity saving rate of up to 15.6%.

Abstract

Heat pump systems are often restricted to operate within a certain temperature range due to the limits on pressure ratio and discharge temperature. A new storage heat pump concept aimed at improving the operating temperature range of a heat pump system is proposed. Performance of an R134a heat pump water heater (HPWH) system with wrap-around condenser coil operating based on the new concept is studied by means of a system model. The storage heat pump cycle involves system operation in two modes to achieve the high temperature lift. In Mode I, ambient air acts as heat source for the evaporator and full length of wrap-around coil is used as condenser, whereas in Mode II, a throttling valve splits the wrap-around coil into a condenser and evaporator. Here, the intermediate temperature water in the lower tank region acts as heat source for the evaporator. This lifts up the evaporating pressure which enables the heat pump to operate at a lower pressure ratio and reach a higher water end temperature. Modeling results obtained for the storage heat pump system are also compared with a conventional HPWH system that uses back-up electric elements to reach the required water temperature when the heat pump is unable to operate.

Keywords: heat pump water heater; operating range; energy storage; modeling

1. Introduction

Heat pump systems operate on the principle of vapor compression cycle and thus offer a much higher energy utilization efficiency as compared to conventional methods like electric resistance heating. The maximum possible temperature difference between the heat source and heat sink for the system is referred as the operating temperature range of the system and it is limited by the compressor operating envelope in conjunction with the refrigerant used. Exceeding the operating temperature range can cause issues such as degradation of lubricant as well as lower heating capacity due to the high pressure ratio and discharge temperature. The heat pump water heater (HPWH) system faces this situation when it is required to provide hot water in cold ambient conditions. A new storage heat pump concept aimed at improving the operating temperature range of a heat pump system is introduced in this paper. The system under consideration is an R134a HPWH with wrap-around condenser coil.

Implementation of the new concept requires a split-condenser design, an energy storage element and the system operation in two different modes. Mode I is same as conventional system operation whereas as the wrap-around coil is split into condenser and evaporator in Mode II. The water contained in the lower portion of tank itself acts as energy storage element for the system, wherein energy stored by the system in Mode I is utilized in Mode II to enable the system to operate at a lower pressure ratio and discharge temperature compared to a conventional heat pump system. Objective of this study is to predict the performance of a storage heat pump system by the means of a system model. Model is used to obtain the system performance under different scenarios and determine the suitable wrap-around coil split ratio along with compressor speed and

\textsuperscript{*} Corresponding author. E-mail address: elbel@illinois.edu
time duration for system operation in Mode II. System model consists of a quasi-steady vapor compression cycle model linked with a transient water tank CFD model. Performance of the storage heat pump system is also compared with a conventional HPWH that uses back-up electric heating elements to reach the target water temperature when heat pump is unable to operate.

Several authors have studied methods such as refrigerant injection in HPWH system (Liu et al., 2008) and usage of cascade heat pump systems (Wu et al., 2012) with an aim to overcome issues of high discharge temperature and low heating capacity when operating the heat pump in cold climate. Refrigerant injection can cause issues such as compressor slugging while the cascade system can lead to increased complexity and cost for the heat pump. The storage heat pump concept introduced in this paper is based on energy storage at an intermediate temperature and can be implemented through a single stage heat pump design.

1.1. New Storage Heat Pump Concept

A schematic of the storage heat pump system operating in two modes is shown in Figure 1. The system operation in Mode I shown in Figure 1a is same as the conventional system operation. For a conventional heat pump system, the ambient air is used as heat source for the fin-tube evaporator and water contained in tank is heated by heat rejection from the condenser. The schematic also shows the water tank temperature stratification which occurs due to the effect of natural convection. As the water contained in the tank heats up, the temperature difference between the ambient (heat source) and water (heat sink) increases. This results in an increase in the pressure ratio and discharge temperature for vapor compression cycle. If the pressure ratio becomes too high, then the compressor has to be cycled off and the system is unable to reach the target water temperature while using the heat pump. Conventional HPWH system often uses back-up electric heating elements to reach the higher water temperature when the heat pump is unable to operate.

The storage heat pump system involves switching between the two modes to achieve the high temperature lift. In Mode I, the water contained in the tank is heated from a low to intermediate temperature while using the full length of wrap-around coil as condenser. Then the system operation switches to Mode II, in which the wrap-around coil is split by means of a throttle valve to use top portion of coil as condenser and the bottom portion as evaporator. The fan attached to the fin-tube heat exchanger is kept off so that the heat exchanger is unused in this mode. In Mode II, the intermediate temperature water present in lower region of tank would act as heat source for the evaporator. This increases the evaporating pressure and reduces the pressure ratio which allows the system to continue to operate and reach a higher water temperature in the upper region of the tank.

Thus, instead of using the back-up electric elements to reach a higher water temperature the storage heat pump system in Mode II would use the heat pump compressor to pump the energy contained in the water in lower tank region to that in the upper region. While evaporator received energy from the ambient in Mode I, the energy received by evaporator in Mode II comes from within the system and the temperature of water in lower tank region reduces. It should be noted that the tank will not heat up faster than in the conventional HPWH because the heating capacity of vapor compression cycle is lower than the heating capacity of back up electric elements used in conventional HPWH system. Instead, the storage heat pump concept allows the system to reach a higher water end temperature that could otherwise not be reached with a conventional system while only using the heat pump.

Figure 1. Heat pump water heat system operating in the two modes: a) Mode I and b) Mode II
2. Model Description

HPWH systems are commonly modeled by combining a quasi-steady vapor compression cycle model with a transient water tank model. Ibrahim et al. (2014) developed a dynamic simulation model for an air source HPWH with immersed coil condenser to obtain system performance under different climatic conditions. Vapor compression system was modeled under quasi-steady assumption and the water tank was modeled through a lumped parameter approach. Shen et al. (2018) developed a quasi-steady HPWH model with wrap-around condenser coil. Water tank was modeled by dividing the tank into several nodes in 1D to model the temperature stratification in the tank. Deutz et al. (2018) used the zonal tank model approach in their HPWH model. The zonal water tank model takes into account the thermal and inertial boundary layer forming along the tank wall when heated by the condenser. Li and Hrnjak (2018) presented an experimentally validated HPHW model in which the vapor compression system model was linked with a transient water tank CFD model. The CFD model of the water tank could give accurate estimation of the water side temperature and flow field inside the water tank.

The linked modeling approach from Li and Hrnjak is used to model the storage heat pump system in this work. System model consists of a quasi-steady vapor compression system model linked with a transient water tank CFD model. The linked modeling algorithm is shown in Figure 2b. System is simulated with water in warm-up condition, where the water in the tank is heated from an initial to set point temperature without any water draw from the system. The vapor compression system model consists of a compressor model, condenser and evaporator models and an expansion valve modeled by isenthalpic process. This model is solved by using an iteration algorithm (shown in Figure 2a) based on the Newton Raphson method adopted from Inampudi et al. (2021). Pressure and specific enthalpy are taken as connecting variables between the various components and the system model is solved iteratively until the refrigerant states at connecting points do not need further modification.

2.1. Compressor Model

For the given refrigerant inlet pressure, inlet specific enthalpy and outlet pressure, the compressor model uses three variables: volumetric efficiency, compression efficiency and isentropic efficiency to compute the refrigerant mass flow rate, discharge specific enthalpy and the electric power consumed by the compressor.

\[
\eta_{\text{vol}} = \frac{\dot{m}}{\rho_{\text{in}} \cdot V_{\text{disp}} \cdot f}
\]  (1)

\[
\eta_{\text{comp}} = \frac{(h_{\text{cp}} - h_{\text{pri}})}{(h_{\text{cpro}} - h_{\text{pri}})}
\]  (2)

\[
\eta_{\text{isen}} = \frac{\dot{m} \cdot (h_{\text{cp}} - h_{\text{pri}})}{W_{\text{electric}}}
\]  (3)

Curve fitting equations that relate efficiencies to pressure ratio were obtained from experimental data. A linear curve fitting between efficiencies and pressure ratio was found to give a reasonable result. Mass flow rate, discharge specific enthalpy and electric power consumption is obtained by solving equations (1), (2) and (3) respectively.

2.2. Heat Exchanger Models

Heat exchangers in the system are modeled by using the finite volume approach. The heat exchanger is divided into discrete elements along the refrigerant flow circuit and the heat transfer and pressure drop in each element is obtained by applying equations for conservation of energy and momentum. Refrigerant inlet pressure and specific enthalpy, mass flow rate and external fluid (air for fin-tube evaporator and water for wrap-around coil heat exchanger) conditions are taken as inputs for the heat exchanger model. Discrete elements are solved sequentially to obtain the refrigerant specific enthalpy and pressure at exit of each element. The model finally gives the refrigerant specific enthalpy and pressure at the outlet of the heat exchanger. The \(\varepsilon - NTU\) method is used for calculating the heat transfer in each element considering a cross flow configuration between external fluid and refrigerant. Table 1 shows the correlations used in calculating pressure drop and heat transfer coefficient for the evaporator and condenser. Water side heat transfer coefficient for the wrap-around coil heat exchanger is obtained from the water tank CFD model.
### Table 1. Correlations used to obtain heat transfer coefficient and pressure drop in each element for heat exchanger models

#### 2.3. Water Tank CFD Model

A transient water tank CFD model is developed in ANSYS Fluent. The three-dimensional cylindrical water tank is simplified to a two-dimensional axisymmetric model by assuming the heat flux from each coil turn to be uniform in the circumferential direction. Each turn of the wrap-around coil is represented by a line segment (of the length equal to the pitch of coil turn) at the tank wall. The heat flux from each coil turn is implemented as a time varying boundary condition by using User Defined Functions in Fluent. The natural convection of water is modeled by computing the density based on Boussinesq approximation. Laminar flow model is selected for the simulation and the SIMPLE scheme is selected for the pressure velocity coupling.

#### 2.4. HPWH System Model Solving Procedure

The system model consists of a quasi-steady vapor compression cycle model linked with a transient water tank CFD model using the linked modeling approach of Li and Hrnjak (2018). Starting from a guess value of heat flux profile \( q''(n,t) \) (here \( n \) is the coil turn number and \( t \) is time) at the tank wall, the CFD model is solved for the full water heating period. The resulting water side temperature and heat transfer coefficient are used as inputs for the vapor compression system model which is then run at various time instances to obtain the new temporal heat flux profile. The water tank model is run again with the new heat flux profile as input and the iterations continue until convergence in heat flux profile through tank wall is obtained. The vapor compression system model takes the air side mass flow rate and temperature (for the fin-tube evaporator), water side temperature and heat transfer coefficient (for the wrap-around coil heat exchanger), compressor speed, superheat (set by EXV) and subcooling (set by system charge) as inputs.

![Flowchart of the HPWH system model](Figure 2)
3. Modeling Results

3.1. Storage Heat Pump System

A previous experimental study (Patel and Elbel, 2022) carried out on a conventional HPWH showed that for an initial water temperature of 25°C the system could heat water only to a bulk average temperature of 48°C by using the heat pump. The heat pump compressor is cut-off when the water temperature reaches 48°C and the conventional HPWH would use a back-up electric coil to reach a higher water temperature. The time taken for the system to heat the water from 25°C to 48°C in warm-up condition (no water draw from tank) was about 180 minutes.

The storage heat pump cycle involves system operation in two modes to reach a higher water temperature than a conventional HPWH could reach while using the heat pump. Performance of the storage heat pump system is obtained for the operating conditions shown in Table 2. System operates in Mode I until the water contained in the tank is heated to bulk average temperature of 48°C. Then the system operation switches to Mode II in order to get the reduction in pressure ratio and discharge temperature.

As shown in Table 2, the compressor speed in Mode I is 3600 min⁻¹, while in Mode II it is taken as 1800 min⁻¹. The compressor speed for storage heat pump system operating in Mode II is lowered by 50% compared to speed in Mode I. The compressor speed is reduced in order to match the compressor capacity with the smaller size of heat exchangers in Mode II. The system uses fin-tube evaporator and full length of wrap-around coil as condenser in Mode I, while splitting the wrap-around coil into condenser and evaporator in Mode II. Due to this, there is a change in the size of the heat exchangers in the system upon switching to the Mode II. The \( \Delta T \) (\( \Delta T_{hx} = T_{ref, sat} - T_{ext, fluid} \)) for a heat exchanger is defined as the difference between the refrigerant saturation temperature and the external fluid temperature. The \( \Delta T \) values of condenser and evaporator for the system operating in Mode I are listed in Table 3. The \( \Delta T \) values predicted for the system upon switching to Mode II and operating with two different compressor speeds are also shown in the Table 3.

It can be observed that if the compressor speed in Mode II is kept the same as the speed in Mode I then the \( \Delta T \) values for the heat exchangers in Mode II are much higher than the corresponding values in Mode I. This indicates that the compressor is oversized for the size of heat exchanger in Mode II and the high \( \Delta T \) values will be detrimental to reducing the pressure ratio in Mode II. Thus, to keep the \( \Delta T \) for heat exchanger in Mode II closer to the value in Mode I, the compressor speed is reduced by 50% in Mode II. The reduction in compressor speed will result in a lower heating capacity for the vapor compression cycle in Mode II compared to Mode I.

As show in Table 2, the compressor speed in Mode I is 3600 min⁻¹, while in Mode II it is taken as 1800 min⁻¹. The compressor speed for storage heat pump system operating in Mode II is lowered by 50% compared to speed in Mode I. The compressor speed is reduced in order to match the compressor capacity with the smaller size of heat exchangers in Mode II. The system uses fin-tube evaporator and full length of wrap-around coil as condenser in Mode I, while splitting the wrap-around coil into condenser and evaporator in Mode II. Due to this, there is a change in the size of the heat exchangers in the system upon switching to the Mode II. The \( \Delta T \) (\( \Delta T_{hx} = T_{ref, sat} - T_{ext, fluid} \)) for a heat exchanger is defined as the difference between the refrigerant saturation temperature and the external fluid temperature. The \( \Delta T \) values of condenser and evaporator for the system operating in Mode I are listed in Table 3. The \( \Delta T \) values predicted for the system upon switching to Mode II and operating with two different compressor speeds are also shown in the Table 3.

It can be observed that if the compressor speed in Mode II is kept the same as the speed in Mode I then the \( \Delta T \) values for the heat exchangers in Mode II are much higher than the corresponding values in Mode I. This indicates that the compressor is oversized for the size of heat exchanger in Mode II and the high \( \Delta T \) values will be detrimental to reducing the pressure ratio in Mode II. Thus, to keep the \( \Delta T \) for heat exchanger in Mode II closer to the value in Mode I, the compressor speed is reduced by 50% in Mode II. The reduction in compressor speed will result in a lower heating capacity for the vapor compression cycle in Mode II compared to Mode I.

The P-h plot obtained for the storage heat pump system for various time instances from t=0 to 240 minutes is shown in Figure 3. The system achieves a lift in evaporating pressure upon switching to Mode II at t=180 minutes. This is because the evaporator in Mode II will use the water contained in the bottom region of the tank as the heat source. The water contained in the tank (heat source in Mode II) would be at a higher temperature than the ambient air (heat source in Mode I) as the water temperature was elevated during system operation.
operation in Mode I. The condensing pressure for the system also increases upon switching to Mode II. This is due to a slightly higher $\Delta T_{\text{cond}}$ (resulting from a smaller condenser size in Mode II compared to Mode I) for system in Mode II. However, the lift in evaporation pressure achieved upon switching to Mode II enables the system to maintain a lower pressure ratio and discharge temperature while the water in the upper tank region continues to heat up.

Figure 4a shows the variation in water temperature with time (at 10 different vertical locations spaced uniformly) as system switches operation between the two modes. The water tank CFD model showed that the water temperature in the tank remains almost uniform in the radial direction other than within a small boundary layer region near the tank wall. The water tank temperature contour at t=240 minutes is shown in Figure 4b. It can be observed from Figure 4a that the water temperature in the upper tank region (4/5th of total tank height for wrap-around coil split-ratio Ne/Nc = 3/7) continues to increase while the water temperature in the lower region increases in Mode I and reduces when operating in Mode II. Water contained in the lower tank region is used an energy storage element, wherein the energy stored in Mode I is utilized by the system in Mode II.

![Figure 3. Pressure vs Specific enthalpy plot for system at different time instances](image3.png)

![Figure 4. a) Water temperature measured at different vertical locations in the tank b) Water temperature contour at t=240 minutes](image4.png)

While operating in Mode II (from t=180 to 240 minutes), the water temperature in the bottom tank region reduces due to the heat extraction by the evaporator. The lift in evaporation pressure achieved upon switching to Mode II also diminishes with time. This limits the time duration for which it is advantageous (in terms of reduced pressure ratio and discharge temperature) for the system to operate in Mode II. However, the system can again switch back to Mode I (at t=240 minutes) as the intermediate operation in Mode II would have resulted in lowering the temperature of water in the bottom tank region. This enables the system to maintain a lower pressure ratio and discharge temperature compared to a system with continuous operation in Mode I. Now when the system operates in Mode I (from t=240 to 265 minutes), most of the heat transfer from the condenser coil would happen from the coil turns located around bottom region of tank. The temperature of water in bottom tank region increases at a much faster rate and once the water in bottom tank region is heated up to an intermediate temperature level, the system can again switch back to Mode II (at t=265 minutes) to use this water as heat source for the evaporator.

The variation in discharge temperature and pressure ratio with time for the storage heat pump system are shown in Figure 5. When operating in Mode I (between t=0 to 180 minutes) the pressure ratio increases as the water heats up and results in an increase in condensing pressure while the evaporating pressure remains almost same due to the ambient temperature being constant. The pressure ratio reduces as the system switches to Mode II (at t=180 minutes). This is due to the lift in evaporating pressure achieved upon switching to Mode II. The reduction in pressure ratio would contribute to lowering the discharge temperature for the system while the higher condensing pressure in Mode II will contribute to increasing the discharge temperature. The combined effect causes the discharge temperature to reduce slightly upon switching to Mode II.

When operating in Mode II (between t=180 and 240 minutes) the pressure ratio increases as the water in upper tank region (heat sink) heats up while the water in the lower tank region (heat source) cools down. The discharge pressure also increases when operating in Mode II. As the system again switches to Mode I (at t=240 minutes) and uses full length of wrap-around coil as condenser, the discharge temperature and pressure ratio drop due to the lower condensing pressure for the system caused by the low temperature of water in the bottom tank region. When operating in Mode I (between t=240 and 265 minutes) the pressure ratio and discharge temperature increase as water in the tank is heated up. Now, when the system switches again to mode II (at
the pressure ratio drops while the combined effect of lower pressure ratio and higher condensing pressure causes the discharge temperature to increase slightly. Compared to a conventional heat pump system (which is equivalent to a continuous operation in Mode I) the storage heat pump system can maintain the lower discharge temperature and pressure ratio. The heating capacity and compressor power consumption are shown in Figure 6. The heating capacity is lower in Mode II due to the reduction in size of heat exchangers and compressor speed in Mode II as compared to Mode I.

3.2. Effect of Wrap-Around Coil Split Ratio on System Performance

The storage heat pump system uses full length of wrap-around coil as condenser in Mode I while splitting the wrap-around coil to use top portion of coil as condenser and bottom portion as evaporator in Mode II. The split ratio for wrap-around coil in Mode II is defined as \( \frac{N_e}{N_c} \) = number of coil turns used as evaporator/ number of coil turns used as condenser in Mode II. The split ratio determines the relative sizes of condenser and evaporator in Mode II and thus impacts the system performance. The model is used to study the system performance in Mode II for four different split ratios. Other than varying the split ratio all the other conditions for the four cases were kept same as listed in Table 4.

<td></td>
</tr>
</tbody>
</table>

Figure 7 shows the comparison between P-h plot of the different cases upon switching Mode II. It can be observed that a system with a higher split ratio achieves a higher lift in the evaporating pressure upon switching to Mode II. This is because the system with a higher split ratio will have a larger size of evaporator compared to the lower split ratio case and this results in a lower \( \Delta T_{\text{evap}}(T_{w,lower} - T_{ref,\text{evap}}) \) for the system with higher split ratio. The system with a higher split ratio also shows a higher condensing pressure in Mode II because of the relatively smaller condenser size that results in a higher \( \Delta T_{\text{cond}}(T_{ref,\text{cond}} - T_{w,\text{upper}}) \) for the system. The discharge temperature and pressure ratio for the different cases is shown in Figure 8. The pressure ratio is almost the same for all the cases while the system with higher split ratio shows a higher discharge temperature due to the higher condensing pressure in Mode II.

The average heating capacity for the system in Mode II (average \( \dot{Q}_{\text{cond}} \) from \( t=180 \) to \( 240 \) minutes) for the different cases is listed in Table 5. The compressor speed in Mode II is kept same for all the cases due to which there is not much difference between the heating capacity among the different cases. With the pressure ratio being almost same for all the cases, the system with a higher split ratio has a higher evaporating pressure which results in higher refrigerant mass flow rate. This leads to a higher heating capacity for system with higher split ratio in Mode II. The average value of the ratio of heating capacity and compressor power consumption in Mode II is also listed in the Table 5. This system with intermediate split ratio such as
Ne/Nc=3/7 and Ne/Nc=4/6 have a higher heating capacity per unit power consumption as compared to other cases which is due to better matching between the compressor capacity and size of condenser and evaporator in these systems. It should be noted that the heating capacity of system is the rate of energy transfer to the water in upper region of the tank while water in lower tank region acts as heat source for the evaporator. Thus, energy received by the evaporator comes from within the system and temperature of water in lower tank region (within bottom of tank to the height at which wrap-around coil is split) reduces when operating in Mode II.

</tbody>
</table>

While the higher split ratio of Ne/Nc=5/5 gives a higher heating capacity, the absolute value of discharge temperature for this case becomes even higher than its value before in Mode I (at t=180 minutes). The lower split ratio case of Ne/Nc=2/8 will have a lower value of condensing pressure and discharge temperature but the heating capacity for this case is lowest and it would take a longer time to reach the required hot water temperature. Thus, an intermediate split-ratio such as Ne/Nc=3/7 can be selected for the wrap-around coil in the storage heat pump system. This split ratio will result in the system having a medium heating capacity (when compared with other split-ratio cases) while also maintaining the value of discharge temperature lower than the value in Mode I.

3.3. Effect of Compressor Speed in Mode II on System Performance

The storage heat pump system operates with a reduced compressor speed in Mode II in order to match the compressor capacity with the smaller size of heat exchangers in Mode I. The compressor speed in Mode I is 3600 m/min (corresponding to full compressor capacity) while it is reduced in Mode II. For a certain split ratio, the upper limit on the compressor speed in Mode II is based on the consideration that the compressor should not be oversized compared to condenser and evaporator in the system.

In the previous section, the system performance was obtained for system with four different values of split ratio and with a compressor speed of 1800 m/min in Mode II. The system with higher wrap-around coil split ratio (Ne/Nc=5/5) in Mode II showed a higher heating capacity due to its higher evaporating pressure compared to system with lower split ratio. However, the higher split ratio could not be selected for the system because the condenser is undersized compared to the compressor capacity in Mode II which leads to system having a much higher condensing pressure and discharge temperature. In order to bring down the condensing pressure and discharge temperature for the high split ratio case the compressor speed would have to be reduced.
Table 6 shows the discharge temperature (at t=182 minutes) for the system with split ratio Ne/Nc=5/5 and two different compressor speeds in Mode II. By lowering the compressor speed from 1800 min\(^{-1}\) to 1200 m\(^{\text{in}}\)\(^{-1}\) in Mode II, the reduction in condensing pressure and discharge temperature is obtained but the heating capacity of the system also reduces. The system with split ratio Ne/Nc=5/5 and compressor 1200 m\(^{\text{in}}\)\(^{-1}\) perhaps shows a lower heating capacity than system with split ratio Ne/Nc=3/7 and with compressor speed 1800 m\(^{\text{in}}\)\(^{-1}\) in Mode II. This shows that the split ratio affects size of heat exchangers and the absolute value of evaporating and condensing pressure for the system in Mode II, but the heating capacity of the system in Mode II is much more sensitive to the compressor speed than the split ratio. Thus, it is more advantageous in terms of heating capacity to keep a higher compressor speed in Mode II with the upper limit on speed being that the reduction in discharge temperature and pressure ratio is achieved upon switching from Mode I to II.

![Table 6. Discharge temperature and heating capacity for the system upon switching to Mode II](image)

### 3.4. Comparing System Performance with Conventional System

Conventional heat pump water heater (HPWH) systems often use back-up electric elements to heat the water to the target temperature when the heat pump is unable to operate. Performance of the storage heat pump system obtained for the operating conditions shown in Table 2 is compared to a conventional HPWH that uses heat pump to heat water from 25°C to 48°C (t=0 to 180 minutes) and then uses back-up electric elements to achieve the water heating from 48°C to 58°C (t>180 minutes). The water contained in the tank is heated without any water draw from the system. The conventional HPWH system usually contains one upper and one lower heating element mounted on the tank wall. Both the elements have the same power rating and only one of the elements is operated at a time to avoid exceeding the limits on the allowable current draw. When using the electric element, the heating capacity for the system will be equal to the power of the electric element. Most conventional HPWH operate on 240V with current draw limited to about 20A and having 4500W heating element. Assuming that the system is powered by a limited electric supply of 120V the power of the electric element reduces to 1125W. Systems having 1125W electric element are not common and the example is used only for comparing storage heat pump system performance with two conventional systems having different power rating of electric elements. The Figure 9 shows the water temperature vs time predicted for conventional HPWH operating on two different electric supplies - a) operating on 120V with limited current draw (1125W electric elements) and b) operating on 240V (4500W electric elements).

![Figure 9. Water temperature vs time for conventional HPWH: a) 1125W electric elements b) 4500 W electric elements](image)
The conventional heat pump water heater system uses the heat pump to heat water until 48°C and then uses the upper and lower electric heating elements until the water temperature reaches 58°C. The system uses the upper electric element first and then uses the lower electric element. When the upper electric element operates, the water contained in the region between upper element and top wall of tank will heat up due the effect of natural convention. Thus, locations T8, T9 and T10 in Figure 9 show an increase in temperature. The upper electric element is turned off once the water in this region reaches the target temperature. The rate of heat conduction between the water layers in vertical direction is negligible and hence the water contained in the tank below the height of upper element stays at almost the same temperature. Then the lower electric element is turned on to finish heating up the remaining water. When the lower electric element operates, water contained in the tank above the height of lower electric element shows an increase in temperature. Thus, locations T2 to T7 in Figure 9 show an increase in temperature. The natural convection in the tank causes the hot water to remain above the relatively cold water and thus a small volume of water located between lower element and bottom of tank does not show a rise in temperature when the lower element operates. The water temperature vs time for the storage heat pump system was shown in Figure 4. Table 7 shows the comparison between storage heat pump system and conventional heat pump water heater system.

| Table 7. Comparison between storage heat pump system and conventional heat pump water heater system |
|--------------------------------------------------|-------------------------------------------------|-------------------------------------------------|
| **Conventional HPWH** | **Storage HP** | **T_water** from 25°C to 48°C (t = 0 to 180 minutes) | **T_water** from 48°C to 58°C (t > 180 minutes) |
| | | 1125W electric elements | 4500W electric elements | (Mode I) |
| Overall energy consumed | 0.9 kWh (Using heat pump) | 0.9 kWh (Using heat pump) | 0.9 kWh (Mode I) |
| Time taken for T_water to reach from 48°C to 58°C | 96 minutes | 24 minutes | 120 minutes |
| Hot water available at end of warm-up (Total tank capacity = 50 gallons) | 44.6 gallons | 44.6 gallons | 40 gallons |

The performance of storage heat pump system is same as conventional system for water heating from 25°C to 48°C (i.e. from t=0 to 180 minutes). The storage heat pump system operates in Mode I until water is heated to 48°C and then switches to Mode II for the first time to get reduction in pressure ratio and discharge temperature. The conventional system uses heat pump to heat water from 25°C to 48°C and then uses the back-up electric elements to heat the water from 48°C to 58°C. The storage heat pump system takes additional time of 120 minutes to heat the water from 48°C to 58°C. The time taken is 25% more compared to conventional system operating on 120V (1125W electric elements) and 5 times more compared to conventional system operating on 240V (4500W electric elements). This is because of the lower heating capacity of vapor compression cycle in the storage heat pump system compared to the heating capacity (power) of the electric elements used by the conventional system. The overall energy consumed by the storage heat pump system is about 70% less than that consumed by the conventional system. For a total tank capacity of 50 gallons, the total hot water available at end of the warm-up is lower than the total tank capacity for all the systems. For the conventional system, the water contained in tank located below the height of lower heating element does not get heated. For the storage heat pump system, the water contained in the tank at a height below which the wrap-around is split into evaporator and condenser is not heated up. The storage heat pump system uses this water as the heat source for evaporator in Mode II.

4. Conclusions

System model for the heat pump water heater system operating based on a new storage heat pump cycle is developed. Storage heat pump cycle involves system operation in two modes to reach the required water temperature while using the heat pump compressor instead of the back-up electric elements. Water contained in lower region of tank is used as energy storage element by implementing a split-condenser design. Mode I is same as conventional system operation, while the wrap-around coil is split to use the top portion as condenser and the bottom portion as evaporator in Mode II. The intermediate temperature water in the lower tank region acts as heat source for the evaporator which lifts up the evaporating pressure and reduces pressure ratio upon switching to Mode II.
Model is used to study the effect of wrap-around coil split ratio and compressor speed on system performance in Mode II. The wrap-around coil split ratio determines the size of condenser and evaporator in Mode II which affects the absolute values of condensing and evaporating pressure for the system in Mode II. System performance for four different split ratios is obtained and it is shown that an intermediate split ratio such as \( \text{Ne}/\text{Nc}=3/7 \) which gives medium heating capacity while giving a reduction in the discharge temperature and pressure ratio can be selected for the split condenser design. The split ratio also limits the compressor speed in Mode II as the speed has to be reduced to match compressor capacity with the smaller size of condenser and evaporator in Mode II compared to Mode I.

Modeling results for storage heat pump system with wrap-around coil split ratio \( \text{Ne}/\text{Nc}=3/7 \) and compressor reduced by 50% in Mode II show that the system can reach a higher water end temperature while maintaining relatively lower pressure ratio and discharge temperature than a conventional system. System performance is also compared with conventional heat pump water heater system that uses back-up electric elements to reach the higher water temperature when the heat pump is unable to operate. The additional time taken by the storage heat pump system to heat the water to a higher temperature is 25% more compared to conventional system operating on 120V (1125W electric elements) and 5 times more compared to conventional system operating on 240V (4500W electric elements). However, the energy consumed by the storage heat pump system is about 70% lower than the energy consumed by the electric elements in the conventional system. The power consumption for storage heat pump system is lower as it uses the vapor compression cycle to heat water to higher temperature instead of using electric elements. The storage heat pump concept is to be evaluated experimentally by modifying a conventional heat pump water heater system to implement the system operation in two modes.

### Nomenclature

**Symbols**

- \( f \): Operating frequency of compressor [revolutions per second]
- \( h \): Specific enthalpy [kJ/kg]
- \( \text{htc} \): Heat transfer coefficient [W/m²K]
- \( \dot{m} \): Mass flow rate [kg/s]
- \( \text{Nc} \): Number of wrap-around coil turns used as condenser in Mode II
- \( \text{Ne} \): Number of wrap-around coil turns used as evaporator in Mode II
- \( P \): Pressure [kPa]
- \( \dot{Q} \): Heat transfer rate/heat exchanger capacity [kW]
- \( q' \): Heat flux [W/m²]
- \( \text{SC} \): Subcooling [°C]
- \( \text{SH} \): Superheat [°C]
- \( T \): Temperature [°C]
- \( \text{T}_{\text{w,lower}} \): Bulk average water temperature in lower tank region [°C] (the region between bottom tank wall to height at which coil is split in Mode II)
- \( \text{T}_{\text{w,upper}} \): Bulk average water temperature in upper tank region [°C] (the region between top tank wall to height at which coil is split in Mode II)
- \( \Delta \text{T}_{\text{hx}} \): Difference between ref. saturation and external fluid temperature [°C]
- \( \dot{W} \): Power consumption [kW]

**Subscripts**

- \( \text{comp} \): Compressor
- \( \text{cond} \): Condenser
- \( \text{cpri} \): Comp. inlet
- \( \text{cro} \): Cond. outlet
- \( \text{comp} \): Compressor
- \( \text{disp} \): Displacement
- \( \text{dis} \): Discharge
- \( \text{eri} \): Evap. inlet
- \( \text{ero} \): Evap. outlet

The Dynamic behaviors on Drying Performance of Heat Pump Dryer using a Reduced Order Model

Yoonjei Hwang*, Jinwook Lee, Wansoo Kim, Kangwook Lee, Yeonha Seong, Mansu Park and Saikee Oh

H&A R&D Center, LG Electronics Inc., 08592 Seoul, Korea

Abstract

Dynamic behaviors observed on a heat pump dryer to maximize drying performance under various conditions through the change of compressor frequency. In order to optimize the drying performance, it is necessary to predict the dynamic behavior of air side and refrigerant side together. However, as the refrigeration cycle is optimized by a constant state condition of air at the design stage, it has less chance to implement design parameters to air flow path. In the study, simulation has been done to refrigerant and air side simultaneously under a concept of model based environment. There was no issues for integrated model because the geometrical model(3D) for air side converted to a reduced order model to make shorten the simulation time. The model for heat exchangers took a finite volume method that calculates the governing equations for several segments. The compressor model came from the analytical models for gas compression in control volumes. For the model for drum, it was predicted through the artificial neural network(ANN) learned by the test data set from experimental set up. In order to verify the system model that integrates the refrigeration and air cycle including drum model in the Dymola® environment, the dynamic characteristics data of the dryer for 2 ~ 8 kg drying load conditions were acquired. The result of numerical study shows reasonably low errors when compared with the experimental data. The pressure of refrigeration cycle and drying time at the drying section showed an error of 10% or less.

Keywords: Heat pump dryer, Model-based design, Reduced order model, ANN(Artificial Neural Network);

1. Introduction

A dryer for clothes be divided into a direct heating using an electric heater and a heating by heat pump using a refrigerant cycle according to a heating method. The heat pump-based clothes dryer is more energy efficient than the electric heater-based because it reuses waste heat to remove moisture from the clothes inside the drum.[1] The heat pump clothes dryer is a closed-loop system where the air passed through drum be cooled to low temperature at the evaporator and re-heated it to high-temperature air through the condenser. The design of the closed loop dryer is more difficult than the direct exhaust dryer, in which the air absorbed a moisture from the clothes in the drum is directly discharged out of the dryer. A Chaloet et al. investigated the effects of key parameters through experiments on the energy efficiency of the clothes dryer[2] and Xiang Cao et al. developed a quasi-steady-state simulation of the heat pump clothes dryer to optimize the design parameter.[3]

The transient behavior, in which the state of air and refrigerant is changed continuously from the start of product operation to the end, be observed at the heat pump-based clothes dryer. Therefore, considering the change of air state according to the evaporation amount of moisture in the clothes inside the drum is important to predict the drying performance. A bunch of tests are repeated to optimize parameters of performance during the design stage of the dryer because the range of operation modes is wide depending on the purpose of

* Corresponding author. Tel.: +82-10-2343-3830
E-mail address: yj.hwang@lge.com.
customer needs. As a result, it causes low product competitiveness and high cost of product development. The analytical model for simulation is need to solve these issues and predict the physical phenomenon at the transient state in the drying process. During the design process of the product, the main components of refrigerant cycle are designed to achieve maximum drying performance after deciding the geometrical parameters of the circulated air flow path to minimize flow resistance through three-dimensional CFD model. In general, the simultaneous simulation in a same environment is limited since each simulation is highly dependent on their own simulation environment. Therefore, optimization must be required at the system level, and a model-based simulation environment makes it happen. The overall system divides into sub-component models based on functional classification and it provides convenient environment where the entire system can be evaluated through only modification and validation for sub-components even if there has a needs to design modification. The mass flow rate of the circulated air at the flow path in the dryer is calculated using a reduced-order model in the model-based environment for simultaneous analysis. The reduced-order model could be a surrogate model, in which the complexity of numerical simulation is simplified even there has a loss of fidelity, it provides shorten analyzing time to the airflow path resistance according to various geometrical parameters. In the study, a dynamic simulation for clothes dryer of a closed-loop using R134a refrigerant as a working fluid was developed to evaluate drying performance and optimize design parameters. The Modelica language in the Dymola be used for system modeling of the heat pump-based dryer. The developed system model was verified through comparison with experiments by loads of clothes and operating conditions.

2. System Overview

The schematic of the heat pump dryer cycle and the change of thermodynamic properties according to the air and refrigerant side conditions are shown in Fig.1. The refrigerant of low-temperature and low-pressure is flowed into a compressor and compressed to the high-temperature and the high-pressure as a vapor state, and phase changes to liquid state through heat exchange with airside. Refrigerant after the expansion valve flows into the evaporator in a low-temperature and low-pressure state, the phase changes to the vapor state through heat exchange with high-humidity air, and the air flows into the drum again through the condenser.

![Schematic diagram of the heat pump dryer](image1)

![P-h diagram of refrigeration side](image2)

![Psychrometric chart of air side](image3)

Fig. 1. Schematic diagram of the heat pump-based dryer
The dynamic model for dryer have to respond to the changes by control logic for individual optimization as well as respond to wide variety of operating modes depending on the user’s requirements. A model considering various physics was implemented to simulate the dynamic characteristics of each component caused by the real-time change of the operating frequency of the compressor, the rotation speed of the fan and drum, and the opening of the electronic expansion valve.

3. Modeling Approach

3.1. Modeling for Refrigerant cycle

The dynamic model developed in the study was created using the Modelica language in the Dymola environment utilizing TIL suite (2022) by TLK Energy. The version of TIL used in the study is 3.10.0. The rotary compressor model was defined as the mass flow rate and power consumption according to condensing and evaporating temperature calculated from both the displacement and frequency as shown in equation from (1) to (3). Each of efficiency was defined using the performance data of the compressor by LGE. The mass flow rate of the refrigerant is calculated from the volumetric efficiency, and the compressor outlet enthalpy can be predicted from the isentropic efficiency. Therefore the power consumption of the compressor can be predicted as well.

\[
\eta_{vol} = \frac{m_{ref}}{\rho_{ref,s} \cdot \text{rps} \cdot V_{dis}} \\
\eta_{isen} = \frac{h_{dis,isen} - h_{suc}}{h_{dis} - h_{suc}} \\
\eta_{eff,isen} = \frac{\dot{m}_{ref}(h_{discharge,isen} - h_{suction})}{P_{shaft}}
\]

In the case of model for the electronic expansion valve, an empirical correlation was proposed using not only the diameter, but also length of the orifice as the geometrical parameter because the characteristics of mass flow rate to an electronic expansion valve are depended on the pressure drop of the refrigerant in orifice.[4] As the coefficient of flow rate is the shape coefficient of the orifice, the variable coefficient was developed based on the experimental data reflecting the component characteristics, because the characteristics are normally different depending on manufacturers even if the diameter is the same.

\[
\dot{m}_{eev} = C_{D}A\sqrt{2\rho_{in}(P_{in} - P_{out})}
\]

Both the condenser and evaporators are fin-and-tube type heat exchangers. Heat and mass transfer in the heat exchanger occurs relatively slow compared to the compressor or the expansion device, however the boundary conditions keep on changed continuously. The change of state properties were calculated through a differential equation including a time derivative by a finite volume method, it calculates a tube through which refrigerant flows by dividing it into multiple control volumes. The heat exchanger model provided by TIL can be divided into a moist air cell and a tube wall cell for airside analysis, as well as VLE Fluid cell for refrigerant side analysis. All cells reflected a geometric information for fin and tube such as number of row, columns, fin pitch, and thickness. Each cell also contains the equations of mass, energy, and momentum balance for the analysis of unsteady states.

3.2. Modeling for Airflow loop cycle

The model for circulated rate of air flow in dryer was developed through the law of similarity based on the data measured from the fan test. After taking P-Q curve for fan by fan test, the pressure losses for each component must be predicted to take a system resistance curve. Eventually, the mass flow rate of air is
calculated at the point where curves the system resistance and the pressure loss intersect. Simulation by three-dimensional CFD model for a complex shape of airflow path must be carried out so that detailed dimensions of components be considered, moreover simultaneous simulation with the refrigerant cycle system should be performed. There have limitations when trying to perform simultaneous analysis, it is limited due to the simulation speed difference between the refrigerant cycle and the three-dimensional CFD for airflow path. The reduced-order model for air flow rate can be a solution to synchronizing time difference. The response surface models for components were prepared based on simulation data for the airflow path to make the reduced-order model. The main advantage of doing that, it doesn’t need to re-simulate performance for the entire area when a new event occurred like partial change of configuration, but only calculate performance using the configured reduced model maintaining fidelity.

The schematic of the cycle of the airflow path is shown in Figure 2. The airflow rate by fan is flowed into the drum inlet after pass through a porous plate and the rear duct sequentially. The air passed through the drum circulates continuously, to the front duct and through two mid ducts between the evaporator and the condenser. The model for air circulation flow was divided into four parts, which are front duct, mid duct (a), mid duct (b) and rear duct respectively, also the factors affecting flow path resistance were defined as input parameters when designing each component. For four sorts of duct, DOE based parameter optimization was conducted by 14 factors, which consist of the shape parameters selected and operating conditions. And then data from flow path analysis were collected through the simulation of the three-dimensional CFD. After, a total of 560 data were generated by this way, the reduced-order models for each duct were developed based on this data.

![Schematic of the circulated airflow path in a closed loop system](image)

The heat exchanger model is defined by seven factors, which can be a tube diameter and relative humidity as an example, and by flow velocity that affect pressure loss. Coil Designer, a heat exchanger design tool, was used to find the data for pressure difference according to the pre-defined factors. During the process, the equation of correlation for pressure difference that be selected as an input to the coil designer, takes the equation developed by LGE. The result of process provides 80,000 simulation data.[5][6] The model for pressure loss in heat exchanger comes the result of learning process from ANN(Artificial Neural Network) based on the collected pressure loss data. For the model of Drum, 32-course data based on the drying loads from 1 to 20 kg, and pre-set drying mode like a Speed, Eco and Auto were collected. To make an ANN model, define first to main influencing factors such as drying load, drying status, moisture content, air temperature and humidity as an input parameter. When comparing the predicted value with the data which is not used for model learning, it was confirmed that there was no overestimation issues because it observed within 5% of the average error of cross-validation. The airflow rate of the system can be predicted by comparing the pressure at various operating conditions of the blowing fan with each of pressure drop model for components. It will be combined with the refrigerant cycle model in Dymola platform for simultaneous simulation. The concept of airside model has shown in Figure 3. When predict a value by implemented model, which is combined air flow and refrigeration cycle, compared with test data, it was confirmed that the accuracy was 97% as shown in Figure 4.
The rate of moisture extraction from clothes, where occurred inside of drum during the process of drying, be affected by the surface area of clothes when it contact with air flow. Therefore, the behavior of the clothes that changes as the drum rotates must be predicted by simulation model. However, there have many difficulties in numerically analyze physical phenomena because there happens heat transfer between air and cloth each other, together with heat exchange occurs between drum and the outside air at the same time. In the study, the data through experiments for the moisture extraction in drums is collected, and the model was developed by techniques for machine learning from based on the data. As shown in Figure 5, the experimental apparatus excluded the influence of the refrigerant cycle to measure only the change of air properties in the drum, and there have a device to make a constant temperature and humidity at inlet through a separate ducting system. The experiment was conducted for various operation modes until the initial moisture content of the clothes reached 0% from start at 60% based on the load commercially used, as shown in Table 1. The type of clothes follows the IEC 61121(International Electrotechnical Commission) standard and consists of Sheet, Pillowcase, Towel combinations. The measuring of a moisture content takes the signal from an electrode sensor of the dryer. ANN technique be introduced for modeling of the drum, the structure of input layer for ANN consists of three factors related to air characteristics (dry bulb temperature, absolute humidity, mass flow rate) and two factors related to clothes (amount of moisture, mass of clothes). Moreover, it has 3 hidden layers consist of 12 nodes per layer to calculate the sensible heat and the rate of moisture extraction between clothes in the drum as a output layer.[6]
Fig. 5. Experimental equipment for acquiring learning data for drum

Pre-processing on the learning data has done to improve the performance of the drum model. During the experiment on drying, there has a tendency to sampled more data under high load conditions compared to low load conditions, and it caused a poor prediction performance to low load conditions. To solve it, not only additional sampling process has done to make a data samples as an even to the load conditions but also data samples, based on moving average line at 200-second, removed to avoid a noise caused by the measuring error from both to humidity sensor and the airflow meter. Figure 6 shows the results of comparing the model with the experimental data at the condition of 10kg and 20kg load. The prediction value for both to the sensible heat and the moisture extraction showed an 8% error if it compared with the experiment data based on movement average besides shown 13% error if it compared with the experiment data including noise.

3.4. The system modeling for co-simulation

The study implemented the dynamic model that enables simulation together with refrigerant-side and air-side as combined systems that affect drying performance. For air flow path, the three-dimensional model be made first, and then it combined with refrigerant cycle model for co-simulation after three-dimensional model converted to 1D model through reduced order technique. The reason why it simulated as a three-dimensional CFD first is that the dimension of structure becomes dominant factor to determine accurate airflow rate, which should be affect to the drying performance in the dryer system, moreover, it could be a reliability issue if the structure model not be handled leakage properly. The 1D model for air-side validated before combining with refrigerant-side model to see how stably data transferred during order change from 3D to 1D. As a next step, the combined 1D system model synchronized again with real time control logic at every time intervals after combining two cycles. System simulation in a model-based environment was run through Dymola as a platform software. Figure 7 is a schematic diagram of the simultaneous simulation of refrigerant cycle and airflow cycle in the heat pump dryer system. The input and output values of the model to the main components of refrigerant cycle be defined as temperature, pressure, and flow rate of the refrigerant. The model for airflow rate calculates the airflow rate during circulation of air from the performance curve of the FAN and the total resistance by the system. Total resistance from the reduced order model of the ducting system that considered the shape of airflow path structures, included the heat exchangers and drum. The air properties during circulation is defined through the models both to heat exchangers and drum.

![Diagram](image.png)

**Fig. 7 Heat pump dryer system dynamic model in Dymola.**

### 3.5. System Controls

In the heat pump-based dryer, the control strategy at starting point is determined depending on the amount of moisture in the clothes initially detected. The compressor frequency is controlled to adjust the drying level, and also the opening of the electronic expansion valve is controlled based on the level of super-heating at compressor suction port. In addition, the fan rpm be set to control the circulating flow rate on the air side, and the rotation speed of the drum is controlled for drying the clothes. Pre-defined algorithm determines the end time by checking the moisture amount of the clothes. Generally, the compressor operating frequency is the most influential factor on the cycle behavior. When the dryer started up, compressor frequency maintains at a high to maximize drying performance for a while. Resulting that the temperature of the circulated air raised as much as the increased pressure difference between evaporation and condensation. However, high frequency mode couldn’t be kept long because the cloth may be damaged by overheating or might be happen to reliability issue of compressor. There has a protection algorithm to control compressor frequency not to cross the specific value based on the outlet temperature of compressor and a target frequency depends on it as well. The reference temperatures for frequency control is pre-defined according to the cloth and operation mode. The control logic for compressor frequency is shown in Figure 8 (a). In the study, input/output variables of control logic for cycles implemented from a dryer product were defined, and all sensors implemented in the product were modeled for connection with the heat pump system model. As shown in Figure 8(b), the control model for cycles receives a feedback from the heat pump model based on the information of the air and refrigerant state, and then the model for cycle control provides a command signal to the heat pump model through the interface.

4. Simulation results and discussion

The validation of the heat pump-based dryer system model is confirmed by whether it predicts well by the change of air and refrigerant cycles according to the change in compressor frequency. The drying process can be defined into three stages. The first stage is a heating section where the drying speed increases as the temperature of the clothes rise to the wet bulb temperature, followed by a constant drying section as a second stage where the surface temperature of the clothes is maintained at the wet bulb temperature, and finally a reduction drying section where the surface temperature of the clothes rises to the dry bulb temperature of the dry air. The result of the simulation to the pressure of the refrigerant cycle under the load condition of 10 kg, it showed an error of 5% during the first and second stages, and it showed about 8% during the reduction section as a last stage. There observed a gap between prediction and experiment as time goes on as shown in Figure 9. The output values from the control model for cycles will be varies depending on the feedback values from the heat pump model in real time. If there happened an underestimation of the discharge temperature of the compressor from the model, it caused an error to predict proper frequency because the compressor frequency be determined by the discharge temperature of compressor during the stage of heating and constant drying as well. Moreover, the cycle control criterion for determining the completion of drying during the reduction drying stage set to the amount of moisture in the fabric. If the amount of fabric moisture is under predicted, there occurred a time difference to reach the minimum operating frequency. The amount of fabric moisture is determined by predicted values of air and refrigerant properties from heat pump system model at the initial stage of drying, in case there has an error and it accumulated continuously as time goes on, it affects the cycle control in the second half of drying. Therefore, the overall error of drying performance is the result of accumulated errors of the physical models for each component. Accuracy of the model for the drying performance depends on the prediction accuracy both of drying time and power consumption with various loads for the clothes. Three sorts of loads for the clothes from 5kg to 20kg were compared, where the drying time was calculated based on the time it took to reach the final moisture content from the initial moisture content of 60%. As the load of the clothes increased, the drying time and accumulated amount of electric power tended to increase as well. When it compared to the experiment, the drying time showed an error of 10%, and the accumulated power consumption showed an error of up to 7%.

![Graph showing drying time and power consumption vs. drying load](image)

Fig. 10 Validation of the drying time and accumulated power consumption according to drying load

To make a further improvement of prediction to drying performance of the model, there have to consider a couple of things as follows. Because the rate of moisture content is the critical value for decision to system control during the drying process, accurate prediction of it serves as the most important factor in predicting the drying time and power consumption. Therefore, in order to improve the accuracy of the simulation, it is necessary to enhance the precision of the electrode sensor that measures the moisture content equipped in a product. In addition, the structure of the airflow path consist of a series of ducts, so it is necessary to more considering to leakage loss between components. And add a heat loss model to the current model can be a good way for improving accuracy because there has a heat transfer between product and environmental condition where it installed.
5. Conclusion

In the study, a dynamic model where combined a functional model and geometric model, was developed to predict the dynamic performance of the heat pump-based dryer system as a design tool. The model has verified that it simulates the drying performance well and control logic works accurately to the changes in various operating conditions. The decision of the end of drying be set at the high load condition because the prediction result of the rate of moisture content shows a relatively not a good accuracy at the condition. From based on this, it was confirmed that the error of the drying time and power consumption was up to 10% and 7%, respectively.

The main contributions brought by the modeling and simulation is that 1) The dynamic model for dryer system can be useful as a platform for design that can shorten the development time by optimizing the design parameters for the target performance in the earlier stage of product design. 2) The dynamic model for dryer system is a combined model where control algorithm and heat pump cycle, it can contribute to find the optimal algorithm scenario without or minimal testing by trying the maximum number of algorithm scenario cases at all design stages. 3) The dynamic model for dryer system consist of a functional model as well as a geometric model, there is flexibility to check the performance in advance by exploring various types of structures without relying on tests when structural or physical changes occur in the air flow ducting system. Finally, due to high energy efficiency, the demand for heat pump type dryers keeps on increasing, and the need for this model is even greater because there are many demands for responding quickly to the complexity and diversity of products in market. The result of the study can be applied very similarly to the washing machine system whose have a washing drum.

Abstract

The introduction of novel Hydrofluorooelefin (HFO) component R-1132E allows for significant improvements in Global Warming Potential (GWP) and thermophysical performance of ultralow GWP refrigerant blends. This paper will provide laboratory test results with R-474A, a binary blend of R-1132E, R-1234yf and provide an comparison and LCCP. It was found that R-474A as a drop-in replacement demonstrated up to a 50% heating and cooling capacity increase compared to R-1234yf and a up to a 30% Coefficient of Performance (COP) increase over R-744 (CO2).

1. Introduction

The 1987 adoption of the Montreal Protocol for the protection of the ozone layer led to the ban of Chlorofluorocarbons (CFC’s) and eventual phaseout of Hydrochlorofluorocarbons (HCFC’s). However, the Hydrofluorocarbon (HFC) gases selected to replace the previous generation have been found to have high levels of global warming potential and are considered to be a contributor to climate change. The parties to the Montreal Protocol agreed to phase down the use of HFC’s, as measured in equivalents of CO2, under the Kigali Amendment ratified in 2016. The United States took action with the passing of the US AIM Act [1] in 2021, seeking an 85% reduction by 2036, measured in CO2 equivalents, in the use of HFC’s.

To lower the overall use of HFC’s, new innovations in developing molecules with shorter atmospheric lifetimes and therefore lower GWP’s are necessary. A class of unsaturated fluorocarbons or HFO’s has been identified as meeting those requirements. Unfortunately, the same factors that create lower atmospheric lifetimes that reduce GWP, also have the potential to reduce thermal and chemical stability that was the foundational strength of HFC’s. As an example, while having similar thermodynamic properties R-1234yf is less stable and more flammable than the low pressure HFC-134a which it replaced in automotive air conditioning applications.

End uses such as automotive, where previously ample waste heat was provided from internal combustion engines, are accelerating the move towards electrification, and thus to the proliferation of heat pumps. As these heat pumps are introduced there is a growing need to identify higher capacity and higher performance refrigerants to meet these additional performance demands. However, automotive was the first sector to move en-masse to GPW <5 solutions such as R-1234yf, thus any replacement alternative would need to not only improve on performance but also meet this extreme GWP threshold expectation.

In this study we will present laboratory test results of R-474A a refrigerant based on novel HFO molecule R-1132E ((E) 1,2, Difluoroethylene) as it compares to R-1234yf, R-134a and R-744. The physical properties of the R-1132 were first defined in studies by Higashi et. al [2] and Pererra et. al [3] and the critical parameters

and equation of state for R-474A, a binary refrigerant blend of 23% by mass R-1132E and 77% by mas R-1234yf, was determined by Akasaka et. al [4]. Table 1 summarizes relevant refrigerant properties.

Previous studies [5] have already covered theoretical modeling, material compatibility and stability of R-1132E Blend R-474A.

2. Laboratory Tests

Two tests were performed in order to evaluate Refrigerant R-474A. First was an evaluation compared to R-1234yf using a standard compressor bench system at Ipetronik laboratories. The compressor calorimeter is shown in figure 2 system utilized a commercial off the shelf 34cc Brose compressor with PAG oil. The compressor tests included both heating and cooling conditions to estimate the compressor COP and capacity impacts of a refrigerant change.

Second, bench testing was performed utilizing two VW ID3 systems one a traditional R-1234yf AC only system with electric heat, and one utilizing an R-744 heat pump system. In the R-1234yf system the TXV was
replaced with an electronic expansion valve. In both systems pressure, temperature and mass flow rate was measured as described in figure 3 and figure 4. Comparative testing was only performed in cooling mode.

For the compressor calorimetry test, the conditions evaluated are identified in table 2.

For system bench evaluation, measurement points were selected from the list of tests available per SAE Standard J2765 [6]; The first set of tests, I60 through H35a were run as an evaluation of max performance / and at max allowable RPM; The second set of tests, I40a through H15 were run at a fixed cooling load to evaluate best case COP. Uncertainty and instrumentation tolerances are listed in section 4 of SAE J2765 for the test equipment and section 5 for the test room. In general, per J2765 section 1.5.2, the test apparatus is designed to give agreement within ±4% between two independent balances.

Lastly before evaluation for the bench system could be performed, a charge determination step was done by measuring superheat, subcooling pressure and temperature, and trying to identify the subcooling plateau. The test was performed with the condenser, coolant temperature and evaporator at 40°C; The compressor at max speed of 8500RPM. The charge determination graph is shown in figure 5 and indicates a 10% charge reduction with R-474A vs R-1234yf

3. Results

Results for the compressor calorimeter test are summarized in table 4 where capacity is given in kW. In general R-474A showed a significant increase in capacity, almost 40-60% greater capacity than R-1234yf in heating mode. R-474A also demonstrated a significant improvement in COP over R-744 and R-1234yf in cooling mode while maintaining a 40% capacity improvement.

Results for the bench test when comparing max cooling are shown in figure 6. R-474A demonstrates a 1200 to 2200 watt improvement in cooling output across the test conditions as compared to both R744 and R1234yf and a small decrease in COP compared to R-1234yf and a significant increase in COP when compared to R-744.

![Comparison COP](image1)

![Comparison Cooling capacity](image2)

Figure 6. Bench System Max Load results

Results when matching cooling capacity are shown in figure 7. We note that R-474A shows an improvement in COP across the entire range of test conditions. We also observe a decrease in the COP of R744.
Figure 7. Bench System Max Load results

4. Conclusion

Based on the bench test results observed, R-474A is capable of extending the heating range of a traditional R-1234yf heat pump system beyond 0°C to -10°C and with this trend extending likely a significant amount of heat being available at -20°C. This indicates that a reduction in the quantity and use of PTC heaters is possible as a potential weight and cost savings.

Additionally at mild cooling conditions when matching capacity, there is a significant improvement in COP, indicating that for a typical automotive drive cycle, there is opportunity to reduce total HVAC energy consumption and thus improve cruising range.

Furthermore, charge determination experiment indicates that the total refrigerant charge for an R-474A system when dropped into an existing commercial system can be as much as 10%.

Lastly, the significant observed improvement in capacity is shown at many of the test points. This can be utilized to either improve HVAC system noise vibration and harshness (NVH) characteristics by reducing RPM, which is significantly more important in generally quieter electric vehicles, or to down size the compressor.

Abstract

Process industries are responsible for a large share of the global energy demand. While refrigeration systems are used in the industry for the supply of cooling, the introduction of high-temperature heat pumps (HTHPs) and electric boilers to supply heat is necessary for the electrification of this industry. Combining the refrigeration system and the HTHP may offer an opportunity to improve the overall efficiency and facilitate the integration of HTHP. However, fluctuating, and non-continuous demands make the integration of a combined heat pump for simultaneous heating and cooling (HPS) more challenging as the heating and cooling capacity for such a system is coupled.

This study compared a cascade HPS with an R-717 bottom cycle and R-718 top cycle to a reference system consisting of a R-717 refrigeration system releasing excess heat to the ambient and a HTHP with R-717 and R-718 using the ambient as a heat source. The HPS configuration included heat exchangers with ambient air, and ambient heat sources to meet all combinations of heating and cooling demands. The comparison was carried out for an industrial brewery case and was based on numerical modelling.

For each combination of heating and cooling load the usage of ambient air as heat source and sink was adapted and simultaneously the pressure levels in the HPS were optimized for minimum electricity consumption. The influence of the ambient temperature was also analysed.

At design conditions the electricity consumption of the HPS was 9.8 % lower than the electricity consumption of reference system, but only 2.1 % lower on a yearly basis, due to the fluctuating demand profiles. This indicates that the HPS did not offer a substantial improvement in in terms of thermal efficiency compared to the reference system.

1. Introduction

Process industries are responsible for a large share of the global energy demand and comparably large CO\textsubscript{2} emissions. According to [1], 69 % of the European industry’s energy consumption is used for process heating and cooling, with 40 % being delivered at temperatures below 200 °C. These processes show great potential for electrification, and through this reducing overall greenhouse gas emissions [2].

Refrigeration systems based on vapour compression cycles have been used in the industry for the supply of cooling since the mid-19\textsuperscript{th} century [3] but the introduction of high-temperature heat pumps (HTHPs) and electric boilers to supply heat is not as prevalent in today’s market in comparison. Nevertheless, HTHPs are an efficient and feasible solution for the total electrification of this industry [4]. However, increasing the temperature lift of the HTHPs to reach higher supply temperatures yields a lower coefficient of performance (COP) resulting in higher operating expenses (OPEX) challenging the economic potential.

Combining the refrigeration system and the HTHP into a single heat pump for simultaneous heating and cooling (HPS) offers an opportunity to improve the overall efficiency of delivering heating and cooling requiring one system instead of two [5]. However, the part-load performance of such systems has not been
analysed. At the same time, the existing cooling utility could be fully or partly replaced facilitating the electrification of the industry.

When operating a HPS, two thermal energy streams, one for cooling and one for heating, are produced simultaneously. Therefore, it is interesting for the user that the HPS operates in simultaneous mode as much as possible. However, the energy demand of industrial processes varies throughout the day.

The combination of batch processes and continuous demands dictates load variations on an hourly and daily basis [6], but weekly and seasonal variations also exist. As the heating and cooling capacity of the HPS are coupled, either heating or cooling will be in excess in most operating conditions when fulfilling the needed heating and cooling demands of the processes. The HPS will therefore either expel the excess to the ambient or fill a thermal storage. However, for large demand variations like seasonal trends, a thermal storage requires substantial amounts of space [7]. The HPS needs to adapt its operation to fulfil its function. Hence, the variability of the non-continuous energy demands makes the integration of a HPS more challenging where both operation during design conditions and during part-load are essential.

This study conducted a case study of supplying simultaneous heating and cooling with a HPS for a Danish brewery. The analysis was based on daily average consumption data assuming that daily variations were covered by existing heat storages. The HPS was designed to cover all demands of cold- and hot water with no further required utilities. The daily and yearly operations were evaluated in terms of electricity consumption and Lorenz efficiency, while being compared to a reference system which consisted of two separate utilities, a HTHP and a refrigeration cycle, respectively.

2. Method

This section presents the method and concepts used for the modelling, analysis, and evaluation of the HPS. First, the investigated case study is presented followed by the thermodynamic modelling of the HPS system and the reference system. Finally, relevant performance indicators are introduced which were used to assess this strategy for electrifying industrial processes.

2.1. Brewery case study

The industrial facilities chosen for this study was a Danish brewery producing a large variety of products. The consumption data and the ambient temperature for the year 2021 was used in the case study. The heating demand of the actual production facilities was traditionally covered by a natural gas boiler supplying hot water. The cold water was supplied by a refrigeration plant covering the cooling of products both during production and storage. The demand profiles used are presented in Figure 1 together with the ambient temperature. The orange curve shows the heat load, the blue curve shows the cooling load, and the grey curve shows the ambient temperature.

![Figure 1: Daily average heating and cooling load supplied by hot water and cold water, respectively. The daily average temperature is presented on the secondary axis.](image-url)
The heating demand follows a bi-weekly schedule with very little influence from the season. The demand fluctuates between 1350 kW and 2330 kW depending on the day. The demand for cold water follows a seasonal trend with lower loads during colder months. The cooling load is also low in May due to the product being transported directly to the customers to a higher degree. The demand varies between 290 kW and 1720 kW. This means that the ratio between the heating and the cooling demand is largest during the winter and smallest during the summer. The ambient changes with a seasonal trend between -7 °C and 21 °C.

The hot water is produced at a temperature of 145 °C by reheating the return water at 110 °C. The cold water supply temperature is 2 °C while it returns at a temperature of 8 °C as presented in Table 1. The design cooling load of the HPS was chosen as 80 % of the maximum cooling demand, i.e., 1380 kW. The design heat load was corresponding to running the described cooling load without expelling any excess heat, resulting in a design heat load of 2230 kW. It is assumed that there is already a storage big enough to mitigate the daily variations in demand.

2.2. Heat pump modelling

The HPS considered for this case study was an electrically driven vapour compression cycle in a cascade configuration.

The model consisted of an evaporator at the heat source and a desuperheater, condenser and subcooler at the heat sink as visualised in Figure 2 to the left producing hot water at 145 °C and cold water at 2 °C at the sink and source, respectively.

In between the source and the sink, a cascade of two two-stage vapour compression cycles was applied. Both cycles were modelled in a configuration with a bubble-through intercooler minimizing the superheat at the inlet of the high stage compressors. The bottom cycle was modelled with ammonia (R-717) as the refrigerant while the top cycle was modelled with water (R-718) as the refrigerant. The two cycles were connected through a set of cascade heat exchangers (HEX). The first one responsible for desuperheating the ammonia (4→5) while the second HEX was assumed to condense the ammonia (5→6). On the secondary side, the mass flow of R-718 was controlled such that a superheat ($\Delta T_{SH}$) of 0.5 K was ensured at state point 21 shown in Figure 2.

The four compressors (1→2, 3→4, 21→22, and 23→24 in Figure 2) represent a compression process. An isentropic efficiency of 70 % was applied for all compressors, since this value is common for theoretical calculations [8]. The expansion valves (7→8, 10→11, 27→28, and 30→31) were modelled as isenthalpic expansion processes leading the refrigerant into the evaporation process or the liquid separator. The liquid separators (state points 9 and 29) were assumed ideally mixed with pure liquid exiting out the bottom (state points 10 and 30) and vapour leaving with a $\Delta T_{SH}=0.5$ K out the top (state points 3 and 23).

The heat exchangers with ambient air (5a→6a and 11a→11b) were used to expel excess heating or cooling capacity of the HPS. A fraction of the mass flows at point 4 and point 11 went to the ambient air heat exchanger to match demand from the process (see Figure 1). The two ambient air heat exchangers were assumed to always be able to transfer enough heat so the conditions of 6a was equal to 6 and 11b was equal to the conditions of 13.

All heat transfer processes were assumed isobaric. A minimum temperature difference of 5 K was chosen for all the heat exchangers at design conditions as in [9]. The subcooling process in the top cycle (26→27)
and the bottom cycle (6b→7) was maximised so the outlet conditions were set to 5 K above the sink inlet temperature and the ambient, respectively.

As described, the heat exchangers with ambient air (5a→6a and 11a→11b) were used to expel excess heating or cooling capacity of the HPS to match the process demand. The corresponding control narrative is presented in Table 3 when heat is either in excess or lacking compared to operation according to the design point.

Table 3: Control narrative of the HPS system during different load conditions.

A minimum of 0.5 K superheating was considered before the low-pressure compressor of each cycle (point 1 and 21). The condensing temperature of the bottom cycle was optimized for the highest Lorenz efficiency (Equation 2), while fan power pressure losses were neglected. The assumptions at design conditions as in Table 1 are summarised in Table 2.

</table>

At the design conditions, the required UA-value of each heat exchanger of the HPS was determined using Equation 1.

$$Q_k = (U \cdot A)_k \cdot \text{LMTD}_k$$  \hspace{1cm} (1)

Where $Q_k$ is the given heat load, $(U \cdot A)_k$ is product of the heat exchanger area and the heat transfer coefficient at design conditions, and LMTD$_k$ is the logarithmic mean temperature difference [10], all for HEX $k$.

During operation at conditions away from the design point, the LMTD changed depending on the heat load experienced by the specific HEX as the UA-values were assumed to be constant.

For the comparison a reference system was modelled as presented to the right in Figure 2. The reference HTHP was modelled using the same configuration as the HPS system with a heat load at design conditions of 2230 kW but utilizing ambient air as an isothermal heat source. Similarly, a refrigeration cycle was modelled for the cold utility. This system was represented by an ammonia cycle like the one shown in the bottom right Figure 2 with the ambient air as an isothermal heat sink. The condensing temperature of the refrigeration cycle was given a lower bound of 10 °C.

The parameter variations are done by varying the total compressor power between 360 kW and 1320 kW and the utilisation of the heat exchangers with ambient air between 0 % and 100 % while optimising the $\eta_{\text{Lor}}$.

2.3. Performance parameters

For evaluating the performance of the HPS two performance indicators were used. The first one is the power consumption of the compressors while the second was the second law efficiency, $\eta_{\text{Lor}}$. This was defined as the ratio between the combined COP, $\text{COP}_{\text{comb}}$, of the HPS and the maximally achievable COP, as in Equation 2.

$$\eta_{\text{Lor}} = \frac{\text{COP}_{\text{comb}}}{\text{COP}_{\text{Lor,comb}}}$$  \hspace{1cm} (2)

Where the COP$_{\text{Lor,comb}}$ denotes the COP of a Lorenz cycle where both heating and cooling is considered a product at the given boundary conditions defined in Equation 3 [5].
\[ \text{COP}_{\text{low, comb}} = \frac{T_{\text{sink, av}} + T_{\text{source, av}}}{T_{\text{sink, av}} - T_{\text{source, av}}} \]  

(3)

With \( T_{\text{sink, av}} \) and \( T_{\text{source, av}} \) being the thermodynamic average temperatures of the sink and source streams. They are defined as the logarithmic means as in Equation 4.

\[ T_{\text{sink, av}} = \frac{T_{\text{sink, out}} - T_{\text{sink, in}}}{\ln \left( \frac{T_{\text{sink, out}}}{T_{\text{sink, in}}} \right)} \quad T_{\text{source, av}} = \frac{T_{\text{source, in}} - T_{\text{source, out}}}{\ln \left( \frac{T_{\text{source, in}}}{T_{\text{source, out}}} \right)} \]  

(4)

Here sink out is the hot water supply, sink in is the hot water return, source in is the cold water return temperature, and source out denotes the cold-water supply temperature.

The COP\(_{\text{comb}}\) is defined in Equation 5 as the sum of the supplied heating, \( Q_{\text{heat}} \), and the supplied cooling, \( Q_{\text{cool}} \), divided by the sum of each of the compressor’s powers, \( W_k \).

\[ \text{COP}_{\text{comb}} = \frac{Q_{\text{heat}} + Q_{\text{cool}}}{\sum W_k} \]  

(5)

The difference in total compressor power of the two solutions, \( W_{\text{diff}} \), was used as a measure to compare the OPEX of the two solutions. This was defined as the difference in compressor power of the HPS, \( W_{\text{HPS}} \), and compressor power of the reference system, \( W_{\text{ref}} \). This is defined as the sum of the compressor power of the high temperature heat pump, \( W_{\text{HTHP}} \), and reference system refrigeration cycle, \( W_{\text{refri}} \) as in Equation 6.

\[ W_{\text{diff}} = W_{\text{HPS}} - (W_{\text{HTHP}} + W_{\text{refri}}) = W_{\text{HPS}} - W_{\text{ref}} \]  

(6)

Lastly, the normalized difference in power, \( W_{\text{diff, norm}} \), is defined using the power of the HPS system at the design conditions, \( W_{\text{HPS, des}} \) as in Equation 7.

\[ W_{\text{diff, norm}} = \frac{W_{\text{diff}}}{W_{\text{HPS, des}}} \]  

(7)

The performance of the cycles was examined by numerical modelling based on energy and mass balances as described in this section using Python [11] and CoolProp [12] for its thermophysical properties. The minimize function in [13] was used for the optimisation of the COP by changing the condensing temperature of the bottom cycle and the intermediate pressures of both the top- and bottom cycle. All data was collected, analysed, and visualised using the Pandas library [14].

3. Results

The HPS and the reference system models were used to assess the performance at design conditions for varying ambient temperatures. Additionally, the compressor power at varying heat- and cooling loads were mapped to assess the off-design performance of the HPS compared to the reference system. Finally, the systems were compared in terms of yearly energy consumption using a quasi-steady state approach.

The calculated compressor power of the HPS is presented in Figure 3 as a function of the required heating and cooling load. The utilisation of each heat exchanger with ambient air was varied from 0 % to 100 % in steps of 5 % for all combinations. The total compressor power is varied from 360 kW to 1320 kW in increments of 120 kW. Each grey diamond represents the results of a simulation with a specific utilisation of the heat exchangers with ambient air. The grey curves indicate the pareto fronts in terms of supplied heating and cooling for a specific sum of compressor power. The design point, as defined in Table 1 is marked with a red dot. The simulations were done at an ambient temperature of 20 °C.

The grey curves in Figure 3 are the most efficient operating points for the HPS for a specific combination of demands. The inclination of the grey curves changes with a varying cooling load. At 0 kW cooling load the evaporator is completely bypassed getting all heat for the bottom cycle from the air source. Following the grey curve for 1200 kW compressor power, for higher cooling the potential heat load decreases. This is due to the higher evaporator utilisation increasing the heat load of the component, increasing the LMTD as in
Equation 1. This trend continues until reaching the design point in the steps of about 5% in correlation with the utilisation of the bottom heat exchanger with the ambient air.

From here, the heat load decreases rapidly for an increased cooling load. This is the second heat exchanger with ambient air bypassing the cascade HEX being used increasingly until the top cycle is fully bypassed. Thereby, the compressor power from the top cycle can be utilised in the bottom cycle instead, hence increasing the potential cooling load. However, the maximal cooling load will reach a maximum, when the bottom cycle compressors reach their maximal operating conditions which are not considered in this study. The remaining combinations of heat exchangers with ambient air utilisation and compressor power yield non-optimal working conditions with lower efficiency.

![Figure 3: Compressor power at varying heating and cooling loads of the HPS at an ambient temperature of 20 °C.](image)

Similar simulations were performed for the HTHP and the refrigeration cycle as in Figure 3. The normalized difference in compressor power of the HPS and the reference system at the same heating and cooling load is presented in Figure 4. The heat load ranges from 0 kW to 2500 kW and the cooling load from 0 kW to 1750 kW. An ambient temperature of 20 °C was assumed. The result is normalised with the compressor power of the HPS at the design point. Negative $W_{\text{diff, norm}}$ indicates a lower compressor power for the HPS. The opposite is true for positive $W_{\text{diff, norm}}$, where the HPS will perform worse than the reference HTHP and refrigeration cycle.

![Figure 4: Difference in compressor power of the HPS compared to the separate systems at 20 °C ambient temperature.](image)
From the contour plot in Figure 4 we observe values of $\dot{W}_{\text{diff,norm}}$ between -9.8 % and +47.1 %. The result may be divided into three cases:

- **Heat and cooling load is balanced according to design point**: The efficiency of HPS is higher as shown by the dark green area. $\dot{W}_{\text{diff}}$ is from 0 % to 9.8 % lower for the HPS than for the reference system in this area, with the highest values close to the design point. The area is a wedge shape (outlined with red) spanning from the design point towards the origin. This is as expected since the HPS will operate at similar ratios between the heating and cooling load in this region with minimal usage of the heat exchangers with ambient air.

- **Heat load exceeds excess heat from the cooling system**: The HPS is less efficient than the reference system by up to 10 %. This is due to the expelling of excess cooling which does not significantly affect the power consumption of the HPS as seen in Figure 3.

- **Cooling load offering more excess heat then the HP system requires**: The HPS is less efficient than the reference system by up to 47.1 %. The HPS is penalised comparatively more from an increased cooling load, especially for low heat loads. This is due to the high lift of the bottom cycle compared to the reference system.

This indicates, that the HPS will benefit from a high, and stable heat load, where the dark green area is the largest. At the same time, oversizing the HPS will lead to a smaller benefit as the area with negative $\dot{W}_{\text{diff}}$ gets relatively slimmer. A lower cooling load than expected will not hurt the performance as much.

Figure 3-4 show results for constant ambient temperature. This is not the case during yearly operation. Therefore, the effect of varying the air temperatures on the HPS and the reference system was analysed. The performance was evaluated in terms of Lorenz efficiencies at the design point (a heat load of 2230 kW and a cooling load of 1380 kW). The results are shown in Figure 5 both as a function of the ambient temperature and the time of year.

The air temperature affects the two systems differently. The Lorenz efficiency of the HPS (blue) is close to constant for varying air temperatures. This is expected since only the possible subcooling of the bottom cycle is affected by the ambient temperature. $\eta_{\text{Lor}}$ increases for lower temperatures, since a higher subcooling can be obtained. The HTHP and refrigeration cycle (orange) experience a larger effect from the air temperature. $\eta_{\text{Lor}}$ increase with higher temperatures. Higher temperatures result in a larger temperature lift of the refrigeration cycle while the HTHP will overcome a smaller temperature lift. The same is seen through the year (Figure 5 to the right), where the HTHP and refrigeration cycle have a higher $\eta_{\text{Lor}}$ in the summer months, while the efficiency of the HPS is close to constant.

The overall result is the same independent of the ambient temperature. The HPS has a higher $\eta_{\text{Lor}}$ at the design point for every ambient temperature. The difference decreases from 6.24 %p for an ambient temperature of 0 °C to 3.99 %p at 21 °C. This is due to the ambient temperature getting closer to the temperature in the cascade HEX. The HPS has the advantage of being able to optimize the temperature between the two cycles which increases the $\eta_{\text{Lor}}$. This means that the difference in performance will be more pronounced during the colder months.

![Figure 5: The Lorenz efficiency of the systems at the design loads for varying ambient temperatures (left) and for each of the days of the year of 2021 (right).](image-url)
In Figure 6 the compressor power of the HPS (blue) is compared to the HTHP and refrigeration cycle (orange) throughout the year 2021. The top figure of Figure 6 shows the compressor power for every day for both solutions. The compressor power varies between 676 kW and 1348 kW for the separate systems and between 684 kW and 1282 kW for the HPS. The biggest differences are during July and August when the HPS has both the highest and the lowest compressor power.

The top figure of Figure 6 shows the compressor power at every day, while the bottom figure shows the difference in the average power used by the compressors up til that date.

The bottom figure of Figure 6 shows the difference in the compressor power throughout the year. The difference is normalised with the compressor power of the HPS. The blue line indicates the average difference through the year which is 2.1 % in favour of the HPS. The difference in power varies between -9.2 % and 14.2 % being highest in August and the end of October while being lowest in February and March. This is expected as the ratio between the heating and the cooling demand is largest during the winter and smallest during the summer as seen in Figure 1. This yields operating points that are further away from the design point, which is in favour of the separate systems, as shown in Figure 4. Furthermore, the warmer temperatures during the summer months yield a higher $\eta_{Lor}$ for the separate systems as seen in Figure 5.

4. Discussion

4.1. Alternative configurations of the HPS

The presented HPS is one potential configuration of a vapour compression cycle. Several other refrigerants and configurations could potentially supply the heating and cooling required by the processes. The work in [15]–[17] shows promising performance for heat pumps with hydrocarbons, water, or zeotropic mixtures as the refrigerant with improvements of up to 36 % compared to conventional solutions.

An alternative cycle that could be analysed was presented in [18] utilising two bottom cycles to produce hot and cold water and the top cycle to produce steam. The cycles were connected by a flooded cascade HEX, which additionally acted as a buffer tank. This buffering effect could potentially mitigate some of the penalties of operating away from the design point. The two bottom cycles will, however, introduce further energy demands to consider for a similar study as in this work. Another alternative is the inclusion of a back-up refrigeration cycle with air-cooled condensers or a condenser after the first pressure stage in the bottom of the HPS. This would grant additional cooling capacity with a temperature lift of the ammonia to the ambient temperature instead of the cascade HEX temperature. This will increase the COP following Equation 3 as $T_{\text{sink,av}}$ will decrease.
4.2. Choice of design point

The choice of design point is not trivial and requires full knowledge of the future energy demands. Even when knowing this, it is not possible to choose a design point matching both the heating demand and the cooling demand. By choosing one, the other one is given by the energy balance and the cycle COP. This is in strong contrast to other HPS cycles like in [19] where a CO2 refrigeration cycle produces space heating as a by-product and cooling as the main product. Thereby, the cooling demand will not define the operating conditions. If the average heating and cooling demand do not correspond to the balanced energy flows of the installed system, off-design conditions will inevitably lead to lower efficiencies for the specific case. In these cases, a HPS will not be suited to deliver the needed heating and cooling without auxiliary equipment. Therefore, more work is needed to determine the optimal design point of the HPS.

4.3. Practical challenges related to the modelled HPS and reference system

The modelled systems were based on a set of decisions that might affect the result. The superheating before all compressors is assumed to be 0.5 K which is normal for flooded evaporators but not for HEX's controlled using thermostatic expansion valves as depicted in in Figure 2. It is not obvious if changing the assumed superheat, will benefit the HPS or the reference system the most. However, the low superheat potentially favours the reference system as it has three evaporators being affected opposed to two for the HPS.

Additionally, the minimum condensing temperature of 10 °C for the ammonia refrigeration cycle potentially implies a two small temperature lift for a 2-stage system. A single-stage cycle could be needed lowering the COP of the cycle, which would favour the HPS. Furthermore, alternative isentropic efficiencies or pinch temperature differences could impact the result.

4.4. Fluctuating heating and cooling demand profiles and potential for the inclusion of storages

As indicated by Figure 4 and 6, the varying demands for heating and cooling substantially lowered the efficiency of the HPS. This was also mentioned by [5], who experienced difficulty delivering the correct amount of heating and cooling simultaneously. The same problem is not addressed by [7], as the HPS only provided 80 % of the heat demand with several backup systems and built-in hot water tanks mitigating the problem, but not leading to full electrification.

An assumption for this study was that all daily fluctuations in the heating and cooling demand profiles could be covered by an already installed storage or buffer capacity. Expanding this assumption with larger storage capacities could mitigate the bi-weekly variations in the heating demand of this case. However, this will require further investigation. Nevertheless, even an infinitely large storage cannot solve this problem if the average heating and cooling demand on a seasonal timescale does fit with the energy balance of the installed system.

4.5. Economic potential

This study showed a 2.1 % decrease in power consumption over a year of operation. This margin indicated that the lower OPEX should not be the only reason for choosing a HPS as the only heating and cooling utility for all industrial cases. It should be noted that fan power has been neglected which will be biggest for the reference system. The operation of large air HEXs could also lead to increased maintenance cost and down-time from required defrosting. Nevertheless, as the HPS had fewer total components than the separate systems, the capital cost could be lower, leading to a better pay-back time on the initial investment. However, the capital cost of the system was shown to be neglectable in [21 - 22] in comparison to the OPEX for high operating hours such as industrial breweries. Therefore, the best solution would allow the HPS to operate at design conditions most of the time while having flexible, auxiliary utilities to cover the variations in demand maximizing the overall efficiency even at higher initial investments.

5. Conclusion

Industrial processes require substantial amounts of energy to cover their heating- and cooling demands. Increased use of electricity in the industry will be necessary for a reduction in the emitted greenhouse gases emitted by the current equipment.
This study evaluated the potential of using a HPS for simultaneously producing hot water at 145 °C and cold water at 2 °C with higher efficiency than a separate HTHP and a refrigeration cycle. The HPS was evaluated by using a case of a Danish brewery with continuous energy demands. The results showed that the electricity consumption of the HPS decreased by 9.8 % at design conditions compared to a separate heat pump and a refrigeration system. However, the separate systems perform better when the ratio between heating and cooling demand differs substantially from the design point. This trend is more pronounced for low heat loads and high cooling loads. The ambient temperature shows a neglectable effect on the combined system while separate utilities vary by 6 % in Lorenz efficiency.

A yearly quasi-steady simulation showed a 2.1 % lower electricity consumption for the HPS indicating neglectable benefits in terms of operational costs. However, the HPS may present a lower initial investment compared to the supply of heating and cooling individually.

Abstract

Large-scale heat pumps are an efficient and cost-effective solution for the generation of industrial heat and district heating. They take up thermal energy from a low-temperature heat source (e.g. waste heat from industries or ambient heat from sea, lakes, rivers, or geothermal sources) and supply thermal energy at higher temperature to a heat sink.

During the next years, heat supply will be electrified and decarbonized step by step, due to the gradual replacement of fossil-fired heat supply by natural gas, coal, and oil. As the electricity generation will be decarbonized further in the upcoming years, more and more renewable electric energy will be available to achieve a climate neutral heat supply.

Siemens Energy has long-term experiences with large-scale heat pump solutions up to 95°C and 30 MW of thermal output per heat pump unit. Several industrial segments need heat pumps with even higher temperatures and higher thermal output. Thus, new heat pump solutions and an enhanced heat pump portfolio to higher temperatures (up to 150°C) and larger thermal output (up to 70 MW in one unit) are being developed. Low pressure steam requirements can be met by these high temperature heat pumps. By adding an additional steam compressor to the high temperature heat pump, even higher steam temperatures and pressures can be achieved (up to 270°C and 55 bara).

Heat pump solutions and possible applications for industrial hot water, steam supply and district heating are presented in this paper. Furthermore, ongoing and future projects of large-scale heat pump installations are shown.

Keywords: High temperature heat pump; Industrial heat pump; Industrial heat supply; Steam generation

1. Introduction

According to the International Energy Agency (IEA), heat is the world’s largest energy end use, accounting for almost half of global final energy consumption in 2021. Industrial processes are responsible for 51% of the energy consumed for heat, while another 46% is consumed in buildings for space and water heating. Along with this heat consumption comes a significant amount of CO₂ emissions. Heat consumption and its related supply structure contributed to more than 40% of global energy-related CO₂ emissions in 2020 [1].

Worldwide industrial heat consumption remains heavily fossil fuel dependent. The share of renewable heat for industrial heat stagnated over the last decade, see figure 1. The growth rate of the renewable share in the heating sector (building and industry) is anticipated to grow from 11% in 2020 to 13% in 2026. To achieve IEA’s “Net Zero Emissions Scenario” (NZE), the renewable share would need to grow 2.5 times faster than currently anticipated [1].
There are several technologies that can supply renewable heat such as solar thermal, geothermal, synthetic climate-neutral fuels (e.g. hydrogen), biomass, and electricity-based systems like electric heaters and heat pumps. The applicability and economic viability of these different technologies depend on the application and its corresponding required temperature levels. For example, it is very efficient and economically viable to apply heat pumps for space and water heating in buildings due to the relative low temperature and easy access to heat sources for heat pumps such as ambient air. The IEA projects for the NZE that more than 50% of all buildings worldwide will be heated by heat pumps (approximately 1.8 billion units) in 2050 [2], see figure 2.

The industrial heating sector shows other requirements regarding the temperature level and energy density. Consequently, the projection of the IEA for the NZE shows a more diverse technology distribution for the heat demand up to 400 °C, see figure 3 [2]. Electricity-based technologies such as heat pumps and electric heaters have the highest share followed by biomass and hydrogen [2].
Today, the share of heat pumps for industrial heating is insignificant and needs to grow very fast to meet the projections in 2030 and 2050. For that the IEA states that “around 500 MW of industrial heat pumps need to be installed every month over the next 30 years” [2]. It is a huge effort for all stakeholders like heat pump manufacturers, heat suppliers, and numerous industry branches to achieve such a growth worldwide.

There are already a few countries in which the number of applications of industrial heat pumps grew substantially in recent years. Figure 4 shows Denmark and Austria as an example [3, 4].

2. Heat pump technologies for large scale heat supply at medium, high and very high temperatures

Industrial heat demand shows a large variety of required temperature levels depending on industry segment and its heat demanding processes [5]. It is important to distinguish heat pumps upon their achievable temperature level as the state of technology is very different depending on the temperature level. Within this paper the following nomenclature is used to categorize heat pumps upon their achievable temperature level:

- Medium temperature: below 100 °C
- High temperature: between 100 °C and 150 °C
- Very high temperature: above 150 °C

2.1. Medium temperature heat pumps (MTHP)

Medium temperature heat pumps (MTHP) are a well-proven and widely implemented technology. There are numerous heat pump installations at large scale (single- and double-digit Megawatt range of thermal
output). These large-scale MTHP are mostly applied for district heating, with the first ones installed in the 1980s. There are several heat pump installations that operate since then for over four decades already. For example, Averfalk et al. [6] and David [7] list about 150 heat pump installations for district heating in 13 countries with an overall installed thermal output of approximately 1.5 GW.

Among them are 50 MTHP units of Siemens Energy that were installed in the 1980s and 1990s. 40 units of them are still in operation today. These units have a thermal output of 5 to 30 MW and an overall combined thermal output of 850 MW [8]. New large-scale MTHP are being installed e.g., for district heating in the city of Mannheim in Germany with up to 20 MW thermal output. This heat pump installation will be commissioned end of 2023 and is described in detail in section 3.

2.2. High temperature heat pumps (HTHP)

Over the last decade, the development of HTHP technology gained momentum. There are several technological developments of research institutes and companies, which increased the applicable temperature range of heat pumps to 150 °C [9-12].

Some of these developments led to new heat pump products and solutions. First large-scale pilot plants for full-scale operation are being commissioned. A HTHP in the city of Berlin in Germany with 8 MW thermal output and temperatures up to 120 °C is installed. This heat pump installation and its application is described in detail in section 3.

2.3. Very high temperature heat pumps (VHTHP)

There are several heat pump concepts with applicable temperature levels above 150 °C. It is important to distinguish these concepts.

There is the well-established technology of mechanical vapor recompression. It is a very efficient method of waste heat recovery under the requirement that the heat source is steam and can directly be recompressed. It is not possible to use this technology by an indirect heat transfer of other media, which closed loop heat pumps do. Some manufacturers call their mechanical vapor recompression product “heat pump” anyway [12]. Due to the previous mentioned requirement and thus widely limited application potential, mechanical vapor recompression as single technology alone is not further considered in this paper.

Some VHTHP concepts use Brayton or Joule cycles in which the working fluid shows no phase change and thus has a sensible heat transfer to the heat source and sink. There are some technological developments with such cycles [12]. However, the largest application potential at temperature levels above 150 °C in the industry is for steam generation. Steam generation requires isothermal heat transfer as liquid water evaporates at a constant temperature to become steam. Thus, a sensible heat transfer is not efficient to generate steam. Consequently, Brayton or Joule cycles are not considered further in this paper.

VHTHP concepts that allow a predominantly isothermal heat transfer to the heat sink and thus are suitable for e.g., steam generation are reverse Rankine cycles. Recently published concepts for large-scale that are currently in technological development consist of one closed loop heat pump cycle combined with a steam compressor. Siemens Energy has developed several of such concepts for applications in the refinery, paper and chemical industry. One of these concepts is described in detail in section 3. A first pilot plant in full scale operation for steam generation in the industry is anticipated to be commissioned in the coming years.

3. Large-scale heat pump applications at medium, high and very high temperatures

Most existing urban district heating networks still operate on a maximum required temperature typically between 90 and 130 °C [13]. Consequently, most district heating applications with heat pumps can be realized by using MTHP or HTHP under the conditions that a suitable heat source is present. Existing MTHP, for example, use sea water, lake water, river water, sewage water or industrial waste heat as heat source [7].

Industrial heat demand shows a much broader temperature range than district heating. Figure 5 shows the industrial final energy demand end-use of the 28 European Union countries in the year 2015 by temperature [14].
Currently developed VHTHP and further anticipated mid-term developments of heat pump technology do not allow to cover the whole temperature range of industrial heat demand. Space heating and process heating below 100 °C can be supplied by MTHP technology. Process heating between 100 and 200 °C can be supplied by HTHP and VHTHP technology. Process heating above 200°C can be partially supplied by VHTHP. This makes up a share that can be supplied by heat pumps of approximately half of the industrial heat demand when considering only the supply temperature. It is important to note that these heat pumps always require a suitable heat source. The higher the heat supply temperature the more challenging it is to identify a suitable heat source that allows an economically viable heat pump operation.

In the following, applications of MTHP, HTHP and VHTHP will be shown. Some of them are existing installations that are commissioned in 2022 or will be commissioned in 2023 (section 3.1). Others are concepts of applications that are very promising to be realized in pilot plants in the coming years (section 3.2).

### 3.1. Large-scale MTHP and HTHP for district heating

#### 3.1.1. Large-scale MTHP for district heating, existing installation, Mannheim, Germany

Siemens Energy has started building a new large-scale heat pump installation in April 2022 in Germany in the city of Mannheim (under construction as of 16th February 2023). It is built for the utility MVV (Mannheimer Versorgungs- und Verkehrsgesellschaft) next to the power plant “Grosskraftwerk Mannheim”. This heat pump is part of the “Living Lab” for Energy Transition with the title “Large-scale heat pumps in district heating networks”. It is a funded program of the German Federal Ministry for Economic Affairs and Climate Action.

This heat pump bases on a reverse Rankine closed loop cycle with refrigerant R1234ze(E). Figure 6 shows the basic cycle configuration of this heat pump. This heat pumps uses the water of the river Rhine as heat source. The Rhine water has a temperature of about 5 to 25 °C depending on the season. The heat source is used to evaporate and superheat the refrigerant in the evaporator. A two-stage centrifugal compressor driven by an electric motor sucks the refrigerant and discharges it at higher pressure and temperature to the condenser. In the condenser and subcooler, heat is transferred from the refrigerant to the district heating water. The heat pump supplies up to 20 MW of thermal output to the district heating network at temperatures up to 99 °C. The expected average COP for the overall system including all kinds of losses (thermal, electrical, mechanical, pressure and so on) is 2.7. After the subcooler, the cycle has two expansion stages. There is a flash tank in between the stages. The part of the refrigerant flow, which is in vapor phase in the flash tank, is fed directly to the second compressor stage. This increases the overall cycle efficiency. Figure 7 shows a model of the heat pump type used for this heat pump installation.
It is expected that this heat pump supplies heat to approximately 3,500 households and will save around 10,000 metric tons of CO₂ emissions per year.

3.1.2. Large-scale HTHP for district heating, existing installation, Berlin, Germany

Siemens Energy started building a new large-scale heat pump installation at the end of 2021 in Germany in the city of Berlin (construction finished, under commissioning as of 16th February 2023). It is built for the utility Vattenfall within their existing site chiller plant (“Kältezentrale”), which supplies cold water to a district cooling grid in the center of Berlin. This heat pump project is funded by the German Federal Ministry for Economic Affairs and Climate Action within the program “EnEff:Wärme”.

At Vattenfall’s site, there are several compression chillers that produce waste heat. This waste heat is currently re-cooled by wet cooling towers at the building’s roof. The heat pump is integrated in a way, that the waste heat can be recovered and utilized for district heating. Figure 8 shows the integration of the heat pump.
The evaporator of the heat pump cools the waste heat of the chillers from 32 to 27 °C and thus recovers this waste heat. The refrigerant R1233zd(E) evaporates and superheats by the heat transfer from the waste heat in the evaporator. A single-shaft centrifugal compressor, see figure 9, sucks the refrigerant and discharges it at higher pressure to the condenser. In the condenser, heat is transferred from the refrigerant to the district heating water. The district heating water enters with about 60 °C and is heated up to between 85 and 120 °C depending on district heating network requirements.

Steam is a universal heat carrier for industrial plants with heat demand e.g. in chemical, refinery and paper industries. Most plants with heat demand in these industries use steam as heat carrier. Usually there is a steam distribution system that supplies the heat to the various production plants. The steam distribution system has a certain pressure level or consists of different pressure levels enabling the heat supply at different temperature levels.

The pressure levels, amount of steam demand per level and time-dependent demand per level varies greatly among different industrial steam distribution systems. It is crucial for the heat pump technology that steam can be supplied to those different systems in a very flexible way.
Siemens Energy has developed a flexible heat pump system where a closed loop heat pump cycle generates steam with pressures up to 3.5 bara. If a high superheat is required at this pressure, the heat pump can be combined with an electric superheater. For even higher steam pressures, the heat pump can be combined with a steam compressor.

The combination of heat pump with an electric superheater is described exemplary by an application developed with a company from the paper industry (see section 3.2.1). The combination of heat pump with a steam compressor is described by an application developed with a company from the chemical industry (see section 3.2.2).

3.2.1. Large-scale VTHP for steam generation in fiber industry

The following application example has been developed together with a company from the paper industry. The company operates an industrial site with several waste heat flows that are not recovered currently. At the same time, steam at a pressure of 3.3 bara and a temperature of 157 °C is required, which is currently supplied by natural gas boilers. Figure 10 shows the heat pump integration concept into the industrial site’s heat sources and heat sink.

Fig. 10. VTHP integration concept, combination of heat pump and electric superheater, application in paper industry

Three different heat sources (process cooler, waste water and exhaust air) are combined and recovered. The heat from the heat sources is transferred to the refrigerant in the evaporator. A centrifugal compressor, driven by an electric motor, sucks and compresses the refrigerant to a higher pressure. The refrigerant enters the condenser and transfers heat to the feed water (heat sink). The feed water enters the condenser with 20 °C and is heated up and evaporated to steam at 3.3 bara and 143 °C. The electric superheater increases the temperature of the steam to the required temperature at 157 °C. The expected average COP for the overall system including all kinds of losses (thermal, electrical, mechanical, pressure and so on) is 1.9.

This heat pump integration is one example of many different possibilities with this combination of closed loop heat pump cycle and electric superheater. As long as there is a sufficient heat source, the heat pump can supply steam at pressure from 1 bara to 3.5 bara and the electric superheater can be flexibly adapted to the required steam temperature.

3.2.2. Large-scale VTHP for steam generation in chemical industry

The following application example has been developed together with a company from the chemical industry. The company operates an industrial site at which process water is available as heat source, which is currently not recovered. At the same time, steam at a pressure of 7 bara and at a temperature of 195 °C is required, which is currently supplied by natural gas boilers. Figure 11 shows the heat pump integration concept into the industrial site’s heat sources and heat sink.
The concept consists of three heat pumps in parallel that are identical in construction. There are several reasons for the parallelization like redundancy and part-load capability.

The heat source (process water) is recovered by cooling it from 80 °C to 60 °C in the evaporators of the heat pumps and partly in the pre-heaters of the heat sink. The heat from the heat source in the evaporators is transferred to the refrigerant to evaporate and superheat it. Centrifugal compressors, driven by electric motors, suck and compress the refrigerant to a higher pressure. The refrigerant enters the condensers and transfers heat to the feed water (heat sink). At first, the feed water is preheated by the heat sources and then enters the condensers. In the condensers, the feed water is heated up and evaporated to saturated steam at 1.5 bara. A two-stage steam compressor sucks the steam and increases the pressure to 7 bara in two stages. There are water injections before, between and after the stages to decrease the superheat. After the last stage, the required pressure of 7 bara and temperature of 195 °C is reached. The expected average COP for the overall system including all kinds of losses (thermal, electrical, mechanical, pressure and so on) is 2.8.

This heat pump integration is one example of many different possibilities with this combination of closed loop heat pump cycle and steam compressor. As long as there is a sufficient heat source, the heat pump can supply steam at a pressure of 1.5 bara and the steam compressor and water injection system can be flexibly adapted to the required steam pressure and temperature.

3.3. Large-scale HTHP and VHTHP integrated with other energy supply systems

The transition of the heat sector from fossil fuel-based heat supply to a climate neutral heat supply requires the installation of new and adapted heat supply units in industry and for district heating. There will be a large variety of different technologies for the heat sector. In the following two heat supply systems are described that can be integrated with heat pumps to increase the overall efficiency and are anticipated to show a high market share in the future.

3.3.1. Hydrogen production by thermally integrated Electrolyzer

Hydrogen will play a major role in future climate neutral energy supply systems. Hydrogen can be produced by electrolysis in electrolyzers. The IEA “Net Zero Emission” scenario projects that in 2030 there will be 850 GW (electric power input) and in 2045 there will be 3 TW (electric power input) of electrolyzers be installed [2].
The production of hydrogen in Electrolyzers also generates waste heat. This waste heat can be recovered and upgraded in its temperature level by heat pumps. Figure 12 shows the integration of a heat pump for steam generation.

The heat pump can recover waste heat from various heat sources like electrolyzer, hydrogen compressor, oxygen compressor and other heat sources. A cold thermal storage that buffers the heat from the heat sources can be integrated if the electrolyzer operation is fluctuating strongly.

The waste heat is typically in the range of 35 to 50 °C. The heat pump lifts the temperature level to supply heat to a heat sink. The heat sink can be hot water or, as in figure 12 shown, steam. For steam at 8 bara and 190 °C, the expected average COP for the overall system including all kinds of losses (thermal, electrical, mechanical, pressure and so on) is 2.1.

Combinations of heat pumps and electrolysers are being developed together with companies from different industrial branches.

3.3.2. Heat supply by exhaust gas condensation for natural gas / hydrogen fired boilers and gas turbines

Natural gas-fired boilers and gas turbines are well-established and widely used technologies. Exhaust gas condensation is often not applied at large-scale and especially when the temperature of the return flow of the heat sink is too high. The integration of a heat pump enables to further cool the exhaust gas and condense the water content in the exhaust gas. In doing so, a large amount of additional heat can be recovered from exhaust gas streams. Figure 13 shows a concept of combining a gas turbine with a heat pump.
There is an intermediate loop (blue lines) that takes up the heat from the heat sources. The heat sources are various machine cooling duties like the generator of the gas turbine and the exhaust gas. The exhaust gas stream is cooled below the dew point of its containing moisture. The heat pump takes up the heat from the intermediate loop in the evaporator and supplies heat at a higher temperature for example for district heating. In some cases, a re-heating of the exhaust gas is required to ensure a stable flow through the chimney.

A typical case is the supply of district heating at 115 °C. The expected average COP for the overall system including all kinds of losses (thermal, electrical, mechanical, pressure and so on) is 2.2.

Combinations of heat pumps and gas turbines are being developed together with companies from different industrial branches and district heating network operators.

In the future it is anticipated that natural gas-fired boilers and turbines will be adapted to use hydrogen or a mixture of hydrogen and natural gas as fuel. The exhaust gas cooling and condensation also works with hydrogen or a mixture of hydrogen and natural gas as fuel.

4. Summary and conclusion

The transition of the heat sector towards climate neutral heat supply is a very challenging undertaking. District heating and industrial heat are still predominantly based on fossil fuel and thus contribute to a large portion of worldwide CO₂ emissions.

There are several technologies that will support the decarbonization of the heat sector. Large-scale heat pumps with supply temperatures below 100 °C for district heating are a well-established technology since decades. The share of these heat pumps for the overall heat supply needs to grow substantially. Siemens Energy has built 50 large-scale heat pumps in the past already and new heat pump installations are being built.

District heating also requires temperatures above 100 °C. There are numerous developing activities for products and solutions for large-scale high temperature (> 100 °C) heat pumps. Siemens Energy builds and commissions a first large-scale high temperature heat pump for district heating for the utility Vattenfall in Berlin with 8 MW of thermal output and supply temperatures of up to 120 °C. This pilot plant is an outstanding step in the advancement of heat pump technology.

Industrial heat supply requires even higher temperatures. Often, steam is used as heat carrier at industrial sites. There are numerous developing activities for products and solutions for large-scale very high temperature (> 150 °C) heat pumps. Several concepts have been developed for the steam generation with very high temperature heat pumps. These concepts can easily be adapted to meet various steam pressure and temperature requirements.
There are technologies that are anticipated to be largely present in future climate neutral energy supply systems, such as electrolyzers and hydrogen-fired gas turbines. Concepts have been elaborated to integrate heat pumps that recover the waste heat of these technologies.

It can be concluded that heat pumps will play a major role in future carbon neutral heat supply systems for district heating and industrial heat supply. More and more pilot plants of high temperature and very high temperature heat pumps will start its operation in full-scale in the coming years until these heat pump technologies are well-established and are widely accepted as standard technology by the involved stakeholders.

Modelling and Simulation of a Thermoelectric Heat Pump with Micro-Channel Heat Transfer

Hanlong Wan*, Bo Shen, Kyle R. Gluesenkamp, Zhenning Li
Oak Ridge National Laboratory, Oak Ridge, TN 37831, USA

Abstract

Thermoelectric heat pumps (TEHPs) have advantages of modularity and simple design for heating and cooling in some applications. Models of thermoelectric (TE) heat pumps are widely studied. Nevertheless, most existing modeling work focuses on the TE material or air-sourced TE modules. TEHP modeling, especially the relationship between modules and heat exchangers, has not been comprehensively conducted. This work presents a water-to-water TEHP modeling framework that combines Goldsmid’s approach for TE material performance, Gnielinski’s correlation for convective heat transfer, and thermal balance theory for heat exchange networks. This combined framework provides an accurate theoretical analysis of the water-to-water TEHP system. Subsequently, the framework was used to empirically determine TE material properties (electric resistivity, thermal conductivity, and Seebeck coefficient) that minimize modeling errors versus experimentally observed values from the literature. Finally, an additional set of experimental TEHP data was used to validate the model, all with relative absolute deviations of approximately 10% when predicting heating capacity and 10%–20% when forecasting cooling capacity at a 30 K temperature lift. For future work, people can further develop models of TEHPs with an air-based heat sink on one side and water channels on the other side.

Keywords: thermoelectric, heat pump, Seebeck coefficient, coefficient of performance;

1. Introduction

In the 1950s, thermoelectric (TE) techniques were originally studied [1]; later, their applications for heat pumps were taken into consideration [2]. TE modules provide benefits such as cheap cost, modularity, easy design, and environmental friendliness [1] while being less efficient than conventional vapor-compression heat pumps [3]. As a result, there has been an increase in interest in using TE modules for applications like building heating and cooling [4–7], refrigeration [8], personal thermal comfort [9], electronics cooling [10], and clothes dryers [11,12].

Some researchers treated the TE modules’ lumped property parameters (Seebeck coefficient S, thermal conductivity K, and electrical resistance R) as temperature-dependent. For instance, Nemati et al. estimated the property parameters using a second-order polynomial correlation with the mean temperatures of the hot and cold sides of the TEHP [13]. However, they neglected to take into account the variation in samples and measurements and instead utilized the coefficients from a study that was published in 2020 [14], which were generated using a different TE module. The identical techniques and coefficients were used by Kaushik et al.

and Feng et al. [15,16]. The attributes were handled as a function of the hot-side temperature by Chen and Snyder et al. [17,18]. Their coefficients, which came directly from the producers, were more trustworthy.

Other researchers treated all or some of the parameters as temperature-independent. Cai et al. treated the properties as constants from the manufacturers’ datasheets [19]. Patel et al. treated S and K as constants but the electric resistance _R_ as a linear function of the temperature difference between the hot and the cold sides [11].

This paper used Cheon’s model [18] to evaluate TE property parameters. In addition, by plugging in the property parameters and applying Goldsmid’s method [21] and Gnielinski’s correlation [22], this paper developed a detailed liquid-to-liquid TEHP model. Furthermore, the proposed model was validated through quasi-steady-state data from a laboratory test.

2. Methodology

Water-to-water TEHPs, which are simply built and often used in several investigations, is the subject of this study [11,20]; an example is shown in Fig. 1. Two mini-channel heat exchangers containing fluid (for example, water) were put on the two sides of one or more TE modules for the TEHP in this investigation. A short distance was maintained between the hot and cold mini-channel heat exchangers using an aluminum space block. _UA_ _hw_ and _UA_ _cw_ are the overall heat transfer coefficients and area of the hot side and cold side, respectively. The model is broadly applicable to scenarios involving liquid-to-liquid, liquid-to-air, and air-to-air interactions thanks to the use of various _UA_ values. This work developed and validated a thermodynamic model using a water-to-water TEHP as a case study. The temperature and _UA_ variables used are marked in Fig. 1., as well.

![Fig. 1. A general liquid-to-liquid TEHP schematic.](image)

The inlet and outlet water temperatures in the TEHP system under consideration were relatively similar (within 1 K). Thus, the system was made simpler by using lumped approaches. _T_ _h_ and _T_ _c_ are the lumped hot- and cold-side temperatures of the TE modules, respectively. The TE surface temperatures can be estimated by measuring the substrate temperatures near the inlet and outlet.

\[
T_h \approx \frac{T_{hsi} + T_{hso}}{2} \tag{1}
\]

\[
T_c \approx \frac{T_{csi} + T_{cso}}{2} \tag{2}
\]

Similarly, the lumped hot and cold side water temperatures can be estimated using the inlet and outlet water temperatures.

\[
T_{cw} \approx \frac{T_{cwi} + T_{cwo}}{2} \tag{3}
\]

\[
T_{hw} \approx \frac{T_{hwi} + T_{hwo}}{2} \tag{4}
\]

2.1. **TE module model**

Goldsmid’s method is commonly agreed upon and used to describe TE module performance [21]. The heat transfer across the cold side and hot side of one TE module can be given by
\[ Q_c = Q_{c,GS} = SITc - K(T_h - T_c) - \frac{I^2 R}{2} \]
\[ Q_h = Q_{h,GS} = SIT_h - K(T_h - T_c) + \frac{I^2 R}{2} \]

where \( Q_{c,GS} \) and \( Q_{h,GS} \) are the predicted heat capacities across the cool and hot sides, respectively, and \( I \) is the current. When multiple modules are used in one TEHP, the capacity needs to be multiplied by the number of the modules used, or the number of models should be connected and iterated in series.

From Goldsmid’s method [21], the lumped parameters (\( S, R, \) and \( K \)) can be expressed by the parameters of the couples in one module:
\[ Af = N \cdot (A_n + A_p) \]
\[ S = N \cdot \alpha_i = N \cdot 2\alpha \]
\[ R = N \cdot R_i = N \cdot \left( \frac{\ln \rho_n + \ln \rho_p + R_i}{A_n + A_p} \right) = \frac{N^2 l}{A_f} 4\rho \]
\[ K = N \cdot K_i = N \cdot \left( \frac{A_n \kappa_n + A_p \kappa_p}{l_p} \right) = \frac{A_f}{l} \kappa \]

where \( N \) is the couple number; \( Af \) is the packing area of the TE module; \( \rho, \kappa, \) and \( \alpha \) are the property parameters of the nodes; and \( l \) and \( A \) are the geometry parameters of the nodes. We can assume the following:
\[ l_p = l_n = l \]
\[ A_n = A_p = d_1 d_2 \]

Cheon’s model was applied in the proposed model [18]. From the manufacturer’s specifications, \( \Delta T_{\text{max}} \), \( I_{\text{max}} \), and \( Q_{\text{max}} \) (performance parameters of TE modules, which are commonly given in the specifications) are 70 K, 8.4 A, and 90 W, respectively, when \( T_h \) equals 27°C, and they are 83 K, 8.4 A, and 98 W, respectively, when \( T_h \) equals 50°C. The literature indicates that \( \Delta T_{\text{max}} \) was related to \( T_h \) by Eq. (13) (\( Z \) is the effective device figure of merit) [18]. The linear interpolation method was used to predict \( \dot{Q}_{\text{max}} \) at other hot-side temperature points.

\[ \Delta T_{\text{max}} = \left( T_h + \frac{1}{Z} \right) - \sqrt{\left( T_h + \frac{1}{Z} \right)^2 - T_h^2} \]

The node properties can be achieved using the following equations:
\[ \alpha = \dot{Q}_{\text{max}} (T_h - \Delta T_{\text{max}}) \]
\[ \rho = \frac{Af (T_h - \Delta T_{\text{max}})^2}{2T_h^2 l} \frac{\dot{Q}_{\text{max}}}{N^2 I_{\text{max}}^2} \]
\[ \kappa = \frac{l(T_h - \Delta T_{\text{max}})^2}{Af T_h^2} \frac{\dot{Q}_{\text{max}}}{\Delta T_{\text{max}}} \]

By plugging in the properties, the lumped parameters can be obtained. In the process, the \( Af \) is eliminated, and thus, the lumped parameters are not related to \( Af \) directly. When the modules’ hot side surface temperature varies from 27 °C to 50 °C, the \( S, R, \) and \( K \) will be in the range of 0.054–0.054 V·K^{-1}, 1.42–1.57 \( \Omega \), and 0.633–0.706 W·m^{-1}·K^{-1}, respectively. \( S \) changes very small (less than 1%) in the temperature difference range.

### 2.2. Heat convection model

In this case study, to estimate \( UA \), the heat transfer coefficient between the fluid and the inner surface of the channel was predicted using Gnielinski’s correlation [22]. For different fluid regimes and channel geometries, other appropriate correlations [23] can be used to predict the heat transfer coefficient.

\[ Nu = \frac{UA \cdot L}{k_w A} = \frac{(f/8)(Re - 1000)Pr}{1 + 12.7(f/8)^{1/2}(Pr^{2/3} - 1)} \]
\[ f = (0.79\ln(Re) - 1.64)^{-2} \]
\[ Pr = \frac{cp k_{\text{tw}}}{k_w} \]
\[ Re = \frac{\rho_w u L}{\mu_w} \]

\( \mu_w \) is the dynamic viscosity of water and is a function of water temperature. \( u \) is the water flow speed and can be calculated from \( m_h \) and \( c_p \) is the specific heat of water, \( k_w \) is the thermal conductivity of water, \( L \) is the characteristic linear dimension (the inner height of the mini-channel in this study), \( Re \) is the Reynolds number, \( Pr \) is the Prandtl number; and \( Nu \) is the Nusselt number.

### 2.3. TEHP model

The proposed TEHP model used any two temperatures in \( T_{cw_i}, T_{cw_o}, T_{hw_i}, T_{hw_o} \) as the inputs and could predict the other two temperatures and the system performance. Fig. 2, shows the thermal resistance network of the system and the modeling flow.

![Resistence network and model flow diagram](image)

The thermal resistance of the aluminum space block was very small (\( UA_{hot} \) is about 8 W/K, while \( UA_{block} \) equals 188 W/K) and could be ignored in the analysis. The cooling capacity and heating capacity can be derived as follows:

\[ Q_c = \frac{LMTD_c}{1} \approx UA_{cw}(T_{cw} - T_c) = \frac{T_{cw} - T_c}{R_{cond} + R_{conv,hw}} \tag{21} \]

\[ Q_h \approx UA_{hw}(T_h - T_{hw}) = \frac{T_h - T_{hw}}{R_{conv,hw}} \tag{22} \]

\( LMTD \) is the log mean temperature difference. Considering the water temperature change,

\[ Q_c = m_c(c_{pw} - h_{cw}) \equiv m_c c_p(T_{cw o} - T_{cw i}) \tag{23} \]

\[ Q_h \approx m_h c_p(T_{hw i} - T_{hw o}) \tag{24} \]

\( m \) is the mass flow rate of the water, and \( h \) is the enthalpy of the water, and \( c_p \) is the specific heat of water. Since the channel surface temperature and the fluid temperature are close and no phase change exists, the capacity can be simplified using Eqs. (11) and (12). Water was used in this study, and its specific heat was treated as a constant. Using Eqs. (1)–(6) and Eqs. (11)–(14) and knowing property parameters and \( UA \) values, all the temperature variables can be solved.

### 2.4. Data source

A dishwasher using TEHPs was developed by the authors’ group [24]. Two TEHPs were used in the dishwasher, and transient laboratory test data from one of the TEHPs were used to validate the proposed model. Compared with the quasi-steady-state TEHP testing previously described, in this testing, two space blocks
were used for each TE module. However, the conductivity of the space blocks is very high, so the resistance can be ignored, and the same model can be applied. In addition, the TEHPs used in this project contained five TE modules.

3. Results and discussion

The results of the transient testing are plotted in Fig.3.

![Fig. 3. Experimental and model-predicted outlet water temperature.](image)

When the TE module is on (i.e., the current passing through the module is greater than 0) and the system is stable, the model has good agreement with the measured values. However, when the module is off, the model cannot predict the outlet conditions perfectly because the thermal mass of the system is not considered in the model. Thus, when the module is off, the predicted temperature of the TE module changes immediately and causes water temperature to change at the same time. However, because of the system’s thermal mass, the experimental water temperature change is delayed.

Unlike in the steady-state test, some noise exists in the temperature signals. The data with positive current were screened out, and the outliers were excluded (as shown in the shaded area in Fig.3.). The performance of the models using the data set is listed in Table 1. The results are close for all three approaches, which implies that the slight change in the parameters (S, R, and K) will not significantly affect the model. The hot- and cold-side temperatures of the TE module were not predicted perfectly because the temperature sensors installed may not reflect the lumped surface temperature of the modules.

Table 2 provides the systematic uncertainty of measured and derived values. Using the information from the quasi-steady-state TEHP test and Lecompte’s approach [24], Propagated uncertainties of the resulting values were computed. The uncertainty of capacity computed from the water side is high due to the low accuracy of thermocouples and the tiny difference between the input and output water temperatures.
Comparatively, the projected cooling capacity was just 50 W. Therefore, utilizing the water-side capacity to calculate the system coefficient of performance (COP) and assess the performance of the models would not yield useful information. On the other hand, the calculation of capacity from the TE module side has little uncertainty when all of the TE material parameters are accurate. The TE hot- and cold-side temperature measurements have the biggest impact on the TE module performance uncertainty. As a result, a suitable metric for assessing the performance of the models is the difference between the measured and simulated TE module surface temperature. A more accurate system COP may also be obtained by computing COP using the TE module-side capacity. Experiments will be conducted in future with RTDs for better water side capacity accuracy.

### 4. Conclusions

A thorough modeling framework was given in this study based on a numerical method that incorporates three sub-models: Goldsmid’s method for TE material performance, Gnielinski’s correlation for convective heat transfer, and thermal balance theory for a heat exchange network. Using this modeling framework, a water-to-water TEHP system was precisely assessed. The TE material performance was estimated through Cheon’s model. Finally, quasi-steady-state experimental data were used to validate the overall modeling framework. The findings are as follows:

- The proposed water-to-water TEHP model can achieve a RME of approximately 10% when predicting heating capacity and 10%–20% when forecasting cooling capacity at a 30 K temperature lift. For larger lifts, the cooling capacity becomes small, and the relative uncertainty in cooling capacity gets larger.
- TE surface temperatures have a major impact on the TEHP capacity and efficiency. In contrast, the impact of temperature-based variations in TE material properties was minor, over the evaluated range of 20 to 50 °C.
- It is common in TEHP applications to have small changes in water temperature across the TE, leading to difficulty in accurately measuring water-side capacity. This work allows engineers to predict capacities and system COP from knowledge of TE properties and heat transfer, without high accuracy measurements of differential temperatures.

For future work, a more accurate liquid temperature measurement method is needed. Furthermore, customer-designed TE modules are also necessary. Models of TEHPs with an air-based heat sink on one side and water channels on the other side should also be developed.

Carbon Mitigation Potential of Heat Pump Integrated with Thermal Storage for Grid-Interactive Residential Buildings

Sara Sultan\textsuperscript{a}, Jason Hirschey\textsuperscript{b}, Zhenning Li\textsuperscript{c}, Bo Shen\textsuperscript{c}, Samuel Graham\textsuperscript{c}, Kyle R. Gluesenkamp\textsuperscript{c}\textsuperscript{*}

Abstract

Residential buildings’ heating and cooling loads are associated with significant carbon emissions and peak electricity demand. Phase change material (PCM) based thermal energy storage (TES) can be used for space heating and cooling by embedding into the heat pump equipment. Past work on TES integrated with heat pumps (HP) has demonstrated significant load shifting and economic benefits. However, the potential for TES to reduce carbon emissions has not been widely explored. This study evaluates carbon mitigation potential of an ice-based TES coupled to HP (HP-TES) based on a simple rule-based control strategy accounting for electric grid emissions data. A vapor compression HP model using Engineering Equation Solver (EES). The modeled HP-TES system for single-family residential building demonstrates decreased carbon emissions with reduced peak utility cost.

1. Introduction

Heating, cooling, and ventilation loads in residential buildings account for about 10\% of energy consumption and CO\textsubscript{2} emissions worldwide and comprises 50\% of the building electricity consumption \[1\]–\[3\]. More than 74\% of electric use in United States is attributed to buildings where heat pumps (HP) exacerbate the demand issues, as, during the summer peak times, 50\% of the electric load comes from residential buildings, which is largely HVAC (Heating, Ventilation, and Air Conditioning) load \[4\]. The potential of onsite thermal energy storage (TES) has mostly been underestimated even though its significance for decarbonization and demand reduction has been established by researchers \[2\].

TES systems locally decouple heating or cooling demand from its production. The thermal storage properties can be leveraged from phase change materials (PCM) to not only design a demand response strategy for peak load shifting, but also for decarbonization. PCM which can be incorporated as passive or active storage, have a capability to store the off-peak energy that can be released during on-peak time.

Studies can be found in literature that investigate the demand response potential of TES. Peak thermal loads have been shifted to off peak time using utility pricing and demand-based controls \[2\], \[5\]–\[7\]. However, only a handful of research works reported in literature have investigated TES for carbon emissions reduction accounting for HP loads. The table below summarizes the literature investigating TES potential for demand management and carbon mitigation. Noticeably, gas consumption for furnace as a base case is compared against electric HP in most papers.

*Calculated from the data given in the paper

As shown in Table 1, the papers reported in literature are either passive or hybrid TES systems. Most researchers either employed passive cooling or heating by using PCM in building envelope or in case of active system, integrated TES with an additional energy production sources like PV systems. There is a large disparity in savings reported. Majority of the works evaluate the electric heat pump CO₂ emission reduction in comparison to gas furnaces as a reference, which yields more than 40% reduction [9], [11], [14]. Other studies compared PCMs with various insulations and passive configurations [13], [16]. In optimization studies, different PCMs and their melting points have been investigated to optimize the savings [15], [17].

Figure 1 below shows the reduced carbon emissions in literature for different regions. Passive TES have varying benefits but for all regions, heat pump coupled systems consistently report more than 35% reduction.

![Figure 1: One representative reference reporting emission reduction by using PCM in various locations and configurations](image-url)
The focus of this paper is to evaluate the carbon mitigation potential of TES assisted heat pumps against the normal heat pump operation, to compare the emissions with and without TES using a rule-based control strategy. Heat pump integrated TES has especially garnered attention for its demand response potential, flexible configurations, and less space requirements. Active HP-TES systems were reviewed to establish that peak loads and cost associated with HVAC loads can be successfully reduced [18]. Many researchers have used demand response control strategies to shift the peak load, but very few papers have investigated the decarbonization potential of TES. Peak load was shifted using various controls and configurations for residential HP-TES, and corresponding emissions were reported [19]. The emissions have been calculated by deriving relations to the energy consumption and power usage. Abu Hamdeh et al. (2022) multiplied the power usage by the amount of greenhouse gases emission per kWh [13]. Arce et al. (2011) used European Commission emission factors, load reduction and energy savings to calculate the carbon emissions reduced [10]. Cabeza et al. (2015) defined CO2 factor as a correlation between CO2 emissions (g) and energy consumption (kWh). The CO2 footprint (g/kWh) is 0.08 times energy consumption [8]. No studies were found that utilize emissions data into the control strategy of HP-TES systems.

The electricity sector has seen a shift from traditional centralized system to a smart grid device. This phenomenon has been ushered in by the increased integration of renewable energies. The rapid proliferation of the ‘Internet of Things’ (IoT) [20], allow major loads, such as HP, to be controlled with the goal of reducing peak power consumption on the electrical grid. In a smart grid, HP can be considered part of the demand side that can be actively managed to stabilize voltage fluctuations caused by high demand or high penetration of renewable energy [21]. With smart control of HP-TES, the system can switch between charging and discharging mode depending on the outdoor temperature, electricity price, desired indoor temperature, renewable energy generation, and COP of HP [20]. It is important to describe how to incorporate a grid’s GHG (greenhouse gases) condition into a site-specific MPC. The grid system-wide emission rate in a specific grid region depends on the total power production rate from grid power generators, and other factors that affect system operating conditions, such as weather. The marginal operating emissions rate (MOER) is the partial derivative of the systemwide emission rate with respect to the total production rate [22]. It means the change of the emission rate in the grid region with respect to the last megawatt produced by dispatchable generators having the unit of metric Ton CO2-equivalent per MWh [mTonCO2/MWh]. Intuitively, this indicates how much carbon emission rate increases/decreases in a grid region when one consumes one megawatt more/less. Therefore, MOER allows for associating the power usage at a specific site with the carbon emission rate in the grid region by simply multiplying the on-site power consumption with the MOER signal. In this paper, we used the MOER signal, based on a proprietary model [22], but adapted for real-time use [23].

In our previous work, we used time-based pricing to determine the economic value of residential TES system [6]. The PCM was incorporated into the conventional HVAC and time-of-use (TOU) utility rate schedule was analysed to evaluate the demand impact and energy savings. The objective of this present work is to evaluate the simple control strategy to reduce grid emissions while shifting the peak load, accounting for both grid and utility data. Marginal grid emissions data is used to determine if the emissions are relatively higher than the average of the previous day. The controls are then applied for the heat pump and TES operation,
and emissions are reported.

A simple building thermal energy model and HP model is evaluated with an active configuration implying direct use of TES for the building cooling during the discharge. The TES is based on water/ice PCM with 0°C storage temperature. TES is not directly conditioning the building but interacts with HP to mediate the heat transfer. The potential reduction in grid emissions is assessed using marginal grid emissions data and peak load is shifted using residential TOU utility tariff. Both correspond to the ASHRAE climate zone 3B, in California. For modelling, Engineering Equation Solver (EES) and Microsoft Excel are used. System overview and decision controls are explained in the Methodology (Section 2).

2. Methodology

The model comprises of various components connected to the building and HP using R410-a refrigerant. A TES heat exchanger with embedded PCM is integrated into HP to modify the vapor compression system and is transferring energy to and from the ambient. Thermostat controls monitor the building indoor temperature. The ambient weather data, TOU utility data, and marginal grid emissions data obtained for the same climate location, ASHRAE climate zone 3B. Marginal grid emissions data and electric utility schedule controls the heat pump to cool the building, and charge and discharge the ice-based TES. The analysis is performed for cooling only during the hottest week of June. The building energy consumption, HP work, and emissions are calculated in Microsoft Excel according to the rule-based control strategy in the minutely time steps.

2.1. System Overview and Configuration

The conventional vapor compression cycle of HP is modified by coupling TES to the system. TES is integrated with HP via active configuration and assists the HP cooling. TES does not cool the building directly, but heat transfer occurs through HP, as shown in Figure 2. PCM-TES can function either as a condenser or an evaporator, dependent upon the mode of operation. It is assumed that TES has an infinite coefficient of heat transfer and is always at constant temperature of 0°C.

![Figure 2: HP-TES configuration in cooling mode (A. TES Discharging B. TES Charging)](image)

HP has four modes of operation. HP is turned off in the standby mode and only thermal energy from outdoors is being transferred to the building. HP is turned on to cool the building through refrigeration cycle in normal mode, and no TES is involved. During charging mode, TES stores the energy from HP as \( Q_{\text{PCM}} \) to be used at later time. During discharging mode, TES releases the already stored energy into the building via HP. This mode has increased COP than the normal mode due to favourable temperature gradient. TES, which is at a colder temperature, is coupled to HP condenser and creates a negative temperature lift to move the condenser heat from building to TES.

2.1.1. Cooling Mode

Operating modes for cooling and respective energy flows are shown in Figure 3. Ambient is at a higher temperature than the building. During cooling normal operation, the condenser heat, \( Q_{\text{cond}} \) is discarded to the ambient while the heat of the evaporator, \( Q_{\text{evap}} \) is removed from the building and directed to the heat pump.

TES behaves as condenser or evaporator depending on the mode of operation. Evaporator is assumed to be the TES during charging. So, the TES is being cooled directly. The heat, \( Q_{\text{evap}} \) is removed from the TES though latent heat of freezing. TES solidifies as the heat stored from the TES is discarded to the ambient via heat pump. In the discharging mode, the TES is defined as the condenser and the evaporator was tied to the building. The \( Q_{\text{cond}} \) is now being stored to the TES instead of ambient and the PCM within the TES is being liquified.
2.2. System Controls

The operating mode of HP-TES is determined by the thermostat decision whether the building needs to be cooled or not, utility off-peak and on-peak time, state of charge of PCM (SOC), and grid emissions. The control strategy of HP-TES model is regulated based on four decision variables: ‘Thermostat call’, ‘Utility Peak’, ‘Emissions Peak’ and ‘State of Charge’.

The thermostat model (section 3.5) regulates the indoor temperature and determines if cooling is needed at a given time to call for cooling. A cooling temperature setpoint is fixed at 21°C, and the need is determined when the indoor temperature is higher than the cooling setpoint. The utility model, explained in section 3.1, determines the utility peak time. The emissions are obtained from the grid emissions model in section 3.6, while the TES model (section 3.5) determines the PCM state of charge.

The operating modes are shown in the decision tree diagram (Figure 4). Assuming the initial PCM SOC as 50%, if the thermostat is calling for cooling during the utility peak time defined by TOU tariff, PCM discharging mode will turn on. But during utility off peak, the emissions peak will determine if the discharging mode should be on. Charging mode is only activated during off-peak times to take advantage of the lower electrical cost and emissions, while thermostat is not calling for cooling, and PCM is not already charged. If during utility off-peak time, thermostat is calling for cooling, the HP goes into normal operation depending on emissions peak. Emissions peak is determined by average of grid emissions in the past 24 hours, if emissions are greater than the average of last 24 hours at a given point, it’s emissions peak. In previous work [6], emissions were not included, and controls were based only on utility data.

2.3. Information Flow

The overall system flow is depicted in Figure 5, which depends on the component models to analyze the
weather, utility and emissions data. All the components are mainly coordinated by the decision tree as a main control to maximize the system efficiency. Some values are updated to use as intermediate inputs in the model, represented by feedback arrows. The building model, HP model, and TES model are used from the previous work [6].

![Information Flow Diagram](image)

**Figure 5: Information Flow Diagram**

### 3. Component Models

#### 3.1. Weather and Utility Data

The TMY 3 weather data used is of Fresno, CA which corresponds to ASHRAE climate zone 3B. The location correlates to marginal grid emissions and utility tariff. The Time of Use (TOU) utility data is a fixed utility rate schedule from Pacific Gas and Electric (PG&E) Electric Schedule E-TOU-B. The analysis for cooling is performed considering both peak and off-peak hours for a hot week of June 24-30, 1994. The peak hours vary by season. For cooling season defined from June till September, on-peak hours are observed from 4pm to 9pm on weekdays, and the utility rate is $0.39689/kWh. At other times, including the weekends, the off-peak rate is $0.29383/kWh. The difference between on-peak and off-peak utility rate is $0.103/kWh.

Figure 6 shows ambient temperature versus utility rate for cooling season. The cost for cooling increases when the demand increases as a function of outdoor dry bulb temperature. The design objective is to take advantage of the low rates and assist heat pump operation using TES when the cost is high during peak hours.

![Ambient Temperature and Utility data for cooling day](image)

**Figure 6: Ambient Temperature and Utility data for cooling day**
3.2. Building Model

Building’s thermal response is simulated by a simple building model that calculates indoor temperature. The model takes into account the heat pump load, building’s thermal capacitance, and ambient load. A balance point temperature of 18°C is assumed to model the ambient load, as shown in Equation 2. An overall heat transfer coefficient of 0.25 kW/K is estimated based on cooling design day.

\[ Q_{amb} = U \times (T_{amb} - T_{bal}) \]  

Indoor temperature is determined by the energy balance where \( Q_{VCS} \) is the cooling or heating load output from the heat pump model in either normal or discharging modes, in one minute time step. A single-family house with 223 m² (2400 ft²) area was selected and the building capacitance was estimated to be 16459 J/K [6]. It was chosen to result in a reasonable rate of change of building.

\[ T_{indoor,i+1} = \frac{-(Q_{VCS} - Q_{amb}) \times dt}{c} + T_{indoor,i} \]  

3.3. Thermostat Model

The thermostat model tracks the indoor temperature and calculates the variable ‘thermostat call’. It uses a constant setpoint temperature to turn on cooling mode. Due to thermal loading from the ambient temperature, when the building indoor temperature exceeds the setpoint cooling temperature of 21°C (with a dead band of +/- 0.5°C), the thermostat calls for cooling. Depending on other conditions (time of day, emissions, and outdoor temperature), the HP will enter into either discharging mode where TES will be used, or normal mode where HP cools the building without TES.

3.4. Heat Pump Model

A heat pump model was simulated in EES and the operating modes with TES were modelled separately. The vapor compression model calculates the COP for cooling from the evaporator output and electric consumption by compressor [6]. The compressor has a constant volumetric flow rate of \( 2.5 \times 10^{-6} \) m³. Equation 4 defines the cooling COP.

\[ COP_c = \frac{Q_{evap}}{W_{comp}} \]  

The outputs of heat pump model, \( Q_{evap} \) from the evaporator and \( Q_{cond} \) from the condenser are called into Excel, where they are coupled to the PCM-TES or ambient depending on the operating mode. The condenser is tied to the ambient in normal mode, thus the dry bulb temperature was used as an input. The condenser is paired to the TES in the discharging mode. Where TES is kept at a constant 0°C. The discharging mode does not depend on ambient temperature and thus its operating parameters are constant. Because the temperature gradient is more favourable, total work during discharging is 0.748 kW, much lower than the normal mode which varies between 2.65 and 7 kW depending on the ambient temperature.

The condenser is coupled to the ambient in charging mode, and now the evaporator interacts with the TES. The decision tree (Figure 4) and thermostat model was used to control the HP and PCM state of use.

3.5. TES Model

The HP vapor compression system is coupled to PCM via heat exchanger in such a way that TES does not interact directly with the building and is not affected by the ambient temperature. An ice/water based PCM with phase change temperature of 0°C is embedded in the TES. TES heat exchanger is assumed to have an indefinite heat transfer rate at a constant temperature maintained at 0°C. TES is modelled as an 80-gallon tank, which can provide up to 27.8 kWh of cooling capacity. The operating modes are controlled by the PCM state of charge which is a function of peak time, and indoor temperature.

The fraction of maximum energy that can be stored by TES is defined as state of charge of PCM (PCM SOC). The PCM SOC is increased during charging to store the energy and reduced during discharging mode when it is consumed. For charging mode, the state of use of PCM (SOU) is -1, for discharging it is +1, and PCM SOU is 0 when it is not being used.
3.6. Grid Emissions Model

Marginal grid emissions schedule is obtained for Fresno, CA from a data driven tool that uses an empirical model. The tool generates emissions schedule based on continuous emissions and electricity generation data from major fossil fuel plants in the U.S. Figure 7 shows the hourly emissions data for the year of 2022 obtained on November 15. The data from January until November 15 is real time, and rest is projected based on historical data. Controls are designed based on average of the last 24 hours and variable called ‘Emission Peak’ is defined. If at any given point, the emissions exceed the average of last 24 hours, it will be considered emission peak. Discharging mode will be turned on if cooling is needed at that time. This strategy avoids using HP during both utility and emission peak times, to assess the maximum grid emission savings.

Figure 7: Fresno annual grid emissions during 2022

4. Results and Discussions

The analysis is performed for one week of cooling season to report utility cost, electric consumption, and carbon emission reduction. The indoor temperature was maintained at 20°C for cooling. For the simulated 7-day period, the grid emissions corresponding to the HP electric consumption are compared for the cases with and without PCM TES. The baseline system is defined as the case without TES.

4.1. Carbon Emissions

Figure 8 shows the grid emissions for both baseline and TES systems. The no-TES baseline case resulted in 181.78 kg of CO₂ over the simulated week, while using the TES system, emissions were 160.1 kgCO₂, reducing 11.92% grid emissions for the simulated week. These savings were achieved by using TES to discharge during emission peak and utility peak.

Figure 8: Emissions reduced using TES
4.2. Electric Consumption

Figure 9 shows the HVAC electric consumption and the peak electric consumption for both baseline and TES systems. TOU tariff for Fresno, CA is used for this study and the on-peak pricing applies from Monday through Friday only, excluding weekends. For the baseline system, where no TES was used, total electric consumption was 353.2 kWh, and on-peak consumption was 98.1 kWh. For the system with TES, the total electric consumption was reduced by 10.19% to 317.2 kWh. TES on-peak usage was 48.8 kWh, which means 50.2% of peak load was shifted. In our previous study [6], 87% of peak load was shifted to off-peak hours using TES under TOU tariff. The present study also implements grid emissions-based controls and TES is more frequently used in discharging mode than in previous study.

![Electric Consumption with and without TES](image)

Figure 9: Electric Consumption with and without TES

4.3. Operating Cost

The utility cost to cool the building is shown in Figure 10. Compared to baseline, 12.68% of system operating cost was saved using TES. The baseline system without TES accumulated $112.52 for cooling during the simulated week, while TES accounted for $98.25. In the previous study [6], 20% utility cost was saved using TES. The cost for the present system has increased when additional emission-based controls were introduced. In the control strategy, the emissions peak has precedent over the utility peak. Therefore, cost savings are not as significant as was seen in the previous study when only cost peak was considered.

![Utility Cost reduced using TES](image)

Figure 10: Utility Cost reduced using TES

5. Conclusion

The objective of this work is to assess the carbon emissions reduction potential of HP-TES using a rule-based strategy accounting for marginal grid emissions data and time-of-use utility tariff. An HP-TES configuration was evaluated with an ice/water based PCM coupled to the HP. A vapor compression model was developed using EES, and Excel was used to compute results for the integrated HP-TES system. The analysis was performed for one week of cooling season. The utility cost for cooling was reduced by 12.68% using TES.
while also maintaining occupant comfort. The total electric consumption was also reduced by 10.19% and 50.2% of peak electric load was shifted to off-peak time. 11.92% of grid emissions were reduced by using TES during emissions and utility peak times defined in the control strategy. The study concluded that while this configuration can still create some economic advantage with a simple control strategy, controls should be further optimized to reduce peak energy consumption. The analysis was performed for 7 days only, and the results should not be extrapolated for annual savings. This work highlights the potential for reducing grid emissions using a rule-based strategy.

Abstract

In the last years, the environmental awareness is pushing the air-conditioning and refrigeration industry towards a massive use of low GWP refrigerants. Generally, despite being environmentally friendly, these new working fluids are mildly flammable, or even flammable, and therefore safety concerns arise. One possible way to cope with the flammability hazard is the reduction of the charge of the refrigerant inside the system. In this scenario, indirect systems, i.e. brine-to-water system with a remote air-to-brine heat exchanger, seem to be a viable solution since they may be built with low internal volume which, in turn, leads to a low refrigerant charge. However, the use of heat transfer fluid between the air and the refrigerant results in an increase in the energy consumption of the system, making this solution less attractive.

In the present paper, a numerical assessment of the use of R290 in an indirect expansion vapour compression system is presented. The analysed system consists of a reversible brine-to-water heat pump able to supply space heating or space cooling depending on the season. The results are compared with those of a baseline R410A system, both in direct and indirect configurations. Although the refrigerant charge is well below the maximum value currently allowed, the indirect systems show a reduction in the energy performance by around 20% with respect to the direct one.

Keywords: Heat pump; Indirect expansion; R290.

1. Introduction

In the last years, the constraints introduced by the environmental regulations such as the EU 517/2014 regulation \cite{1} and the Kigali amendment to the Montreal Protocol \cite{2} are pushing the air conditioning and refrigeration industry facing the transition towards the use of low-GWP refrigerants.

Among the possible options, natural refrigerants such as R290 and R744 \cite{3} have received a lot of attention, especially in heat pump applications and/or refrigeration application and their application is becoming more and more widespread. Focusing on propane only, it has very good thermodynamic properties that may lead to high performance systems but has the drawback of flammability that may limit its diffusion. Indeed, in the open literature it is possible to find a lot of studies that deal with the reduction of the charge in propane-based systems \cite{4-7}.

In this scenario, for air-to-water heat pumps one interesting option lies in indirect expansion systems, i.e. systems in which the air is not used directly as cold heat source directly in an air-to-refrigerant evaporator, but is used in an air-to-brine heat exchanger to heat a brine flow which, in turn, acts as cold heat source in a brine-to-refrigerant evaporator. This layout leads to significant reduction in the inner volume of the refrigerant circuit, and of the refrigerant charge, which is beneficial for the system safety and risk reduction. However, some inherent energy penalization may arise since the evaporating temperature in indirect systems is generally lower than that found in direct ones because of the use on an intermediate heat transfer fluid.

This paper wants to contribute to this general discussion presenting the results of a numerical study aimed to analyse the performance of an indirect expansion heat pump working with R290. The results are compared with those achieved by a traditional air-to-water heat pump working with R410A, which is the baseline for the comparison, and by an indirect heat pump, again operated with high-GWP refrigerant R410A.

2. Modelling

As stated, in the present study the performance of an indirect expansion heat pump is analysed and compared with that of classical air-to-water systems. Figure 1 shows the layouts of the two heat pumps considered. The main difference between the direct expansion system and the indirect one is the addition of a heat exchanger beyond the condenser-evaporator pair. Indeed, while in an air-to-water system the evaporator is a fin-and-tube coil that exchanges heat directly with the air, i.e. the cold heat source of the heat pump, in an indirect system the evaporator is a plate heat exchanger that transfers heat between the refrigerant and a secondary fluid in liquid state. This fluid, which is the “direct” cold heat source of the heat pump, is then heated in a finned coil in which a heat transfer process with air occurs. Air is then the “indirect” cold heat source of the heat pump. When the operation of the heat pump is reversed from heating to cooling, i.e. the heat pump behaves like a chiller, the secondary fluid receives heat in the plate heat exchanger, that acts as a condenser, and, in turn, rejects heat to the environmental air through the fin-and-tube heat exchanger.

The simulation model of each system is built with a bottom-up approach, i.e. connecting the sub-models of each component of the heat pump.

![Diagram of heat pump systems](image)

Fig. 1. Layout of the direct system (left) and indirect system (right) considered in the present study.

2.1. Compressor modelling

The compressors considered in the present study are hermetical, variable speed scroll compressors that are modelled through the ten coefficients polynomial curves that express the refrigerant mass flow rate processed by the compressor and its power consumption as per EN 12900 [8]:

\[
\dot{m} = a_0 + a_1 T_{\text{EVAP}} + a_2 T_{\text{COND}} + a_3 T_{\text{EVAP}}^2 + a_4 T_{\text{EVAP}} T_{\text{COND}} + a_5 T_{\text{COND}}^2 + a_6 T_{\text{EVAP}} + a_7 T_{\text{EVAP}}^2 T_{\text{COND}} + a_8 T_{\text{EVAP}} T_{\text{COND}}^2 + a_9 T_{\text{COND}}^3
\]  

(1)
\[ P = b_0 + b_1T_{EVAP} + b_2T_{COND} + b_3T_{EVAP}^2 + b_4T_{EVAP}T_{COND} + b_5T_{COND}^2 + b_6T_{EVAP}^3 + b_7T_{EVAP}^2T_{COND} + b_8T_{EVAP}T_{COND}^2 + b_9T_{COND}^3 \] (2)

The coefficients that appear in Eqs. (1-2) are valid for a well-defined rotational speed, so different sets of coefficients are needed to compute the compressor performance when its rotational speed is changed. Finally, due to the heat pump application, the compressor is assumed to be adiabatic and, therefore, the refrigerant enthalpy at the compressor discharge is calculated through the following equation:

\[ h_{DIS} = h_{SUC} + P/\dot{m} \] (3)

2.2. Plate heat exchanger modelling

Plate heat exchanger models are developed using the finite volume method. Each heat exchanger is divided in small slices and the amount of heat transferred between the hot and cold fluid in the small volume is calculated using the ε-NTU method according to the following equations:

\[ \varepsilon = \frac{\dot{Q}}{\dot{Q}_{MAX}} = \begin{cases} 1 - e^{-NTU(1-R^*)} & \text{counterflow} \\ 1 - R^*e^{-NTU(1-R^*)} & \text{parallel flow} \end{cases} \] (4)

\[ \dot{Q} = \dot{m}_Hc_p,H(T_{H,IN} - T_{H,OUT}) = \dot{m}_c c_p,C(T_{C,OUT} - T_{C,IN}) \] (5)

\[ \dot{Q}_{MAX} = \min (\dot{m}_Hc_p,H, \dot{m}_c c_p,C)(T_{H,IN} - T_{C,IN}) \] (6)

\[ R^* = \frac{\min (\dot{m}_Hc_p,H, \dot{m}_c c_p,C)(T_{H,IN} - T_{C,IN})}{\max (\dot{m}_Hc_p,H, \dot{m}_c c_p,C)(T_{H,IN} - T_{C,IN})} \] (7)

\[ NTU = \frac{UA}{\min (\dot{m}_Hc_p,H, \dot{m}_c c_p,C)(T_{H,IN} - T_{C,IN})} \] (8)

\[ (UA)^{-1} = R_H + R_{FOU,H} + R_{WALL} + R_{FOU,C} + R_C \] (9)

The overall heat transfer rate is, then, the sum of the infinitesimal heat transfer rate at volume scale.

The correlation used for the calculation of the heat transfer coefficient are the correlations proposed by Longo et al. [9-10] for the evaporation, for the condensation and for the single phase fluid (water in the condenser/evaporator, secondary fluid in the evaporator/condenser, refrigerant in the vapour zone and liquid zone in the condenser and refrigerant in the vapour zone in evaporator).

The heat exchangers are designed with counterflow arrangement in the heating mode and with a parallel flow during the cooling mode.

2.3. Expansion valve modelling

The expansion valve is modelled considering an isenthalpic process and assuming that it is able to keep the superheat at the evaporator outlet at the set value of 5 K in any operating conditions.
2.4. Fin-and-tube heat exchanger modelling

The model of the fin-and-tube heat exchanger is developed using a finite volume approach [11]. Furthermore, since the flow rate of fluid is evenly divided in the exchanger circuits, it is decided to model only one circuit to reduce computational effort. Similarly to the plate heat exchangers, the heat transfer within the single element is solved by applying the \( \varepsilon \)-NTU method. Indeed, the same set of equations (5)(9) is used with an update of the equation for the effectiveness calculation to account for the flow arrangement:

\[
\varepsilon = \frac{Q}{Q_{\text{MAX}}} = \begin{cases} 
\frac{1}{R^*} \left( 1 - e^{-R^*(1-e^{-\varepsilon \text{NTU}})} \right) & \text{if } (\dot{m}c_p)_{\text{AIR}} < (\dot{m}c_p)_{\text{INN}} \\
1 - e^{-\left(1-e^{-\varepsilon \text{NTU} R^*}\right)/R^*} & \text{if } (\dot{m}c_p)_{\text{AIR}} > (\dot{m}c_p)_{\text{INN}}
\end{cases}
\] (10)

The correlations used for the convective heat transfer coefficient calculation are the Gnielinski correlation [12] for single phase flow inside tubes, the Diani et al. [13], for evaporation and the Kedzierski and Goncalves [14] for condensation. The air side heat transfer coefficient is calculated using the Wang et al. correlation [15] in dry mode and the Wang et al. [16] in wet mode.

Depending on the season and on the characteristics of the air, there can be different types of heat transfer (dry, wet and frost) as detailed in the next sections.

2.4.1 Dry mode: sensible heat exchange

The simplest case is related to the sensible heat transfer. In the dry mode, the surface temperature of the heat exchanger is higher than the dew point temperature of the air. The air changes its enthalpy by changing only the temperature whereas the water content, i.e. the humidity ratio, is constant. In the \( \varepsilon \)-NTU method, the dry bulb temperature is used to characterize air conditions and the Schmidt’s model [17] is used to compute the fin efficiency. In the counterflow arrangement, the process to solve all the elements is iterative, since the fluids enter from two opposite sides and only the inlet temperatures are available. It is necessary to assume the outlet temperature and iterate to check the convergence. Instead, in the parallel flow, the resolution is straightforward.

2.4.2 Wet mode: latent heat exchange by air dehumidification

In the wet mode, the surface temperature of the heat exchanger is lower than the dew point temperature of the air but higher than 0 °C. In this situation, air dehumidification occurs. This phenomenon consists of the condensation of the water vapour which is in the air and it involves both the sensible heat transfer and the mass transfer (latent heat transfer).

The resolving method is the same as reported for the dry mode. However, it is necessary to modify some parameters in order to consider the mass transfer. First, the latent heat of condensation of water has to be considered in the calculation of the overall heat transfer rate as per eq. (11) in which the condensed water flow rate is computed using the mass transfer coefficient which, in turn, is estimated through the Lewis’ analogy [18].

\[
\dot{Q}_{\text{LAT}} = \dot{m}_{\text{COND}} \Delta h_{LV} = h_{MT}(x_{\text{AIR}} - x_{\text{WALL}}) \Delta h_{LV}
\] (11)

Additionally, considering that the heat transfer takes place between air and a wet surface, both the convective heat transfer coefficient and the fin efficiency change. The former is computed through an appropriate model [18] whereas the latter is modified to account for the mass transfer resistance as done in the model proposed by McQuinston et al. [18]. Finally, in order to use the \( \varepsilon \)-NTU method, the wet bulb temperature of the air must be used instead of the dry bulb temperature, which is directly connected to the air enthalpy.

2.4.3 Frost mode

In the frost mode, the surface temperature of the heat exchanger is lower than the dew point temperature of the air and, at the same time, lower than 0 °C. In this situation, frost formation and accumulation on the finned surface occurs.
In this case, the water vapour directly sublimates on the surface of the heat exchanger, passing from the gaseous state to the solid state. The heat transfer is determined by the temperature gradients between the air flow and the frost surface, while the mass transfer is determined by the vapour concentration gradients. Part of the total transferred water vapour diffuses into the existing porous frost layer, and undergoes phase transformation to ice, contributing to increase the frost density. The remainder freezes on the frost surface, contributing to increase the frost thickness [19].

Following Qiao et al. [19], the mass balance of the total water vapour transferred from the air stream to the frost layer can be expressed as:

\[ \dot{m}_V = \dot{m}_p + \dot{m}_\delta \]  

(12)

The sensible heat flux exchanged between the air stream and the frost surface is:

\[ \dot{Q}_{SENS} = \dot{m}_{AIR} c_{p,AIR} (T_{AIR,IN} - T_{WALL}) \left( 1 - e^{-U/A/m_{AIR} c_{p,AIR}} \right) \]  

(13)

Similarly, the flow rate of vapour transferred to the surface of the exchanger is calculated as:

\[ \dot{m}_V = \dot{m}_{AIR} (x_{AIR,IN} - x_{WALL}) \left( 1 - e^{-h_{M,T,AIR}/m_{AIR}} \right) \]  

(14)

The latent heat flow due to the solidification of the vapour that freezes on the frost surface is calculated by the following equation:

\[ \dot{Q}_{LAT,\delta} = \dot{m}_\delta \Delta h_{SL} \]  

(15)

The total flux transferred during the frost formation process is given by the sum of sensible and latent contributions.

The frost formation, besides influencing the heat transfer process, also determines a variation of the fan consumption. Indeed, the frost thickness reduces the air cross-sectional area which, in turn, increases the pressure drop and changes the operating point of the fan. The new operating point, that changes over time as frost accumulates, has typically a lower flow rate and a higher power consumption.

In order to remove the frost, bringing the finned surface back to the initial, frost-free condition, defrosting cycles are designed. Two main issues are considered: the defrosting time and defrosting cycle frequency. The defrosting time is the period required to ensure the correct melting of the frost accumulated on the surface. The value is proportional to the mass of ice, which can be calculated as:

\[ M_F = \rho_F A \delta_F \]  

(16)

While the energy needed to melt the frost mass is:

\[ E_F = M_F \Delta h_{SL} \]  

(17)

For the sake of simplicity, a constant defrosting time equal to 300 s is assumed.

On the other hand, the choice of the defrost frequency is essential to ensure proper heat pump operation. Indeed, too infrequent defrosting cycles lead to the formation of large thicknesses of ice on the surface, while too frequent defrosting involves waste of energy. To accurately define the correct defrost start time, the defined thickness should be evaluated instantaneously. However, the frost thickness is difficult to measure, so, the defrost frequency is set on the excess of the fan pressure increase that arises from the increase of air pressure drop. Indeed, once the maximum value of the pressure increase is reached, the operation of the fan is stopped and the 300 s defrosting cycle starts.
3. Case study description

3.1. Building

The building considered in the present study is taken from the scientific literature [20]. It is a new single-family house that consists of two levels with a floor area of 70 m² each. Radiant floor is considered as the indoor emitting system. The main feature of the building are reported in Table 1.

Table 1. Main feature of the building

The thermal loads are calculated in TRNSYS environment and considering the two levels as a single thermal zone. From the annual simulation, the maximum heating load is equal to 6340 W (T_{AIR} = -12 °C) while the maximum cooling load is equal to 6317 W (T_{AIR} = 32 °C). For the sizing of the heating/cooling system, these values are “rounded” to reproduce a slight oversizing that would be found in a real application. The building is characterized by a heating period longer than the cooling period. For this reason, the system works mainly as a heat pump. The guideline used to choose the components is to prefer and guarantee the maximum efficiency in winter conditions. As a result, the nominal conditions on which the systems are designed are: T_{AIR} = -12 °C, Q_{BUILDING} = 7000 W, duration of heating season equal to 2822 h.

3.2. Heat pump

In the present study, three different heat pumps are considered:

- The first heat pump is an air-to-water heat pump working with R410A. This heat pump allows for the direct installation and, therefore, is considered as the current, largely diffused baseline technology.
- The second heat pump is a water-to-water heat pump working with R410A. This heat pump allows for indirect installation. It is considered as the term of comparison for indirect systems.
- The third heat pump is a water-to-water heat pump working with R290. This heat pump works with propane and is used in indirect installation with the aim of reducing refrigerant charge. It is the innovative system in indirect systems.

Air-to-water heat pump working with R290 is not considered in the present study since it requires a large refrigerant charge.

The R410A air-to-water heat pump is sized considering the constraint shown in Error! Reference source not found. On the other side, considering the water-to-water heat pumps, to allow them to work even when the outside air temperature drops below 0 °C, a mixture of water and ethylene glycol is chosen as secondary fluid to avoid mixture freezing. The glycol concentration is set to 40% so that the freezing temperature is -24.8 °C whereas the inlet and outlet design temperatures are -20 °C and -17 °C respectively since the minimum air temperature is -12 °C.

All the three heat pumps are sized considering real, commercially available components. The characteristics of the main components of the three heat pumps considered are collected in Table 2.

Table 2. Main characteristics of the components of the three heat pumps

<tr>
<td>Compressor</td>
<td>Scroll compressor</td>
<td>Scroll compressor</td>
<td>Scroll compressor</td>
</tr>
</tbody>
</table>
It is worth mentioning that the compressor for R290 is not a native variable speed compressor. However, for the sake of homogenous comparison, in the present study it is assumed that it is possible to drive it through an inverter. In order to compute the compressor performance at rotational speed different from 50 Hz, corrective look-up tables are prepared starting from the data available with the R410A, variable speed compressor. Tables that report the refrigerant mass flow rate and compressor power consumption as a function of the shaft rotational frequency and in broad ranges of evaporating and condensing temperatures are first generated and, then, normalised considering the nominal rotational frequency equal to 50 Hz. This results in correction coefficients that represent the reduction (increase) in the refrigerant mass flow rate or compressor power as a result of the reduction (increase) in the shaft rotational frequency. These values are applied to the R290 compressor to simulate its behaviour under variable speed regime.

The heat pumps sizing is then completed with the estimation of the refrigerant charge. The amount of refrigerant which is contained in each component is computed dividing the inner volume by the refrigerant specific volume. More in detail, for the components in which the refrigerant is in single phase, i.e. compressor, pipes, desuperheating zone and subcooling zone of the condenser and superheating zone of the evaporator, the specific volume is calculated considering the average inlet-outlet pressure and temperature. On the other hand, for the components in which the refrigerant undergoes a phase change, i.e. the condensing
zone of the condenser and the evaporating zone of the evaporator, the average specific volume is computed starting from those of the saturated liquid and saturated vapour and using the void fraction models proposed by Steiner [21] in the fin-and-tube heat exchanger and by Smith [22], as suggested by Mancini [23], in the plate heat exchangers. Finally, refrigerant mass trapped in the oil is accounted for considering the solubility diagram of the refrigerant-oil pair that is provided by the compressor manufacturer. Overall, the refrigerant charge in the R410A air-to-water heat pump is estimated to be 3561 g. This value is 20% lower than that of a real air-to-water heat pump of similar capacity which, as per the manufacturer’s catalogue, is filled with 4320 g of R410A [24]. However, it must be mentioned that the calculation of the charge does not consider any liquid receiver which, in turn, is installed in the real heat pump. As a result, it is possible to state that the charge calculation is quite accurate. For the water-to-water heat pumps, the refrigerant charge is estimated in 899 g with R410A and in 467 g with R290. The water-to-water heat pump has a lower internal volume with respect to the air-to-water one since the fin-and-tube evaporator is replaced by a plate heat exchanger. As a result, the refrigerant charge of R410A reduces by 75%. The charge of the R290 heat pump is even lower since the density of R290 is significantly lower than that of R410A in the full set of operating conditions.

Finally, pumps and fans used to supply the secondary fluid flow rate are chosen. The main characteristics of these devices are reported in Table 3.

### 3.3. Seasonal simulation and performance index

The analysis of the performance of the three heat pumps is carried out considering one year of operation. The yearly simulation is carried out considering a time step equal to 3600 s and assuming that the heat pump operates in steady state regime in it. If frost formation occurs, the time step is reduced to 300 s but, again, the heat pump is assumed to work in steady state in the time step while it changes its operating point from one time step to the other.

At each time step the building load is available from the building simulation whereas the heat pump heating capacity is computed from the simulation tool. Since each heat pump is built with a variable speed compressor, the matching between the end-user need and the capacity delivered by the heat pump may occur by varying the rotational frequency of the compressor shaft, or by on-off cycling. In the former situation, the compressor speed is changed so that the heat pump delivers exactly the building load; in this scenario, the heat pump is assumed operate continuously for the full time step. On the other hand, in the latter situation, which typically occurs at high ambient temperatures, despite the compressor speed is set to the minimum value, the heat pump capacity is higher than the building load and, so, it undergoes on-off cycling with the aim of providing a time step average capacity equal to the building energy need. This working condition is not optimal since additional power consumption related to electronic board arises even when the compressor is switched off. To account for it, a correction of the COP as proposed by EN 14825 [25] is used:

\[
COP_{\text{on-off}} = \frac{CR}{1 - C_D + C_D \cdot CR} \cdot COP_{\text{CONTINUOUS}} \tag{18}
\]

In eq. (18) \( CR \) is the capacity ratio, i.e. the ratio between the building load and the heat pump capacity, whereas \( C_D \) is the degradation coefficient for on-off cycling, equal to 0.9, and \( COP_{\text{CONTINUOUS}} \) is the coefficient of performance of the heat pump that operates without on-off cycling. It is worth specifying that the control of the heat pump capacity is achieved acting simply on the rotational frequency of the compressor shaft. All the other components that may vary their rotational speed, i.e. the fan of the evaporator for the...
direct system and the fan of the air-to-glycol heat exchanger and the glycol pump for the indirect ones, are instead kept at the maximum speed.

Overall, the performance indexes that are used to compare the three different heat pumps are the seasonal coefficient of performance and the Total Equivalent Warming Impact \((TEWI)\) that are calculated as follows:

\[
SCOP = \frac{\sum_{i=1}^{n} Q_{BUILD},i\Delta t}{\sum_{i=1}^{n} (P_{COMP,i} + P_{PUMP,i} + P_{FAN,i} + P_{DEFROST,i})\Delta t}
\]  \hspace{1cm} (19)

\[
TEWI = \alpha_{LEAK}M_{REF}nGWP + (1 - \varepsilon_{REC})M_{REF}GWP + E_{EL,n}M_{CO_2}
\]  \hspace{1cm} (20)

4. Results

Starting from, the energy performance index, Fig. 2 shows the \(SCOP\) and the \(SCOP_{HP}\) of the three different heat pumps considered in the present study. \(SCOP\) is defined as per Eq. (19) and accounts for the power consumption of the compressor, the auxiliaries and the defrost, whereas the \(SCOP_{HP}\) is the Seasonal Coefficient Of Performance of the heat pump only, i.e. it accounts for the compressor consumption only. The rationale behind these indexes is pointing out the differences that arise not only from the system layout, i.e. direct and indirect, but also to highlight the performance of the use of different refrigerants.

From the analysis of the figure, it is possible to conclude that the performance of the heat pump only is very similar since a reduction in the \(SCOP_{HP}\) of around 3% is found passing from direct R410A system to indirect ones. Additionally, in indirect systems a slight tendency of R290 to perform better than R410A may be found because the \(SCOP_{HP}\) of the heat pump that uses the natural refrigerant is around 2% higher than that of R410A-based heat pump. However, a significant difference arises when the consumptions related to the auxiliaries and the defrosting cycles are taken into consideration. Indeed, the \(SCOP\) of the overall system is around 26% lower for the indirect heat pumps with respect to the direct one. This is related to the strong increase in the fan and pump consumptions that arises in the indirect systems. Indeed, as shown in Error! Not a valid bookmark self-reference, in these systems the fan consumption is around 5 times higher than the fan consumption in direct system and also the consumption of the water-ethylene glycol mixture is not negligible since it is even higher than the consumption of the fan of direct systems. The first result is not surprising: in indirect system, the evaporating temperature is significantly lower than the air temperature since heat is extracted from the water-ethylene glycol mixture which, in turn, is colder than air. As a result, in indirect systems there is an increase in the range of air temperature and humidity conditions in which the frost formation and accumulation phenomenon occurs. This result in an increase in the air side pressure drop.
which, in turn, leads to an increase in the fan consumption. Similarly, although the pump power consumption is small, the large number of operating hours, i.e. the full heating season, leads to a not negligible energy consumption.

Table 4. Details on energy consumption of the three heat pumps

<tr>
<td>Water-to-water R290</td>
<td>674.4 kWh</td>
</tr>
</tbody>
</table>

Finally, the TEWI of the three systems is in Fig. 3. For the calculation of this environmental index, the GWP values are taken from the last IPCC report [26] resulting in GWP$_{100}$ = 0.02 and GWP$_{100}$ = 2256 for R290 and R410A respectively. The refrigerant leakage is assumed to be 2% and, additionally, it is assumed that it does not influence the heat pump performance. This may be a source of error, especially for indirect systems that might not be built with liquid receiver, but it is done for the sake of simplicity since the model developed for this study is not able to simulate the operation of a heat pump in undercharged conditions. The other parameters are: lifetime of the system equal to 10 years, end-of-life recovery efficiency 90% and emission of CO$_2$ per unit of electrical energy 247 g/kWh [27]. Comparing the results, it is possible to state that, despite its lower energy performance, the system using R290 largely benefits from the low-GWP of this refrigerant since its TEWI is around 5% lower than that of the baseline solution despite its higher energy consumption. On the other hand, comparing the two systems working with R410A, the indirect one has a lower direct impact, as a consequence of the lower charge, but higher indirect emission since it shows higher energy consumption. Overall, the two effects approximately compensate each other resulting in a TEWI only around 4% higher than that of the baseline system.

![Fig. 3. TEWI of the three systems.](image)

5. Conclusions

In the present paper, the performance of an indirect expansion heat pump working with R290 is analysed and compared with that of R410A heat pumping systems. For this refrigerant, both well-established air-to-water heat pump, i.e. direct system, and water-to-water heat pump, i.e. indirect system, are considered.

The analysis is carried out on a yearly basis using a simulation tool designed and built for this purpose. Seasonal coefficient of performance (SCOP) is used as energy performance index whereas total equivalent warming impact (TEWI) is used to measure the equivalent carbon dioxide emissions of the three systems.
Overall, the direct system performs better than the indirect one both from the energy efficiency point of view and the environmental point of view. Indeed, the SCOP of the indirect systems are around 25% lower than that of the direct system whereas the TEWI is around 9%-15% higher. However, the refrigerant charge in indirect system is significantly lower than that required in a direct system, resulting in an improvement in the system safety.

Decarbonization of Affordable Multifamily Housing – Application of high-efficiency monoblock heat pumps

Maggie Sheng\textsuperscript{a}, Zack Allen\textsuperscript{b}, Siva Sankaranarayanan\textsuperscript{a}\textsuperscript{*}

\textsuperscript{a}EPRI, 3420 Hillview Ave, Palo Alto, CA 94340, USA, \textsuperscript{b}Silicon Valley Mechanical, Palo Alto, CA.

Abstract

Affordable multifamily housing presents one of the hardest residential sectors to decarbonize. Many of these housing units have the bare minimum in terms of HVAC (e.g., swamp coolers + gas wall furnaces, etc.) and are compromised on occupant comfort. A recent innovation in the heat pump retrofit market is the development of monoblock heat pumps which do not have separate indoor-outdoor units and are relatively simple to install. These are also high-efficiency inverter-driven systems that operate on a 120V single phase. The authors were part of a project team that worked with a multifamily affordable housing complex in Fresno, CA to install 140 monoblock heat pumps in 60 living units. The project investigated various aspects of the retrofit process and collected energy use data from all the units to derive insights into the efficacy of these heat pumps for providing comfort while reducing GHG emissions. The results indicate that residents used their heat pumps similar to swamp coolers in the main living areas, and with additional heat pumps in the bedrooms, were able to achieve better cooling while staying within the building’s overall current capacity. In winter, the use of heat pumps significantly reduced energy use consequently reducing the overall GHG emissions from this community. A set of recommendations on applying these heat pumps in utility customer programs to help to decarbonize affordable multifamily housing is developed.

Keywords: affordable housing; decarbonization; retrofits; monoblock heat pumps; 120V heat pumps;

1. Introduction

Historically, higher-income communities have been the early adopters of emerging energy technologies—such as rooftop solar photovoltaics (PV), high-efficiency appliances, light-emitting diode (LED) lights, heat pumps, heat pump water heaters (HPWHs), and electric vehicles. The idea behind this market-driven approach is that as deployment becomes more widespread, the technologies will eventually become more affordable to low-income communities, further expanding the market.

Today, as governments and utilities establish aggressive climate goals, the need to electrify and decarbonize residential and commercial buildings—which account for about 12% of U.S. greenhouse gas emissions—becomes more urgent. However, advanced electric building technologies such as electric heat pumps and HPWHs are generally expensive and out-of-reach for low-income households.

The cost of adoption of heat pump technologies goes beyond the equipment and labor costs for affordable multifamily housing (which houses low-to-moderate income residents) as these buildings are heavily constrained by existing electrical capacity. In a recent study conducted by the authors in a garden-style multifamily affordable housing complex in Fresno, CA, each building with up to 8 apartments each had a total capacity of 200A with each apartment having 100A panels. Full scale electrification of this community using traditional mini-split heat pumps and heat-pump water heaters would have significantly exceeded the capacity constraints in many of the buildings. The solution to this challenge required scouting, analyzing, certifying,
and installing 120V monoblock air-source heat pumps for space conditioning. The use of 120V monoblock heat pumps helped to eliminate costs for panel upgrades, additional wiring (for 240V), and potentially higher costs associated with increasing a building’s current capacity all of which collectively would have doubled the per unit cost of the overall retrofit. In the following sections, we describe why the use of these monoblock heat pumps and other decarbonization measures that can form a “package” solution for decarbonizing affordable multifamily housing.

Recognized as a critical technology for efficient space conditioning and building decarbonization, electric heat pumps have become an increasingly popular option in residential buildings across the country and the globe. Using electricity instead of fossil fuel as energy source, heat pumps enable the large majority of current space heating demand to be met with lower carbon emissions. By leveraging a vapor compression refrigeration cycle to harness ambient thermal energy, heat pumps can efficiently provide heat with one-third to one-fifth of the electricity consumed by conventional electric heating equipment [1].

In the US, electric heat pumps are most adopted in single-family houses, but there is an increasing trend of electric heat pump adoption in multi-family apartment buildings as well. As of 2005, apartment buildings accounted for about 10.2% of total installed residential electric heat pump. This number has increased to 13.2% in 2015 [2]. 2021 has been a record-high year for heat pump sales. In the US, heat pump sales grew by around 15% year-on-year. Air-source heat pumps (ASHP) account for most sales, with a market share of more than 60% [1]. With continued advances in heat pump technology, heat pumps can perform well across nearly all climate zones in the country [1]. ASHPs operate most efficiently in mild and coastal climates [3]. Therefore, California climate is ideal for ASHP implementation. According to the survey of California Heat Pump Residential Market Characterization and Baseline Study, most of the construction professionals in the survey expected the heat pump market to grow in the next five years in California. Half of these professionals reported they already install heat pumps regularly and see heat pumps becoming increasingly critical to meet California’s energy goals. Even in cold places like Lake Tahoe, manufacturers make heat pumps that work effectively at very cold temperatures [4].

However, there are still some barriers to widespread adoption. In addition to the negative perception carried by historical poor performance at low outdoor temperature, heat pumps require more complex and proper maintenance than furnaces to keep optimal performance. The expected average lifetime for a heat pump is 10 years or more, while 15-20 years for a gas furnace [5]. Moreover, customers and technicians are more familiar with gas furnaces and air conditioners. The lack of appropriate skills and knowledge and high upfront costs are the two other major barriers to widespread heat pump adoption, especially in the placement of the equipment of the compressor unit [4].

In the Net Zero Emission by 2050 scenario, the global heat pump stock should cover at least 20% of global heating needs in buildings, while heat pumps still only meet about 10% of the need for now [1]. Policy support for heat pumps is rapidly increasing to meet decarbonization ambitions [1]. Several manufacturers are expanding heat pump production with emerging business models. Further policy support and technical innovation are still needed to reduce upfront purchase and installations costs, remove market barriers, improve energy performance, and exploit potential to enable power system integration and flexibility [1].

2. Decarbonizing Affordable Multifamily Housing

2.1. What is the motivation?

Affordable multifamily housing is one of the most challenging segments of buildings to decarbonize and this is especially true for retrofits. There are several extenuating circumstances that makes this challenging, some of these are listed below:

- **Energy Burden**: Any upgrades and technology investments made cannot result in increasing the energy burden in affordable housing communities. With decarbonization pathways that utilize electrification, there is a need to be cognizant of the potential for electrified end-uses being higher operating costs for community residents and measures to help mitigate these cost increases are necessary.

- **Split Incentives**: Given that community residents don’t own the infrastructure in affordable multifamily housing communities, there is a need to make sure that the investment made by the building owner/operator has a return for the building owner/operator.

---

1 Throughout the paper, the term monoblock heat pumps refer to specific class of heat pumps that have a single unit form-factor (indoor unit only) as opposed to the traditional indoor/outdoor (dual-unit) form factor.
Retrofit Costs: In addition to the cost of equipment and labor, retrofits need to explicitly account for retrofit costs which could include costs for additional panel capacity, wiring for 240-V end-use devices, cost of removal of existing (old) infrastructure, asbestos abatement for older vintage buildings, etc. These costs could significantly add to the overall cost of decarbonizing affordable housing communities.

Infrastructure upgrade costs: This impacts electrification based decarbonization measures which are currently being served for space and water heating via natural gas. The additional electrical load that may arise can trigger the need for upgrading distribution infrastructure such as service transformers and requires the local utility to invest in these upgrades.

Given these set of challenges, it is safe to say that if there is a way to engineer a decarbonization solution for affordable multifamily housing, there is a very high likelihood of these decarbonization solutions to find wider applicability. In that sense, this challenge has high innovation potential both in terms of technology as well as business model. The above list is not exhaustive as each community is different and may have their own set of issues that makes decarbonization challenging. However, the market availability of 120V monoblock heat pump products present a viable answer to many of these challenges.

2.2. How does 120V Monoblock heat pumps help?

To help address the challenges with decarbonizing affordable multifamily housing, the use of 120V monoblock heat pumps in conjunction with other electrification and decarbonization technologies can be considered to develop packages of energy conservation measures that can provide for decarbonization while reducing the first cost of upgrades and operating cost of energy.

- **High Efficiency**: The 120V monoblock heat pumps that are currently available in the market are high efficiency inverter driven variable speed heat pumps which have operating Coefficient of Performance (COP) of 3.0 or higher. This effectively provides for a 3x increase in efficiency compared to even the most efficient natural gas heating solutions. This increased efficiency helps to offset the cost of natural gas with higher electricity use that is more efficient for the same amount of heat.

- **120V as opposed to 240V**: The use of 120V as the operating voltage and less than 15A as the operating maximum current draw allows these heat pumps to used in capacity constrained multifamily buildings. This is especially true if these heat pumps are replacing existing low-efficiency evaporative coolers or window air-conditioning units. This also significantly reduces the risk of higher costs related to retrofit constraints. The unit’s operation at lower power draws also allows for not requiring distribution infrastructure upgrades if the unit is replacing an existing low-efficiency system at the living unit level.

- **Monoblock requires less construction**: The use of monoblock heat pump technology also requires less construction impacts as the heat pump unit does not have any ducting, wires, tubes that runs from the outdoor unit to the indoor unit. Additionally, the models used in our case study use two 6” holes for air intake and exhaust allowing for tighter air sealing.

- **Additional decarbonization**: Additional measures such as envelope improvements, community-scale solar PV, etc. with the ability to avail of federal, state, and utility level incentives such as the U.S. Department of Energy’s Weatherization Assistance Program (WAP), California’s Solar on Multifamily Housing (SOMAH) all help to address issues with split incentives, reducing energy burden, etc. and when done in conjunction with the installation of 120-V monoblock heat pumps helps to further address the challenges with decarbonizing affordable multifamily housing.

3. Case Study

3.1. Project Description

Constructed 50 years ago, Pleasant View is a 60-unit affordable housing community in Fresno, California. It is a family community comprised of 1-, 2-, 3-, and 4-bedroom units spread across ten buildings, each of which contain between four and ten apartments. The units were previously cooled by evaporative coolers and heated by natural gas wall furnaces. A closet in each apartment stored a 40-gallon natural gas water heater. The community is master metered for both electricity and natural gas, with the property owner LINC Housing paying all utility costs to PG&E, the serving utility. Each apartment is served by a 100-A electric panel, while
each building is served by 200-A mains panel (regardless of number of apartments). Limits on the local distribution system precluded full-scale electrification of the property.

The project team installed the monoblock heat pump and limited (limited to 3 of the 10 buildings) centralized HPWH retrofits in the first half of 2020. Retrofits involved installing 120-V, 12-hp Innova D.C. inverter heat pump units with an energy efficiency ratio (EER) of 3.3 (min outside ambient temp of 14F in heating mode) in each apartment. Two advantages of the Innova heat pumps, also referred to as packaged terminal air conditioning (PTAC) stood out: 1) Historically most residential heat pumps installed in the U.S. are 240-V units, which would have required new electric panels and rewiring at Pleasant Hill. The 120-V Innova units minimized any need for upgrades and represented one of the first large scale retrofit installation of 120-V heat pumps in affordable multifamily housing; 2) Historically, heat pumps have been split systems, requiring heat pump components to be installed on opposite sides of the inner and outer wall. Innova's monoblock unit involves installing only a single heat pump component on the inner wall. The monoblock configuration lowers installation costs and possibly long-term maintenance costs. Innova units were installed in the living room of all living units in the building. In two-bedroom units, Innova units were installed in the living room and master bedroom. In three- and four-bedroom units, Innova units were installed in the living room, master bedroom, and secondary bedroom. No further electrical infrastructure changes were made to the living units.

The project team performed the following additional energy efficiency upgrades listed in Table 1. The utility energy savings assistance programs covered some of the common area measures, but the air conditioning upgrades were out of pocket for the property owner.

3.2. Data Collection and Methodology

Data collection from the community was performed primarily at the circuit level wherein each living unit was fitted with a current-transformer based circuit level load monitors that helps to provide highly granular (1-min level frequency) disaggregated load data. The need for this level of disaggregated load monitoring was motivated by the fact that the community is master metered for both electricity and natural gas thereby not having granular energy consumption at the individual unit level. Data was collected over a 3-year period ranging from 2019 (pre-retrofit) into 2020 (mid-retrofit) and 2021 (post-retrofit). While the heat pump retrofit was done in 2020, many of the other measures such as envelope and solar PV installation happened much before (2018-2019 timeframe). Load calculations were all based on disaggregated circuit level loads with a dedicated CT monitoring the living room Innova unit and master and second bedroom Innova units monitored via 15A shared circuit CTs. The monitors provide cumulative energy data based on per-minute current and voltage measurements which was aggregated to obtain appropriate hourly energy use values. Additionally master metered electric and gas data was used to calculate community level energy use and associated GHG using CAISO provided emissions factors.
3.3. Results

3.3.1. Summary

Total energy increased a small amount in the summer (shown as the small negative orange bars in Figure 1) but decreased significantly in the winter (shown as the orange bars at right). In other words, gas consumption decreased, while electricity consumption increased. Gross energy use decreased by 22%, mostly from winter gas savings.

![Figure 1 Total Energy (Gas and Electric) Usage](image1)

Replacing evaporative cooling with compressor-based cooling, combined with the stay-at-home Covid-19 effect, increased summer GHG emissions. Electrification of water heating all year round overcame these increases, leading to a net GHG emission reduction. Figure 2 indicates the energy use converted to lb CO2e using California Independent System Operator (CAISO) published hourly emissions intensity. Overall emissions (site emissions + source emissions from grid electricity) decreased by 13%, largely due to winter gas savings.

![Figure 2 Monthly GHG emissions](image2)

While these results indicate the overall effect of PTAC and heat pump water heaters for the time periods under consideration (as indicated in Figure 1 and Figure 2), a detailed analysis of the 120V monoblock heat pumps was conducted to characterize the field performance of this new & emerging heat pump technology.

---

2 This is total community level energy use based on master metered gas and electric meter data could not be further disaggregated for the periods shown without combining data from utility meters and circuit level monitors which don’t have the same levels of accuracy.
3.3.2. Field performance of monoblock heat pumps

The field performance of monoblock heat pumps (PTAC units) were analyzed from the point of view of four research questions:

- How are residents of the community using these PTAC units? Is there a significant behavioral difference between living units?
- How does the load shape of the PTAC unit relate to the load shape of status-quo cooling solution? Can the load shape differences be attributed to efficiency or more to customer behavior?
- What happens when multiple PTAC units are used concurrently in buildings? Does simultaneous use of multiple PTAC units cause significant current draws that can potentially trip circuit breakers?
- What is the result of the use of PTAC units compared to status quo in terms of overall energy use (and potentially energy bills) in summer and winter?

3.3.2.1. Average user behavior

The July performance of the Innova heat pumps in the 1-bedroom units are shown in Figure 4. Most one-bedroom units show continuous, low-power draw, without significant periods of non-use. There is high efficiency due to variable-speed performance. The load increases moderately with higher outdoor air temperatures. The data shows afternoon peaking performance and significant differences between living units with some living units running the PTAC units continuously in summer. With the status quo being inefficient evaporative coolers, which were under-utilized because of non-performance, many residents were happy to use a functioning high efficiency air conditioning unit. A qualitative survey of customer satisfaction was corroborated by data collected from the living units.

![Figure 3 Innova Heat Pump Use Characterization (July 2021 – 1BR)](image)

The January performance of the Innova heat pumps in the 1-bedroom units are shown in Figure 4. The data shows very low energy draw during the winter for heating. Significant variation between units is observed. When actively being used, the data shows dual peaking behavior corresponding to early morning and late evening hours, which is to be expected.
3.3.2.2. Comparison of monoblock heat pump load shape to status quo

The average summer load shapes for 1-bedroom units, displayed in Figure 5, show that 1-bedroom units use the heat pump to gain more comfort and that the living room Innova performance is similar to the swamp cooler. The higher efficiency mode allows less power despite continuous use. Note that winter load shapes couldn’t be compared because the status quo is a natural gas wall furnace.

3.3.2.3. Impact of simultaneous multiple PTAC use on building’s current draw

Figure 6 shows the hourly building level current draw in July 2021. The maximum current draw with multiple Innova heat pumps is an average of about 15-A per living unit. At a maximum of about 7.5-A per Innova, use of a second Innova is not likely to cause the circuit breaker to trip unless other current loads are on the same circuit.
Figure 6 Innova Heat Pump Current Draw at Building Level in July 2021 (2 BR)

Figure 7 show the maximum current draw with multiple Innova heat pumps is an average of about 6-A per heat pump (or 42-A total for the 7 units). At a maximum of about 6-A per Innova, use of a second Innova is not likely to cause the circuit breaker to trip unless other current loads are on the same circuit.

Figure 8 shows that the monthly energy consumption is slightly higher for the Innova heat pumps than for the swamp coolers due to Innova continuous use. Higher energy use of Innova is also due to increased cooling needs in 2021 compared to 2019. However, Figure 9 show that energy consumption is significantly lower for the Innova heat pumps than for the gas wall furnace in the winter (electricity consumption in kWh was converted to US Therms for comparison). Significant performance improvement may also be attributed to envelope improvements that were added.

3.3.2.4. Summer and Winter energy performance of PTAC and status quo

Figure 8 shows that the monthly energy consumption is slightly higher for the Innova heat pumps than for the swamp coolers due to Innova continuous use. Higher energy use of Innova is also due to increased cooling needs in 2021 compared to 2019. However, Figure 9 show that energy consumption is significantly lower for the Innova heat pumps than for the gas wall furnace in the winter (electricity consumption in kWh was converted to US Therms for comparison). Significant performance improvement may also be attributed to envelope improvements that were added.
4. Conclusions & Recommendations

The Pleasant View project was a showcase illustration of the unique application of emerging technologies to surmount barriers to electrification.

The results indicate that the Innova units are ideal for smaller living units, given the increased usage (and possibility for increased energy bills) in summer compared to reduction in gas use in winter. In a few cases, high overall usage (indicated by continuous use and low thermostat set points) caused maintenance issues. The product supports a “hoteling” mode that can help prevent extreme set points from causing maintenance issues, especially in master-metered facilities. Further, with a peak around 700-W and an average load of about 400-
W, each of these monoblock heat pumps represent about 300-W in flexibility potential, assuming adoption of a suitable controls platform that can implement demand-side flexibility.

While the technology itself shows promise in terms of performance, projects need to address split-incentives, and consider that total energy costs may increase with electrification depending on the energy use patterns and local utility rates. Improved energy efficiency and on-site PV are important steps to reduce tenant and owner energy costs.

The project team recommends the following actions to develop better pathways for the scaling of electrification retrofits of affordable multifamily and other residential markets to maximize decarbonization impacts.

- **Improve planning and implementation models**: The process for understanding and integrating the many support programs for the affordable multifamily market is daunting. For example, coordinating solar PV, roof upgrades, and energy conservation measures is essential for optimizing the electrical upgrades needed for the entire decarbonization retrofit.

- **Improve economic models for split incentives**: Scaled community decarbonization retrofits are emerging as evidenced by this project. To accelerate market adoption, improved models for overcoming split incentives and distribute savings from the community solar and other decarbonization retrofits are needed.

- **Upgrade policy or codes for electrification/decarbonization**: The shift to carbon-based metrics and incentives is underway in many utility service territories and are important to the successful scaling of decarbonization retrofits for affordable multifamily communities. Using carbon savings metrics can increase the incentives and cover a significant portion of the first cost of decarbonization retrofits as shown by California’s Low-Income Weatherization Program incentives. Solutions for mitigating the electric infrastructure costs are essential for stimulating the electrification/decarbonization retrofits. New federal, state, and utility programs need to be developed and tested to cover these costs.

- **Work with manufacturers and stakeholders**: A significant barrier to the electrification retrofits of affordable multifamily communities is the lack of heat pump products for the retrofit market. New heat pump products designed for the retrofit market are needed. Recent advances such as the Innova monoblock heat pumps and Gradient window cold-climate heat pumps are good examples. A sustained program working with domestic and international manufacturers, utilities, designers, installers, and government organizations is recommended.

- **Demonstrate evaluation of integrated solutions**: Demonstration programs and test beds for utilities and stakeholders is needed for rapid evaluation of new integrated decarbonization retrofit solutions to accelerate market adoption of these new solutions.

**Acknowledgements**

The authors would like to thank the California Energy Commission which funded the research conducted in this paper under grant CEC-EPC-15-053. The authors would also like to thank their colleagues Corey Shono, Evan Giarta, and Herb Yaptinchay for all the help with data collection and project management.

Tracking the carbon impact of space heating appliances from cradle to grave

Laure Meljac*, Martin Forsen

NIBE, Hannabadsvägen 5, 285 32 Markaryd, Sweden

Abstract

To keep the global warming below 1.5°C, the European Union (EU) committed to carbon neutrality by 2050. The EU acknowledge that achieving this goal will require to track the greenhouse gases (GHG) emissions of organisations, products and buildings, from cradle to grave. Carbon, and more generally environmental, impact of products and buildings is evaluated while performing life cycle assessments (LCAs). LCAs are not widespread so far in the EU. However, several signs show that LCAs will become the norm sooner or later. LCAs are governed by precise and strict rules that are described in standards which describe the LCA’s process as well as how the environmental product declaration shall be performed and handled.

In the French law, before any building construction, it is compulsory to perform a LCAs. Construction projects shall demonstrate that GHG emissions from cradle to grave do not exceed defined thresholds. LCAs provide a much wider picture of the environmental impact of products or buildings and can serve for building up the best strategy for reducing the GHG emissions.

Keywords: space heating appliances, carbon footprint, climate change, carbon neutrality

1. Greenhouse gases emissions tracking

1.1. Worldwide commitment

In order to fight against the climate change, the United Nations Framework Convention on Climate Change (UNFCCC) was adopted in 1992 and has since been ratified by 195 Parties. The Kyoto Protocol was adopted in 1997 to implement the UNFCCC and entered into force in 2005.

In short, the Kyoto Protocol operationalizes the United Nations Framework Convention on Climate Change by committing industrialized countries and economies in transition to limit and reduce greenhouse gases (GHG) emissions in accordance with agreed individual targets.

Under the Protocol, countries' actual emissions have to be monitored and precise records have to be kept. Reporting is done by Parties by submitting annual emission inventories and national reports under the Protocol at regular intervals.

A compliance system ensures that Parties are meeting their commitments and support them to meet their commitments if they have problems doing so.

At the conference of the parties organized in 2015 in Paris (COP 21) 196 Parties signed a legally binding international treaty on climate change.

Its goal is to limit global warming to well below 2, preferably to 1.5 degrees Celsius, compared to pre-industrial levels.

To achieve this long-term temperature goal, countries aim to reach global peaking of GHG emissions as soon as possible to achieve a climate neutral world by mid-century.

The Paris Agreement is a landmark in the multilateral climate change process because, for the first time, a binding agreement brings all nations into a common cause to undertake ambitious efforts to combat climate change and adapt to its effects.

The Paris Agreement works on a 5-years cycle of increasingly ambitious climate action carried out by countries. By 2020, countries submit their plans for climate action known as nationally determined contributions (NDCs).

In their NDCs, countries communicate actions they will take to reduce their GHG emissions in order to reach the goals of the Paris Agreement. Countries also communicate in the NDCs actions they will take to build resilience to adapt to the impacts of rising temperatures [1].

In 2020, the European Union (EU) published its NDC where the EU set a binding target of a net domestic reduction of at least 55% GHG emissions by 2030 compared to 1990 [2]. The EU is pushing even further and targeting carbon emissions neutrality by 2050.

1.2. European Union actions

After the Kyoto protocol was signed, the EU put in place the first measures aiming at tracking and limiting the GHG emitted by the energy related activities, and several other very high GHG emitting sectors. However, the carbon neutrality cannot be achieved unless, the emissions in almost all the human activity sectors are tracked and limited. Therefore, the EU launched the Emission Trading System (ETS) that tracks the GHG emitted by the energy utilities and industries and other pieces of legislation addressing energy related products; buildings, transportation and many more. The EU also set GHG reporting obligation (DIRECTIVE 2014/95/EU) for the largest organisations, both public and private and set the ambition of tracking both direct and indirect GHG emission.

This paper is focusing on the measures impacting products, and more specifically energy related products, such as heat pumps.

- Large organisations’ GHG emissions

Every company employing more than 500 persons must report on their direct and indirect GHG emissions as well as on information on the management’s approach to reduce them. The reporting periodicity is defined at the member state level. It is recommended to report according to the scope 1 and scope 2 as defined by the GHG protocol standards.

The GHG protocol is a partnership of businesses, non-governmental organisations (NGOS), governments, and other organisations convened by the World Resources Institute (WRI) and the World Business Council for Sustainable Development (WBCSD). It first established in 2001 the most widely used international accounting tool for quantifying and measuring GHG emissions.

The GHG Protocol breaks GHG emissions down into three categories: scope 1 emissions are defined as those caused directly by an organisation’s activities while scope 2 emissions count indirect emissions resulting from an organisation’s energy consumption. Scope 3 encompasses all other indirect emissions, caused along an organisation’s value chain, included the products that are purchased and placed on the market [3]. The three scopes concepts are illustrated on figure 1.

![Diagram of GHG Protocol scopes and emissions across the value chain](image-url)

Fig. 1. Overview of the GHG Protocol scopes and emissions across the value chain [4]
As of today, reporting on emissions under scope 1 and 2 is mandatory while reporting under scope 3 is optional. However, in some member states, like France, reporting under scope 3, which requires accounting for the carbon footprint of products and goods, is recommended.

- Energy using products

The EU started to tackle the energy related products already back in 1994 when the energy label was introduced for several household appliances before being subsequently expanded in 2004. The EU energy label has been a key driver for helping consumers choose products which are more energy efficient. At the same time, it also encourages manufacturers to drive innovation by using more energy efficient technologies.

The energy labelling directive was then followed, in 2009 by an eco-design directive. This directive is an effective tool for improving the environmental performance of products by setting minimum energy performance standards. This eliminates the least performing products from the market, significantly contributing to the EU’s energy and climate targets.

The Ecodesign directive and Energy labelling regulation are both addressing energy efficiency, meaning the energy used by products during their life stage. Even though the GHG emissions from the usage phase of the energy using product often stand for a significant share of the overall GHG emissions, the GHG emissions from energy using products start when the raw material is extracted from the mines and stop when the products are either recycled, burned or land filled. To reach the 2050 zero emission target, the EU has to reduce the GHG emissions of products while taking in account their entire life cycle. An assessment limited to the usage phase is not enough.

A proposal for “Ecodesign for sustainable products regulation” is under development [6]. This regulation will replace the present Eco-design directive and is aiming at adding criteria addressing resource efficiency. In particular, the regulation proposes a mandatory carbon and environmental footprint declaration for the energy using products.

In parallel, the EU aims at switching its economy from a linear to a circular one. The actions taken in the framework of the circular economy action plan [6] will further speed up the GHG emissions’ reductions and favor EU independency towards raw material.

- Buildings

In the EU, buildings represent 40% of the total energy consumption and 36% of all GHG-emissions [7]. The GHG emission reduction target cannot be met without substantial reduction of the GHG emitted by buildings. The European Energy Performance of Building directive is the legislative instrument aiming at reducing the energy consumed by new buildings. As addressing new built buildings is not enough, the EU initiated, in 2020, the renovation wave which is targeting the existing buildings and is aiming at increasing the speed of renovation of the building stock. The renovation wave action plan includes a 2050 whole life-cycle performance roadmap to reduce GHG emissions form buildings [8].

Improving the energy efficiency of building is a good start as it helps reducing the GHG emissions over the life stage of the buildings. However, measuring the GHG emissions exclusively over the use phase of the building is misleading. As for the energy using products, reducing the energy use during the life stage would not be enough to reduce the GHG emissions so that carbon neutrality can be achieved by 2050. Indeed, a study on the Austrian building stock showed that the GHG “embodied” in building-related processes (e.g., material production, transport, refurbishment, or end-of-life) is four times higher than the GHG emitted during the use phase of the buildings [9].

In the recast of the Energy Performance of Building directive, a new requirement is added on a mandatory calculation of the life-cycle Global Warming Potential (GWP) of new buildings [7]. This new directive is to be published in 2023.

- General rules for life cycle assessment

Reporting on the GHG emitted over the use phase of products and buildings and directly or indirectly emitted by organisations is not enough to cut down GHG emissions so that the 2050 goal can be achieved. For that reason, carbon or environment footprint criteria are appearing in pieces of legislation related to reporting obligations for organisations, products and buildings.

The European Commission acknowledged that Life Cycle Assessments (LCA) provide the best framework for assessing the potential environmental impacts of products currently available. The need for consistent data and consensus LCA methodologies was underlined. Mid-2005. A joint project between DG Environment and the Commission’s Directorate-General Joint Research Centre was initiated and the European Platform on Life Cycle Assessment was created.
2. Life Cycle Assessment

2.1. Definitions

The term “carbon footprint” has been widely established, including the public domain. However, this term is not clearly defined and moreover, several definitions can be found in the literature [8]. In the proposal for a regulation on Ecodesign for sustainable products [5], the carbon footprint is defined as “the sum of greenhouse gas (GHG) emissions and GHG removals in a product system, expressed as CO₂ equivalents and based on a life cycle assessment using the single impact category of climate change”.

The “environmental footprint” is defined as “a quantification of a product’s environmental impacts, whether in relation to a single environmental impact category or an aggregated set of impact categories based on the Product Environmental Footprint method”.

Looking at the above-mentioned definitions, it seems that the “carbon footprint” is limited to the GHG emissions, whereas the “environmental footprint” has a wider scope and includes other types of impact than GHG emissions. In any case, both the carbon and environmental footprints are quantified by performing a life cycle assessment (LCA).

2.2. LCA methodologies

Two LCA methodologies are described in the literature: the bottom-up, based on process analysis and the top-down, based on environmental input-output (EIO) analysis [10]. The top-down method is an economic quantitative method to study the interdependence between various parts of the economic system, which runs in the whole industry cycle. The method aims at estimating all purchases and activities in a supply chain leading up to final manufacture in an industry. The carbon or environmental footprints are then calculated based on these transactions within the supply chain.

Process analysis is a bottom-up method, which has been developed to understand the environmental impacts of individual products from cradle to grave. The bottom-up approach describes the environmental footprint calculation of individual materials, products or processes. Setting the boundary conditions is key while performing a LCA using the process analysis method. Omrany et al [11] made an extensive review of existing LCA in buildings and showed that there is no common way of defining boundary conditions. However, comparing carbon or environmental footprint of similar materials, products or services is only possible if the boundary conditions are identical. For that reason, it is essential to describe common ways and method for performing LCA.

2.3. LCA international standards, process-based method

The development of the international standards for life cycle assessments by the International Standardisation Committee (ISO), ISO 14040 series was an important step to consolidate procedures and methods of LCA. Their contribution to the general acceptance of LCA by all stakeholders and by the international community was crucial.

ISO 14040 describes the four phases of an LCA: goal and scope definition, life cycle inventory analysis (LCI), life cycle impact assessment (LCIA) and life cycle interpretation. The scope definition includes, among others, the boundary conditions. ISO 14041, ISO 14042, ISO 14043 ISO 14044 provide details and guidelines on the four phases.

ISO 14040 series contains overarching standards that are addressing a very wide audience. In order to establish the carbon or environmental footprint of materials, products, services… the ISO 14040 series is complemented by more specific standards addressing specifically material, buildings, products…

2.3.1. Environmental product declaration (EPD)

EPDs are Type III environmental declarations, according to ISO 14025 (2006) and are often a good source of environmental data for a life cycle analysis.

ISO 14025 standard establishes the principles and specifies the procedures for developing Type III environmental declaration programs and Type III environmental declarations. It specifically establishes the use of the ISO 14040 series of standards in the development of Type III environmental declaration programs and Type III environmental declarations.

Type III environmental declarations present quantified environmental information on the life cycle of a product to enable comparisons between products fulfilling the same function. Such declarations
Type III declaration process is illustrated in figure 2.

In the development of Type III environmental declarations, all relevant environmental aspects of the product throughout its life cycle shall be taken into consideration and become part of the declaration. If the aspects considered to be relevant do not cover all stages of the life cycle then this shall be stated and justified. The data shall be generated using the principles, framework, methodologies and practices established by the ISO 14040 series of standards (i.e. ISO 14040 and ISO 14044).

The organisations acting as program operator are elaborating product category rules (PCR) which are defined as a set of specific rules, requirements and guidelines for developing Type III environmental declarations. PCRs set the rules, among other, for the environmental aspect and the life cycle stages to be considered, for the data quality requirements and the boundary conditions.

An EPD is a particular type of LCA, conducted using a defined set of Product Category Rules (PCR). Many PCR can be used for construction products (CPA, 2012) but only EPD following the same PCR can be compared.

EPDS are stored in dedicated database such as the INIES database or “the international EPD system” database.

2.3.2. Product standards

The European Committee for Standardisation (CEN) was mandated in 2004 for the development of horizontal standardised methods for the assessment of the integrated environmental performance of buildings. CEN TC350 works on the two standards dedicated to the evaluation of the environmental impacts of buildings: the EN 15978 (2011) and the EN 15804 (2012), for the building and material/product levels, respectively.

- Building level (EN 15978)
  EN 15978 provides calculation rules for the assessment of the environmental performance of new and existing buildings based on a life cycle approach. It is intended to support the decision-making process and documentation of the assessment of the environmental performance of a building.

- Product level (EN 15804)
  At the product level, EN 15804 standard defines the product category rules to develop Environmental Product Declarations (EPD) of construction products. The product category referred to in this standard includes all construction products and construction services for buildings and other construction works.
2.4. EU recommendations for LCA

The European Platform on Life Cycle Assessment (LCA) was created in 2008. This platform is aiming at proposing common methods to quantify the environmental impacts of products (goods or services) and organisations.

The European Commission proposed the Product Environmental Footprint (PEF) and Organisation Environmental Footprint (OEF) methods as a common way of measuring environmental performance.

The overarching purpose of PEF and OEF information is to enable to reduce the environmental impacts of goods, services and organisations taking into account supply chain activities (from extraction of raw materials, through production and use to final waste management). This purpose is achieved through the provision of detailed requirements for modelling the environmental impacts of the flows of material/energy and the emissions and waste streams associated with a product or an organisation throughout the life cycle.

The EU in COMMISSION RECOMMENDATION (EU) 2021/2279 sets the rules for establishing product environmental footprint. The document describes general procedure to conduct a LCA and the rules for establishing the Product Environmental Footprint Category Rules (PEFCR). The general procedure follows the same steps as these describes in ISO 14040 while the rules to establish the PEFCR are based on the minimum recommendation of ISO 14025. The recommendation also provides guidance to elaborate Product Specific Rules (PSR) which are vertical rules addressing specific products. While PEFCR describe horizontal rules to be followed by products belonging to the same category, the PSR are addressing sub-categories.

The term PEFCR is used instead of PCR in order to avoid confusion between ISO 14025 and EU recommendations.

The recommendation 2021/2279 goes into the very details of each phase of the LCA and PEFCR.

3. LCA in the French building code

3.1. French building code RE2020

The building code is associated to a calculation tool that calculates the yearly energy consumption of a building based on its structural characteristics (shape, insulation, walls, windows...), equipment (heating, ventilation systems...) and location. Prior to each new building construction, the building project shall demonstrate compliancy with the building code requirements.

Until 2022, the building code requirements were mainly addressing the energy consumption, the building envelop performance and the amount of renewable energy used.

On 1st of January 2022, the new French building code, RE2020 entered into force. The RE2020 includes the calculation of the LCA of the buildings, including equipment, from cradle to grave.

3.2. Buildings’ LCA

3.2.1. General methodology

The whole process for the LCA follows the approach as recommended by the EU in COMMISSION RECOMMENDATION (EU) 2021/2279.

The buildings’ LCA is conducted according to ISO 14040 and ISO 14044 and follows the four steps of the LCA as defined in ISO 14040: definition of scope and goal, life cycle inventory, life cycle impact assessment, interpretation and declaration. The buildings’ LCA is performed according to NF EN 15978 and comes as the sum of the LCA of the construction material, including heating, ventilation and air conditioning (HVAC) equipment, the impact from the energy used during the life phase and the impact of the construction services.

The LCA of construction materials and HVAC equipment are conducted according to ISO 14025, NF EN 15804 and NF EN 15804/CN (national complement to the standard for construction products) and are delivered as EPD.

The energy used during the use phase includes the energy needed for lighting, ventilation, space heating and domestic hot water production. In tertiary buildings and multifamily houses, energy needed for the lift and for lighting the car parks are also accounted for.

The impact of the building on the climate change is defined as the global warming potential (GWP) expressed in kg CO₂ eq/m².
The life-time of the building is assumed to be 50 years. A life-time is also defined for each piece of equipment. As an example, the life-time of heat pumps is 17 years. The GWP is calculated over the 50 years and the calculation takes into account the replacement of equipment. Primary energy factor for electricity is equal to 2.3 and it is considered constant for the entire life time of the building. The CO₂ content of the energy carriers are also considered constant over the 50 years.

3.2.2. Boundary conditions for the EPD

LCAs are performed from cradle to grave (according to NF EN 15804). The EPD shall be established while considering the following stages of the building life:

- Production: (modules A1-A3 according to NF EN 15804) extraction of raw material, transportation to the manufacturing site, manufacturing. Management of residues including packaging not leaving the factory gates are including in this stage
- Construction: (modules A4-A5 according to NF EN 15804) transportation from the production gate to the manufacturing site, construction or installation of the material or product, management of waste and packaging
- Usage: (modules B1-B7 according to NF EN 15804) use stage including maintenance, repair and replacement, energy and water used
- End of life: (modules C1-C4 according to NF EN 15804) deconstruction, transportation of the discarded products, waste processing
- Benefits and loads beyond the product system boundaries: (modules D according to NF EN 15804) environmental benefits or loads resulting from reusable products, recyclable materials and/or useful energy carriers leaving a product system.

The details of all the modules are described in NF EN 15804.

![Fig. 3. Stages that shall be observed for a cradle to grave LCA (Source: NF EN 15804)](image)

The EPD might be established for equipment providing one or several functions or for material and services. The EPD shall be established for clearly defined and measurable functional (equipment) or declared (material and services) units to allow for the comparison of equipment, material and services.

3.2.3. Environmental impacts covered in the EPD

The EPD shall provide, at least:

- The global warming potential indicator
  - This indicator accounts for the GHG emitted over the entire life cycle of the product. It is expressed in CO₂ equivalent.
- 6 energy indicators: basically the renewable and non-renewable energy used during the use phase of an equipment.
- 12 indicators related to circular economy.
- 11 indicators related to biodiversity which include air, water and sea pollution.
3.2.4. EPD types

• General rules
  The environmental product data shall be made available through EPD. However, in cases where no EPD is available, default values might be used.
  The EPD are managed by the organization called INIES and made available on INIES database publicly and freely accessible on the internet.

• Default values
  Default values are established for construction material and equipment by the French authorities (ministry). They are penalizing compared to specific data from EPD.
  Default values are also established for services that are not covered by any program and thus cannot beneficiate from any EPD. These services are: waste treatment, transportation…, energies (electricity, wood, district heating…), refrigerants…

• FDES
  FDES (Fiche de Données Environnementales et Sanitaires) are the EPD for construction material. INIES is the operator for the FDES and defines the program rules.
  There are two main categories of FDES: collective and individual FDES. The collective FDES are established by several companies and concern a given material type (eg: clay roof tiles) while individual FDES is established for a given material reference of a given manufacturer.
  The FDESs are valid for 5 years.

• Product Environmental Profile (PEP)
  The operator for the equipment’s EPD is an organization called PEP Ecopassport which is dedicated to electric, electronic and HVAC-R products. The EPD managed by PEP Ecopassport are called PEP (product environmental profile).
  PEP Ecopassport is managing the electric, electronic and HVAC-R product category rules as well as specific product rules.
  Just as FDES, there are two main categories of PEP: collective and individual PEP. The collective PEP are established by several companies and concern a given material type (eg: combination air to water heat pumps using R410A) while individual PEP is established for a given material reference of a given manufacturer.
  The PEPs are valid for 5 years.

3.3. Minimum RE2020 criteria

RE2020 set minimum requirements related to the global warming potential (GWP). Two thresholds are defined, one addressing the construction phase: construction work, material and equipment, one addressing the energy used during the usage phase.

In order to be compliant, the calculated GWP of the construction phase and the calculated GWP of the energy used during the usage phase shall be lower than the thresholds.

• GWP of the material and equipment
  The GWP is calculated as the sum of the GWP calculated in modules A, C and D for all the construction service and material, equipment that constitute the building

• GWP of the energy used during the usage phase
  The GWP is calculated as the sum of the GWP calculated in modules B for all the material, equipment and services that constitute the building

3.4. Example of results of LCA performed on a single-family house

The LCA is performed on a 100m² single family house located in the West part of France. Table 1 shows the GWP values for both construction and use phase achieved if both the space heating and domestic hot water demand are covered by either an air to water heat pump or a wall-hung condensing gas boiler providing both space heating and domestic hot water. The heat pump considered in the example has a seasonal energy performance equal to 3 while the gas boiler has an efficiency of 94%.
Table 1. GWP calculated and GWP thresholds in kg CO\(_2\) eq/m\(^2\) when an air to water heat pump is installed

<table>
<thead>
<tr>
<th>Phase</th>
<th>Construction phase</th>
<th>Use phase</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Air to water combination heat pump / wall hung gas boiler</td>
<td>Air to water combination heat pump / wall hung gas boiler</td>
</tr>
<tr>
<td>LCA GWP values kg CO(_2) eq /m(^2)</td>
<td>630 / 528</td>
<td>52 / 419</td>
</tr>
<tr>
<td>RE2020 thresholds kg CO(_2) eq /m(^2)</td>
<td>640</td>
<td>140</td>
</tr>
</tbody>
</table>

One can observed that the GWP impact of the construction phase is higher for the air to water heat pump than for the wall-hung gas boiler. However, the gas boiler is not compliant as the GWP on the use phase is higher than the authorized threshold.

4. Opportunities of the LCA calculations

So far, the EPBD mainly focus on the yearly energy use in buildings. However, setting up a building construction strategy on the basis of the energy consumption might be completely different from the one that might be adopted while considering the GHG emissions during the life-time of the building or the total GHG emissions from cradle to grave.

Let’s consider the example above (100m\(^2\) single family home in the West part of France). Let’s consider an existing similar house, located in the West part of France as well, built in the 60s and equipped with a 20-years-old non condensing gas boiler which achieve 75% efficiency. The primary energy used for space heating and domestic hot water for the new built house and the existing one over 50 years (for the existing building, the web tool [13] has been used) are shown in figure 4. Figure 5 shows the GHG emissions, calculated for 50 years corresponding to the energy used for space heating and domestic hot water production while considering the data listed in table 2.

![Figure 4: Primary energy used for space heating and domestic hot water production over 50 years in kWh/m\(^2\)](image-url)
In figure 5, the GHG impact of the heat pump and new gas boiler installation and two replacements are considered, while it is assumed that the existing boiler will last for 50 years.

</tr>
</tbody>
</table>

Figure 6 shows the emissions savings achieved while considering the following scenario:
- Scenario a: only the GHG emitted during the use phase of the house are considered
- Scenario b: GHG emitted by both the use and construction phase of the house are considered
Would only the use phase be considered, the conclusion would be that in order to achieve the highest GHG saving the old house should be torn down and replaced by a new one.

However, would both the use and the construction phases be considered, the best option would be to replace the existing gas boiler by a heat pump.

The conclusion here is only valid for France. Indeed, the conclusion could be very much different in countries where the CO\textsubscript{2} content of electricity is higher than the one in France. Figure 7 illustrates where the breaking point is.

![Fig. 7. CO\textsubscript{2} savings achieved depending on the CO\textsubscript{2} content of electricity](image)

In countries where carbon intensity of electricity is lower or equal to the emission factor of gas, 0.25kg CO\textsubscript{2}eq/kWh, it is worthwhile tearing down the existing building and rebuild a new one. Indeed, the GWP of the use phase become much more impacting than this of the construction phase.

This calculation illustrates the potential behind the life cycle assessment. Moreover, the calculation done here is only considering the GHG emissions impact. While accounting for more than one environmental impact, it would be possible to be sharper on the best strategy to adapt in order to protect our environment and preserve the natural resources.

5. Conclusion

In order to meet the COP 21 target and to achieve carbon neutrality by 2050, it is not enough to track the GHG directly and indirectly emitted by organizations and the GHG emitted during the use phase of the energy related product and buildings. Tracking the GHG emitted over the entire life cycle of products and buildings, from cradle to grave, has become a necessity. The tracking is done through the LCA that leads to environmental impact declarations for product, material and services. EPDs allow for a fair comparison of equivalent products and help choosing the less harming products in order to reduce the impact on the climate change.

In the EU, signs show that EPDs will become the norm soon or later for material and products, and in particular for heat pumps.

In France, since January 2022, EPDs are needed for construction material and HVAC equipment where installed in new buildings. In their national building code, RE2020, the French authorities go even beyond the GHG emissions as a full LCA is to be performed prior to every building construction. The LCAs include many impacts and not only the GWP impact. Even so, for the time being, minimum requirements are only addressing the GWP.

LCAs provides much more information than the GHG impact of a product, material or service. Other environmental impacts are assessed that give a much broader overview of how armful a product, material or service can be for the environment. Indeed, Life cycle assessment allows for establishing construction strategy based on more extensive environmental criteria. In France, because the CO\textsubscript{2} content of electricity is low, it is better to replace existing boilers by heat pumps than to tear down the building and build up new ones.

Abstract

The growing need for thermal comfort has resulted in an increase in refrigeration systems and, as a result, increased electricity demand for these systems. Waste heat-driven devices for refrigeration systems appear to be a potential alternative to traditional compression-based refrigeration technologies for reducing energy consumption. These devices in the refrigeration cycle can be driven by waste heat (free or inexpensive low-temperature energy source) as the primary energy source instead of electricity. This study investigates the ejector-driven and converging Tee-driven refrigeration systems (EDRS & CTDRS) using waste heat, aiming to provide an alternative to traditional VCC. An experimental setup is developed with a 3.6 mm nozzle size of an ejector and a converging tee diameter of 12.7 mm. A comparative experiment was conducted to assess the coefficient of performance (COP). In terms of performance, the EDRS COP outperformed the converging-tee-driven refrigeration cycle. The results showed that the proposed concept is promising to develop an alternative to the traditional refrigeration cycle and heat recovery.

Keywords: Refrigeration; Vapor Compression Cycle; Waste Heat; Ejector; converging Tee;

1. Introduction

Air conditioning is a need for humans in everyday life. Air-conditioning using a large amount of electric power results in a considerable proportion of fossil fuel combustion. Air conditioning and refrigeration systems consume a big part of the electricity used worldwide. There has been a huge growth in air conditioning usage, particularly in southern nations, causing major supply challenges during peak load hours. Furthermore, predictions show a tremendous increase in energy use. Another effect is the rising energy cost. Thus, many alternatives need to be considered to overcome the electricity demand. An ejector is a widely used device for energy conversion \cite{1}, \cite{2}. A refrigeration system powered by an ejector has the ability to minimize energy usage and consequently increase performance.

The EDRS is a vapor compression cycle (VCC) modification. Low-grade thermal energy use is considered as an essential kind of energy conversion that is both ecologically friendly and energy-saving. Low-grade thermal energy is an energy resource, and its recovery will improve energy efficiency. The ejector-driven refrigeration system, being a heat-driven device, provides a practical technique for converting low-grade heat into useful cooling. Low-grade heat sources, such as solar collectors \cite{3}, industrial processes, and automobiles \cite{4} power the ejector. An ejector compresses refrigerant vapor from the evaporator and discharges it to the condenser rather than pressuring it with a mechanical compressor. The vapor generator, which is heated by a low-temperature heat source generated the motive vapor. An appropriate ejector substantially increases the system's performance.

Many studies have demonstrated that a suitable ejector increases the system's performance. For instance, the authors \cite{5} developed an ejector-driven refrigeration system to overcome the throttling losses. The system performed optimally, with a 5 to 13\% greater COP than a typical refrigeration system with a nozzle diameter

\* Corresponding author. Tel.: +82-64-754-3626.
E-mail address: ycpark@jejunu.ac.kr.
of 2.3 mm and a corresponding ratio of 15.3. The researchers of [6] investigated the variable area ratio on a multi-evaporator refrigeration system. The results indicate that the energy saving increased by 112% by the variable area ratio compared to the traditional refrigeration system. An experimental investigation of the R134a EDRS was conducted by [7]. The outcomes indicate that with the rise in boiler temperature (motive), capacity, COP, and entrainment ratio improved and then reduced. Hence, the motive temperature must be optimized for the set condenser and evaporator temperatures to achieve maximum COP. Our previous study [8] compared the ejector nozzle sizes for an EDRS. The findings revealed that an ejector with a nozzle size of 3.6 mm performed well compared to 1.8 and 5.4 mm nozzle sizes. Moreover, compared to the VCC, the refrigeration cycle performed well at below 0ºC. A similar study by Chaiwongsa et al. [9] investigated a motive nozzle’s various nozzle outlet diameters for system performance. The ejector nozzle with an outlet diameter of 2 mm yielded the highest COP.

This study aims to utilize the ejector and converging tee to reduce power consumption and improve the COP of conventional refrigeration systems. An ejector and converging tee with nozzle sizes of 3.6 mm and 12.7 mm are considered, respectively. A comparative analysis is discussed in this study. The present study is subdivided into four sections. The first section provides an introduction, while the second is about methodology. Section 3 contains the results and discussion, and section 4 has the conclusions.

2. Materials and Methods

A heat-driven ejector and converging tee may be used to power a refrigeration system instead of or in addition to a compressor. The ejector and the converging tee have no moving parts, are cost-effective, have high reliability, have simple construction, and have minimal installation and operating expenses. Furthermore, both the ejector and converging tee have two intake ports, a motive, and a suction port, as well as one discharge port, allowing the primary high-pressure stream to hold the secondary low-pressure stream. Two streams are mixed in an ejector, discharged at a predetermined intermediate pressure, and actuated by fluid energy rather than electricity.

Both devices (ejector and converging tee) operate on low-grade thermal energy generated by waste heat. Second, the second level of compression is known to exist in order to lower the energy required by the input of a mechanical compressor. Furthermore, these devices serve as a pump to transport refrigerant via the refrigerant circulation channel. The efficiency of the ejector and converging tee directly influences the effectiveness of the refrigeration system. According to the working conditions, the ejector and converging tee have the maximum entrance ratio, continuously allowing the system to operate optimally.

The proposed refrigeration system uses an ejector and a converging nozzle to investigate the system's energy consumption and COP. The refrigeration systems' key parts are the expansion valve, receiver, condenser, ejector or converging tee, generator, evaporator, accumulator, and compressor. A system's performance relies on the working fluid's thermal characteristics. Thus, R134a refrigerant is employed as a working fluid, while waste heat is used as a primary fluid for the ejector and converging tee motive. In order to circulate the condensing water and waste heat (in the form of hot water) to the generator, two circulation pumps are employed. Table 1 displays the test conditions for the ejector and converging tee-driven refrigeration systems.
Moreover, pressure sensors, T-type thermometers, and refrigerant and water flow meters are used to measure the system's characteristics. A refrigerant receiver is installed at the condenser outlet to ensure that refrigerant flows continuously toward the expansion valve and generator. The primary flow reaches the ejector's motive or converging tee to entertain and compress the secondary refrigerant flow from the evaporator at high temperature and pressure. A heater with an output of 2.8 kW (Rainbow) is employed as the evaporator load. Brazed-plate heat exchangers are both a condenser and an evaporator. As a generator, a brazed-plate heat exchanger is used. Table 2 contains all additional technical characteristics. The refrigeration system schematic diagram for understanding the performance characteristics is depicted in Figure 1.

3. Results and Discussion

An ejector refrigeration system operating characteristics, such as pressure and temperature at the motive against the evaporator inlet temperature, are depicted in Figure 2. In this refrigeration system, an ejector is installed with a nozzle size of 3.6 mm. The pressure and temperature of the ejector motive change with the change of evaporator inlet temperatures such as 5, 7, 10, and 20ºC. As the evaporator's inlet temperature decreased, the ejector motive's pressure and temperature also decreased. As a result, there is no refrigerant flow, as shown in Figure 2. The motive flow rate is 0 g/sec. This phenomenon is because as the refrigerant temperature at the ejector motive and evaporator inlet decreases, the opening degree of the expansion valve and metering valve decreases, resulting in much resistance to the refrigerant flow.

Fig. 2. Variation of ejector discharge pressure and temperature according to evaporator inlet temperature

Fig. 3. Variation of the evaporator, compressor, motive, and condenser pressure according to evaporator inlet temperature
At 15 and 20°C, the refrigerant flow rate is 0.3 to 0.51 g/sec when the refrigerant passes through the generator, and heat exchanges between the hot water and refrigerant. So, the pressure discharged from the generator goes higher before entering the ejector. On the other hand, the pressure discharged from the ejector did not change significantly. This phenomenon is believed to be because of the refrigerant temperature at the ejector inlet increases. The pressure of the refrigerant discharged from the generator goes higher before entering the ejector. On the other hand, the pressure discharged from the ejector did not change significantly. This phenomenon is believed to be because of the refrigerant temperature at the ejector inlet increases. The pressure of the refrigerant discharged from the ejector is further affected by the refrigerant flow rate in the ejector. The change in ejector motive temperature due to the generator was not affected at 5°C and 7°C temperatures of the evaporator inlet. So, the ejector temperature discharged was 4.9 ºC and 7.6 ºC. However, at 15 ºC and 20 ºC evaporator temperatures, where the mass flow rate of the refrigerant at the ejector motive is 0.3 to 0.51 g/sec, the refrigerant temperature of the ejector motive was 44 ºC and 58 ºC by exchanging the heat through a generator. So, the ejector discharged temperature was 19 ºC and 21 ºC at the evaporator inlet temperature of 15ºC and 20ºC.

![Diagram](image)

Fig. 4. Variation of the refrigerant temperature of an ejector refrigeration system according to evaporator inlet temperature

Figure 3 shows the inlet pressures of a compressor, condenser, and evaporator versus the evaporator inlet temperature. The results revealed that the refrigerant pressure at the inlet of the compressor and evaporator is almost the same at 5 ºC and 7 ºC, where there is no flow at the ejector motive. However, the compressor inlet pressure is slightly higher at 15 ºC and 20 ºC. This is because of the refrigerant flow rate at the ejector motive. The inlet pressure of the condenser is higher than the inlet pressure of the compressor. It is also depicted that condenser pressure increases with evaporation inlet temperature. Nevertheless, the operation remained stable as the condenser capacity was designed to be larger than the compressor capacity. Figure 4 represents the compressor, condenser, generator, and ejector motive and discharge temperatures against the evaporator inlet temperature. There is a slight difference in ejector discharge and compressor inlet temperatures. The generator inlet temperature is the lowest among others because a metering device is used to maintain the required experimental conditions. Regarding the ejector motive, the temperature remained the same at 5 ºC and 7 ºC because of no refrigerant flow from the motive. Besides, the refrigerant temperature increased at 15 ºC and 20 ºC because of refrigerant flow at the ejector motive.

The refrigerant flow rate (g/sec), power consumption, and cooling capacity versus the evaporator inlet temperature are presented in Figure 5. As shown, there is a slight change in the capacity and power consumption at 5 ºC and 7 ºC, whereas cooling capacity and power consumption increased at 15 ºC and 20 ºC. Although, the increase in cooling capacity trend was higher than the power consumption trend. On the other hand, the ejector motive flow rate remained constant at 5 ºC and 7 ºC, while slightly increasing from 15 ºC to 20 ºC. The generator capacity and COP of an ejector refrigeration system are depicted against the evaporator inlet temperature.
inlet temperature in Figure 6. There is no change in the generator capacity at 5 °C and 7 °C; there is no flow at the ejector motive as well. Nevertheless, the generator capacity is 45.61 and 65.86W at 15 °C and 20 °C, respectively. On the other hand, in the COP of the ejector-driven refrigeration system, there is a slight increase from 5 °C to 7 °C, after slightly increasing to 15 °C after that, COP rose dramatically but remained below one on all evaporating inlet temperatures. Although, the COP of the system remained low in the experimental results. The COP can be improved by optimizing capacity and ejector nozzle size. This is one of the solutions to improve the COP.

Fig. 5. Variation cooling capacity and compressor power consumption according to evaporator inlet temperature and ejector motive flow rate

Fig. 6. Variation of generator capacity and COP according to evaporator inlet temperature
A comparative experiment was conducted on the operation and performance characteristics of the refrigeration system installed with the ejector and converging tee to confirm the ejector's effectiveness. A comparison of the ejector and converging tee discharge temperature and pressure is presented in Figure 7. As shown, the ejector discharge pressure is dominant on all temperatures 5 °C, 10 °C, 15 °C, and 20 °C. On the other hand, in terms of ejector and converging tee discharge temperatures, the ejector discharge temperature is higher on all temperatures, such as 5 °C, 10 °C, 15 °C, and 20 °C, indicating the domination of ejector-driven refrigeration systems over converging-tee-driven refrigeration system. The cause of this phenomenon is that in the converging tee, only the refrigerant is mixed inside, and in the case of the ejector, refrigerant is sucked from the evaporator outlet and mixed inside. The refrigerant temperature rises and leaves the ejector diffuser with intermediate pressure.

Fig. 7. Variation of discharge temperature and discharge pressure in an ejector and converging tee

Fig. 8. Variation of power consumption and COP in an ejector refrigeration system and converging tee
Figure 8 shows the power consumption and COP of the ejector-driven and converging tee-driven refrigeration systems according to the evaporator inlet temperature. As a result of the comparative analysis, it is found that the power consumption of the CTDRS was higher than the ejector-driven refrigeration system in all cases of temperature. This is because of the high pressure and temperature in the ejector-driven refrigeration system, causing the compressor to do less work. Regarding COP, the ejector-driven refrigeration system COP is higher than the converging tee-driven refrigeration system. For instance, at 20 °C, the converging tee-driven refrigeration system COP is 2.25, and the EDRS COP is 2.65 showing the higher COP of the ejector-driven refrigeration system. It is evident that when the ejector-driven refrigeration system power consumption is low, the COP will be higher.

4. Conclusions

A vapor compression cycle-driven refrigeration cycle integrated with an ejector and converging tee is investigated in this study. This study has two goals: to minimize power use in order to achieve energy savings which will result in cost savings and to use waste heat as a renewable energy source. Thus, a comparative analysis has been conducted to identify the results of both cycles. The ejector nozzle & converging tee diameter sizes were 3.6 mm and 12.7 mm. In terms of power consumption, the ejector refrigeration system showed less power consumption against the evaporator inlet temperature in comparison to the converging tee refrigeration system. In terms of COP, the results revealed that the ejector-driven refrigeration system COP is better than the converging tee refrigeration system COP.

Abstract

This paper presents an overview of the IEA HPT Annex 52, “Long term performance measurement of ground-source heat pump (GSHP) systems serving commercial, institutional and multi-family buildings.” Energy use intensities are a common system metric, but comingle the performance of the building envelope, occupancy effects and the system performance. The annex utilizes performance factors and a new boundary schema which facilitates characterizing the performance of different parts of the system. The annex delivered a library of quality long-term system performance measurements in the form of case studies, improved methodologies to better characterize system performance in larger buildings, and guidelines for instrumentation, uncertainty analysis, key performance indicators, data management and quality assurance. This paper focuses on performance measurements of the heat pumps, covering both internal and external approaches, instrumentation and uncertainty guidelines. Though aimed at water-source heat pumps, the annex schema and guidelines are applicable to air-source heat pumps (ASHP) and air-conditioning systems also.

1. Introduction

Field measurements of building heating and cooling system performance are rarely made but are essential to ensure that performance expectations are actually met. For GSHP systems, owners have made significant investments with expectations of high performance. Hence, it is particularly important that high performance is achieved. Though some field measurements have been reported in the literature, there is little or no consistency on how to measure the performance or how to report the results. Cost-effective measurement programs are hindered by this lack of consistency and a lack of guidance regarding measurement system design.

The four-year international collaboration project IEA HPT Annex 52 - Long-term performance monitoring of GSHP systems for commercial, institutional and multi-family buildings - was carried out by seven countries: Sweden, the USA, the UK, the Netherlands, Germany, Norway and Finland. The Annex was initiated to improve the state-of-the-art in GSHP system performance measurement, going beyond energy use intensity (EUI) measurements that comingle the performance of the building envelope, occupancy effects and the system performance. Instead, performance factors are used to characterize the system performance. As introduced by a 1948 Edison Electric Institute report [1], a performance factor (PF) is similar to a coefficient of performance (COP) except the COP is an instantaneous value and the PF covers a specified time period. Performance factors are field measured; COPs may be field measured, but most commonly COP measurements are made in a laboratory. Performance factors are commonly defined for different system boundaries (e.g. the heat pump, the heat pump & source-side circulating pump) and different time periods (e.g. daily, weekly, monthly,
seasonal). Performance factors depend on system design and operational parameters such as setpoints, part-load conditions, source- and sink temperatures. The high degree of granularity with five system boundaries aids in analysis of the system performance. The specific objectives of Annex 52 were to:

- Create a library of quality long-term measurements of GSHP system performance for commercial, institutional, and multi-family buildings served by any type of ground source (e.g. vertical boreholes in rock, pile heat exchangers in soil, open-loop groundwater wells.)
- Refine and extend current methodology to better characterize large-scale GSHP system performance and to provide a set of benchmarks for comparisons of such systems. The improved methodology will be beneficial for the IEA and will facilitate collection of more accurate and uniform statistics, and thus help in estimating, with less uncertainty, how much energy we can produce and how much CO2 emissions we can reduce with GSHP systems.
- Provide guidance for instrumentation, uncertainty calculation, key performance indicators and system boundaries that cover as many GSHP system features as possible.

Outcomes from the Annex include new boundary schema and guidelines for instrumentation, uncertainty, key performance indicators, data management, and quality assurance. In addition to the final report [2], four subtask reports [3-6] and 27 case study reports [7,8] containing 29 monitoring projects have been published, comprising more than 1000 pages in total. These reports are published on the Annex 52 webpage https://heatpumpingtechnologies.org/annex52/documents/. In addition, the Annex has so far resulted in three sets of open-source measurement data from two GSHP systems, seven published peer reviewed scientific journal papers and 14 peer reviewed conference papers.

Prior to the Annex, there have been relatively few long-term performance measurements of ground-source heat pump systems serving larger commercial buildings. Gleson and Lowe [9] reported a meta-analysis of field measurements for residential buildings in Europe in which 216 ground-source heat pumps were included, but the analysis was complicated by inconsistent boundary schemas. Spitler and Gehlin [10] reported on 55 GSHP systems serving commercial and multifamily residential buildings. Both references [9,10] noted a significant range in SPF values that cannot be explained solely by different equipment or different climatic conditions.

This paper gives an overview of the boundary schema, then focuses on methods and results for the heat pump boundary (Level 1). Measured SPF for the heat pump only are summarized for 20 systems with a total of 78 years of measurements.

2. Boundary Schema

The overall performance of a GSHP system is affected by the performance of the source side ground circuit, as well as the heat pump (HP) unit performance and the load side circuit performance, including supplementary heating and cooling. Hence, performance factors are necessarily defined for a specific set of boundaries. However, in the literature, there is little consistency in the use of system boundaries, and, in many cases, the system boundaries are not clearly defined. This makes it difficult to compare published performance factors for GSHP systems. The SEPEMO system boundary schema [11] was initially used for calculation of performance factors within Annex 52. However, the SEPEMO system boundary schema has limitations when accounting for the complexity of larger GSHP systems used in commercial, institutional, and multi-family residential buildings.

Annex 52 has sought to harmonize system boundary definitions and identify and recommend performance indicators that will allow evaluation at multiple clearly stated system boundaries. A new system boundary schema consisting of six defined boundaries and an indicator for use of supplemental heating or cooling was defined within Annex 52 [2]. It is based on the SEPEMO schema but is revised and extended, such that every SEPEMO boundary matches one of the Annex 52 boundaries (see Figure 1 and Table 1). This improves the applicability to larger and more complex GSHP systems of various types. The Annex 52 system boundary schema has been applied on all case studies within Annex 52.

3. Heat Pump Boundary (Level 1) Methods

There are two approaches for determining heat pump performance factors – the so-called external and internal approaches [12]. Further diagrams illustrating these two approaches are found in the Annex 52 instrumentation guideline [4].

3.1. External Approach

The external approach makes use of measurements that are made external to the vapor compression cycle of the ground-source heat pump:

- Power measurements of the compressor, and other devices if needed to establish performance factors at different boundaries.
- Entering and exiting temperature measurements of the secondary refrigerant or air on the load side of the heat pump.
- Mass flow measurements made of the secondary refrigerant (heat transfer fluid) or air on the load side of the heat pump.
- For measurement of cooling performance factors with water-to-air heat pumps, humidity measurements of the air entering and exiting the evaporator are also needed.
- Thermodynamic properties or thermodynamic property routines for the secondary refrigerant or air.
The cooling or heating capacity is determined calorimetrically – by multiplying the measured mass flow rate by the difference in enthalpy. For flows without phase change, the enthalpy difference would usually be estimated as the product of the specific heat and the temperature difference. Uncertainty calculations are illustrated for this method in [5].

3.2. Internal Approach

The internal approach [13] makes use of:
- Pressure and temperature measurements of the refrigerant at the compressor suction and discharge.
- Temperature measurement of the refrigerant at the condenser discharge.
- Power measurements of the compressor, and other devices if needed to establish performance factors at different boundaries.
- An estimate of the compressor heat loss.
- Thermodynamic property routines for the refrigerant.
- Temperature measurements of the entering and exiting temperatures of the condenser and evaporator on the secondary refrigerant or air side.

The pressure and temperature measurements at the compressor suction and discharge and the temperature measurement at the condenser discharge are used, with the aid of the refrigerant property routines, to determine the enthalpies at all state points in the cycle. Coupled with the compressor power measurement and the estimate of the compressor heat loss, the refrigerant mass flow rate can be determined. With this information, instantaneous values of COP, cooling capacity, heating capacity, and isentropic efficiency can be determined. By making enough time series measurements, the performance factor for the heat pump can be determined by integrating the instantaneous values of the cooling or heating provided and the electrical power input. The temperature measurements of the secondary refrigerant and/or air are used to determine 2nd law efficiencies of the individual components. This capability allows better diagnosis of internal heat pump problems, compared to the external approach. Further refinements and uncertainty analysis are discussed in references [5,12,13].

3.3. Discussion

Both approaches may be used to determine performance factors and both approaches require careful attention to propagation of uncertainties. Each approach has its own advantages and disadvantages, which may be summarized as follows:
- The internal approach uses more sensors but can provide additional information about the performance of the individual components in the heat pump. This information is very useful for diagnosing problems.
- In some systems, the secondary refrigerant may be “over-pumped”, that is, the pump has been conservatively selected and delivers high flow rates and low temperature differences. If insufficient care has been taken in specifying the sensors, the low temperature differences may lead to low accuracy with the external approach.
- The external approach does not require making connections (pressure measurements) to the refrigerant, and, so, is less invasive. On the other hand, heat pumps increasingly have more and more internal measurement points, decreasing the required additional instrumentation and connections.

As internal heat pump controls and monitoring become more sophisticated with additional sensors, it seems likely that the internal approach or a variation on it could be implemented by the manufacturer, if desired. This would further lower the cost of monitoring and fault detection and diagnosis.

4. Heat Pump Boundary (Level 1) Results

In this section, we present seasonal performance factor results based on measurements made in the Annex 52 case studies. 20 systems that provided building heating and cooling (in some cases) were monitored that could provide SPF at boundary level 1; a total of 78 years of SPFs were measured. The measured values are summarized in Table 2. With three exceptions (IKEA Uppsala, Backadalen and Rosenborg), the external method has been used for these case studies. Unfortunately, there were no case studies within Annex 52 comparing the internal and external approaches.
For heat pumps operating in heating mode, the average SPF$_{H1}$ is 3.9, whether taken as the simple average of 12 systems, or the average of 78 years of operation. For cooling operation, the average SPF$_{C1}$ is 3.9 taken as the average of 8 systems or 3.7 as the average for all years. For heat pumps that provide both heating and cooling, the combined SPF$_{HC1}$ is 3.7 as the average for 6 systems, or 3.5 taken as the average for all years.

For comparison purposes, Spitler and Gehlin [9] found an average SPF$_{H1}$ of 4.0 for 39 systems and an SPF$_{C1}$ of 5.5 for 12 systems reported in the literature.

*Estimated undisturbed ground temperatures (UGT) based on local annual mean air temperature.
One finding of multiple studies, e.g. [9,10] is, that there is no clear relationship between ground temperature, system type, or other variables and the reported SPF. Figure 2 illustrates this, showing average $SPF_{H1}$, $SPF_{C1}$ and $SPF_{HC1}$ for (1) the 20 Annex 52 case studies and (2) 55 systems reviewed in [10] versus undisturbed ground temperature (UGT) at the locations. Not all systems reported all measures; $SPF_{H1}$ is reported by 8 of the Annex 52 studies and 39 of the literature review studies; $SPF_{C1}$ is reported by 8 of the Annex 52 studies and 12 of the literature review studies. $SPF_{HC1}$ is reported by 8 of the Annex 52 studies and none of the literature review studies. All but four of the Annex 52 locations have measured UGT and the remaining values were estimated by the case study authors based on the annual mean air temperature at the locations. UGT values for the literature review cases have been estimated with a model [32-34] based on weather data.

Some of the systems in Table 2 show marked variation in year-to-year values of SPF. For some systems, these changes in SPF are connected to changes in load or equipment. The Crystal Building in London undergoes some abrupt changes in $SPF_{C1}$ due to apparent control and operation issues. In the system serving the AOV building [28] a modest decline in the ground temperatures occurs over nine years of operation, as evidenced by the heat pump entering and exiting fluid temperatures shown in Figure 3. The $SPF_{H1}$ values in Figure 4 show a corresponding decline in performance associated with the heat pump entering fluid temperatures. However, with the limited sample size, it seems year-to-year variations are more likely to be caused by other factors than changes in the ground temperatures.
The Frescati building [19] has exceptionally high SPF$_{HI}$ and SPF$_{HCl}$. The borehole system is connected to a local thermal network and operates with three parallel heat pumps of which the two larger heat pumps are frequency regulated and deliver heat at 30°C while the third heat pump is a smaller on-off regulated heat pump delivering heat at 40°C. The small heat pump has lower performance but is used less frequently than the other two heat pumps, so has little influence on the combined SPF$_{HI}$ for all three heat pumps. The system uses district heating to meet peak loads. This allows the lower supply temperature and higher performance.

The EFB building [30] is another building with very high performance at system level 1. The heat pumps are connected to a large number of energy piles below the building and provide heating via concrete core activation, with a very low distribution temperature (22°C). Significant supplementary heating is provided from a district heating system via radiators and ventilation. The heat pumps are operated in this way to cool the ground surrounding the pile heat exchangers so that free cooling can be provided in the summer. This combined with the very low distribution temperatures leads to high values of SPF$_{HI}$. The system has been monitored over 14 years and although SPF$_{HI}$ has been above 5 all the measured years, the performance has increased significantly to values around 7 in the later three years (2017-2019) after refining the operating strategy.

Apart from the 20 buildings listed in Table 2, the Emmaboda case study [35] also reported SPF for system level 1. The Emmaboda system is, however, an industrial system, originally a high-temperature borehole thermal energy storage (HT-BTES) without heat pumps, used to store waste heat from the foundry. After several years in operation, the system design and operation were altered by installing heat pumps and decreasing the average storage temperature from ~45°C to ~30°C. The system now serves as a high-temperature process cooling with very high performance at system level 1. The measured SPF$_{Cl}$ over the three measured years after the heat pumps were installed reach 13.1 on average but can’t really be compared with the performance of ordinary building heat pump systems.
5. Discussion, Conclusions and Recommendations

Some of the main findings of Annex 52 include the following:

- Annex 52 has contributed to systematization of field measurements by introducing a new boundary schema that accounts for a wide range of system features that go beyond typical residential systems.
- Annex 52 has developed guidelines for key performance indicators, instrumentation, measurement, and uncertainty analysis. These guidelines will allow better planning of field measurements at lower costs and facilitate fault detection/diagnosis and optimization of system design and operation.
- While field measurements of ground-source heat pump system performance factors are still relatively rare and uncertainty analysis of performance measurements is even rarer, the Annex has contributed a significant increase in the number of published field measurements of larger GSHP systems. The Annex sought to collect data for benchmarking, but this is only provided to a limited degree. Most of the systems are located in northern Europe. Further studies covering a larger geographic area would be welcome.
- This paper has only presented SPF for the heat pumps, but the Annex is much broader, covering SPF for a range of boundaries. A general trend is that SPF decreases as the boundary is extended to include the source-side distribution system and some or all of the load-side distribution system. In fact, even systems with “free cooling” via use of ground loop fluid to provide cooling may have SPFC that is not markedly different from GSHP systems that use the heat pump to provide cooling. It should also be noted that, though often ignored, the energy used by distribution systems is not unique to GSHP systems or ASHP systems. Field measurements of energy at all boundaries used by other competing heating and cooling systems would be a welcome contribution to the field, as this would shed light on the need for increased efficiency in heating and cooling distribution systems.
- System SPFs at all boundary levels are highly variable from system to system, with, for the most part, no clear relationship between SPF and other factors. This was illustrated in this paper for the heat pumps, but similar disparities were found at other boundary levels.
- A number of the case studies found that short-term performance factors (e.g. hourly and daily) were generally higher during periods of higher load, even though source temperatures were less favorable.

With regards to seasonal performance of the heat pumps:

- The measured system average heat pump SPFs (Level 1) presented in this paper range between 2.2-4.9 for SPF_{HC1}, 2.5-6.2 for SPF_{H1}, and 2.2-5.2 for SPF_{C1}, with overall average values for all systems being 3.9 for SPF_{HC1}, 3.9 for SPF_{H1}, and 3.7 for SPF_{C1}. These are in line with results from systems previously reported in the literature.
- Two systems with very high SPF_{H1} had significant supplementary heating and were designed so that the heat pumps used a very low distribution temperature allowing excellent heat pump performance.

The Internet of Things (IoT) is rapidly developing. Many of the measurements needed to calculate seasonal and other performance factors are already internally measured within currently available heat pumps, though this information is often not available to end users. It seems likely to us that making this information available and lowering the cost of field measurement combined with a higher degree of automated evaluation would lead to wider use of field measurements and much better understanding of real-world performance. This in turn will lead to improved system performance and a higher degree of renewable energy in our heating and cooling systems. Finally, we note that though the focus of the annex and this paper is ground-source heat pump systems, much of the work on field measurements can be and should be directly applied to air-source heat pump systems and air-conditioning systems also.

Abstract

Heat pumps are the key technology to defossilize the heat supply of buildings, which for now is predominantly based on burning fossil fuels. In Germany, 19 Million residential buildings consume about 865 TWh of fossil fuels and emit about 120 Million tons of CO\textsubscript{2} each year, mainly for heating purposes. Reducing GHG emissions is critical to achieving climate goals, and replacing combustion-based heating technologies is crucial to GHG mitigation. To recommend appropriate alternative technologies and accelerate the corresponding deployment, there are standardized indicators for heat pumps in each sustainability dimension: For instance, economic and environmental aspects can be represented by energy labels, while social aspects (e.g., acoustics) are currently not in focus. In particular, from an environmental point of view, the focus is on labeling emissions due to the refrigerants’ Global Warming Potential (GWP) and operating-related emissions. However, the focus on GHG emissions bears the risk of unnoticed burden shifting to other environmental impacts, such as ecotoxicity or land use. To avoid burden shifting, a holistic assessment of heat pumps and refrigerants using life cycle assessment (LCA) is necessary.

This work investigates the environmental assessment metrics beyond climate change and applies them to heat pumps and refrigerants in existing buildings in Germany. To evaluate essential assessment metrics simultaneously, a fundamental data basis is prepared through an extensive literature and database review. While there is scientific consensus on the fundamental understanding of heat pumps and refrigerants, some assumptions still need to be made to obtain meaningful results. Therefore, a key finding of this work is that further research is mandatory. In addition, we identify the main contributors to improving the environmental impacts of heat pumps and refrigerants using LCA: For low GWP refrigerants in heat pumps, the refrigerant choice is less important in terms of environmental aspects, here resource availability (flour range) and proper handling (avoidance of leakage) are essential. Currently, emissions from electricity generation dominate the environmental impacts of heating with heat pumps. Using renewable electricity instead will lead to some burden shifting but reduce most environmental impacts so that the production of heat pumps and refrigerants gains importance for further impact reduction. For future research, consider potential improvements in the supply chains of materials and refrigerants using dynamic LCA.

1. Introduction

To adjust to comfortable indoor conditions, heating and cooling are crucial in the building sector. Particularly during the heating season, the building sector throughout Europe requires enormous energy to meet its heating demands. Currently, most residential heating systems are based on conventional combustion

* Corresponding author. E-mail address: cvering@eonerc.rwth-aachen.de
technologies, which cause greenhouse gas (GHG) emissions during operation, mainly in the form of CO₂. However, GHG emissions must be drastically reduced by 2050 to achieve climate targets. In this context, the transition to low-carbon heating systems is taking place with increasing acceleration replacing conventional with heat pump-based systems. Heat pumps use refrigerants to upgrade environmental heat and provide suitable heat for buildings. The upgrading requires an additional energy supply to raise the temperature level of environmental heat. In building applications, the energy supply powers an electricity-driven compressor with refrigerant-dependent efficiency. Therefore, the overall heat pump performance and emission reduction potential depend mainly on the refrigerant and the refrigerant-dependent compressor efficiency. In the past, heat pumps used refrigerants (Hydrochlorofluorocarbons, HCFC) that were very efficient and simultaneously neither flammable nor toxic. These favorable properties were achieved using fluorine (F) and chlorine (C) atoms in the hydrocarbon chains of the refrigerant. However, in the event of a leak, chlorine was released into the atmosphere, contributing to ozone depletion. Therefore, refrigerants with ozone depletion potential (ODP) were largely banned. [1]

The ban has led to the developing of new refrigerants that are also efficient and safe but do not require a chlorine atom to make a stable molecule. This group of refrigerants is called hydrofluorocarbons (HFCs), which consist of hydrocarbons and fluorine. However, many HFCs have high global warming potential (GWP) due to the fluorine atoms. Therefore, in the event of leakage, HFCs would contribute to global warming and climate change. Therefore, HFCs should also be used less or even completely banned in heat pumps to comply with long-term climate targets to reduce this risk. According to current research, the most superior alternatives for the future are natural refrigerants such as hydrocarbons (HCs) or other organic refrigerants such as ammonia or CO₂ and hydrofluorolefines (HFOs). These refrigerant groups have no ODP and a low GWP (<150), thus potentially not compromising climate goals. However, future refrigerants must also be very efficient to achieve a high performance of heat pumps and, accordingly, low GHG emissions. [2]

To extend the environmental assessment of refrigerants to heat pumps, the (extended) Total Equivalent Warming Impact (eTEWI) [3], [4] or Lifecycle Climate Performance (LCCP) [5] evaluation methods are often used in the current literature. Both methods focus on evaluating the climate change impact of refrigerants and heat pumps' operation, i.e., the electricity consumption of the compressor. However, in the future, regenerative energy sources can reduce the climate impact of the operation, potentially shifting the impact to other life cycle stages, e.g., emissions from the production of heat pumps, or increase other environmental impacts, which is called burden shifting. To avoid burden shifting, more advanced environmental assessment methods must be applied, which consider further impact categories. For example, in addition to operation, the heat pump's production, disposal, and recycling will gain importance. However, the influence of these phases is insufficiently considered in current methods. Therefore, Life Cycle Assessment (LCA) [6] is needed to consider all phases and impacts adequately. Moreover, in the early design stages, LCA will already help identify potential environmentally friendly refrigerants that have less impact on the environment than conventional refrigerant groups.

Compared to conventional eTEWI and LCCP, this work investigates the environmental assessment metrics beyond climate change by using LCA and applies them consistently to heat pumps and refrigerants in existing buildings in Germany. An LCA model is formulated to evaluate essential assessment metrics simultaneously (Section 2), and an extensive literature and database review provide relevant information and assumptions. As a case study (Section 3), we use seven refrigerants in a simple heat pump cycle and assess 16 environmental impact categories. For discussion (Section 4), we apply different electricity mixes and compare our results to a conventional gas boiler system. Finally, we summarize our findings and give a perspective for future work (Section 5).

2. LCA Modelling

This section addresses the Goal and Scope definition (Section 2.1) of this study, the Life Cycle Inventory (LCI, Section 2.2), and the data sources (Section 2.3).

2.1. Goal and Scope Definition

The LCA serves for the environmental evaluation of heat pumps and refrigerants in residential buildings in Germany. The LCA aims to investigate the influence of the refrigerant on the GHG emissions caused within the life cycle of a heat pump. In addition, trade-offs with other environmental categories will be considered, and levers to reduce the overall environmental impact will be identified.
This work investigates the life cycle of a simple air-to-water heat pump according to Figure 1. While the production of refrigerants and heat pumps and the operation of the heat pumps are in the foreground of the investigations (red), additional aspects (black) must also be modeled to develop reasonable conclusions. The function of the air-to-water heat pump is to provide space heating over an observation period of 20 years, matching the heat pump's lifetime [7]. This paper does not consider other parts of the building energy system, such as the distribution system, the buffer tanks, or the building envelope, as this work is intended to provide a basis. However, these other parts of the building energy system should be integrated into future work. The functional unit in the LCA is the provision of space heating for a German residential building over the heat pump’s life cycle (20 years). The system boundaries include the production of refrigerant and heat pump, the operation of the heat pump, any leakage of refrigerant, and upstream processes, e.g., materials and energy. In contrast to the LCCP method, the recycling of heat pump and refrigerant is not included in the system boundaries, as there are no sufficient data sets for the environmental impacts of the recycling processes.

Figure 1: Life cycle of an air-water heat pump and assumed system boundaries.

This study follows the ILCD (International Life Cycle Data system) recommendations to characterize elementary flows to environmental impacts, comprising 16 environmental impact categories, e.g., climate change, acidification, and ozone depletion [8], [9]. All 16 categories are assessed, while the focus lies on climate change.

2.2. Life Cycle Inventory

To conduct the LCA, we need a sound basis comprising the assumptions within the calculation procedure. Table 1 sums up all assumptions depending on the refrigerant. To exchange the conventional refrigerant R410A, we investigate six potential refrigerants with lower GWP than 1000 and no ODP from four substance groups: R1234yf (HFO), R32 (HFC), R290, R1270, and R600a (HC), and R717 (Anorganic). Except for R717 (safety class B), all refrigerants are assigned to safety class A. However, all potential refrigerants are at least low flammable (2L and higher). Thus, if one of these six refrigerants prevails in the long term, increased safety requirements will be imposed on heat pumps. To assess the environmental impacts concerning the entire life cycle, we need additional information about the production (refrigerant and heat pump), the heat pump operation, and refrigerant leakage during the heat pump operation and end-of-life (EOL).

Table 1: Main assumptions to model the life cycle of an air-water-heat pump. Most of the assumptions are independent of the refrigerant choice, while some are influenced by the refrigerant.

### 2.2.1. Refrigerant Production

While potential environmental impacts are known and available in ecoinvent [10] for producing natural refrigerants R290, R1270, R600a, and R717, few primary sources exist for the refrigerants R410A, R32, and R1234yf, which generally consider only GHG emissions. Therefore, for R410A and R32 production, data sets from Frischknecht et al. are used [11], [12]. Frischknecht models the production of refrigerants using chemical reaction equations with additional assumptions about the energy required, recovery, chemical leakage, and the production route. Data sets from Baral et al. are used for R1234yf production [13]. Baral et al. study the GHG emissions from the production of R1234yf using the CHEMCAD simulation tool. The reported production process starts with the reactants chlorotrifluoroethylene and chloromethane. Moreover, leakages of chemicals, reactants, or intermediates can occur during refrigerant production. In particular, the leaking of substances with high GWP or ODP can account for a large portion of the total environmental impact of production and thus have to be modeled for a holistic assessment. As a first estimate, an emission rate of one mass percent is assumed, made up of the reactants and intermediates.

The required charge in the heat pump depends on the refrigerant considered and determines the amount of refrigerant that needs to be produced. Commercial heat pumps for residential buildings exist for the three refrigerants R410A, R32, and R290 so that data sheets can be accessed. The data sheets approximate the specific charge for R410A, R32, and R290. The specific charge of the remaining refrigerants is estimated using the UNEP report published in 2014 [14]. In addition to the amount of refrigerant required for operation, we consider the heat pump production and refrigerant leakage that may occur during operation. The leakage reduces the heat pump's charge, so refilling the system becomes necessary to ensure its efficiency.

### 2.2.2. Heat Pump Production

The mass composition of the heat pump under study is based on a 10 kW brine-to-water heat pump from Hoval, operated with R134a. In Heck et al. [15], the masses and compositions of the individual components are reported. The mass composition of a heat pump will vary depending on the production company and the choice of components used. Since no known mass compositions of heat pumps operating with the refrigerants studied, the mass composition is used for all refrigerants studied except R717 (Figure 2).
R717 attacks copper and copper alloys, so copper for piping and heat exchangers is not currently approved. Since no sources on mass composition and weight of R717 small heat pumps are known, any other system technology is neglected below, and the mass fraction of copper is replaced by low-alloy steel. These material compositions can be scaled to the heating power of the heating system under study using specific gravity, i.e., the total weight per heating power.

The specific gravity of the heat pump depends on the design of the heat pump and the refrigerant used. The volumetric heating capacity (VHC) influences the required installation space as well as the size of the heat pump. In addition, the required wall thicknesses of the tubes depend on the maximum operating pressures of the heat pumps, which are determined by the refrigerant used. Examining data sheets of commercial heat pumps results in a specific weight of 15 kg/kW for heat pumps operating with R32 and R410A and a specific weight of 20 kg/kW for heat pumps operating with R290. Differences could not be attributed to the refrigerant and thus might result from design choices by the manufacturers. To the author's knowledge, no publication exists that examines the refrigerant's influence on the heat pump's weight in isolation from other influencing factors. Therefore, the same specific weight of 18 kg/kW is assumed for all refrigerants, as it is the average of the reported specific weight based on manufacturer data. In addition to the environmental impacts from material production, we consider the heat pump's assembly and the subcomponents' manufacture using the generic ecoinvent data set for metalworking.

2.2.3. Refrigerant Leakage

Leakage to the atmosphere results in different environmental effects depending on the refrigerant. As described in Section 1, the use of CFCs was regulated by the Montreal Protocol in 1989 because leakage of CFCs depletes the ozone layer. While the refrigerants studied in this work do not have ODP as a measured characteristic, i.e., do not cause ozone layer depletion when released, refrigerant leakage may contribute to the heat pump's total impact in other environmental categories. This work assumes a leakage rate $L_{\text{Use}}$ of 5% per year in operation and a leakage rate $L_{\text{EOL}}$ of 30% at the end of life (EOL) [16], [17]. Although leakage of refrigerants has no direct impact on ozone layer depletion, during the production of some of the refrigerants, leakage of intermediates (see 2.2.1.) can cause ozone layer depletion, which we attribute to refrigerant manufacturing.

2.2.4. Heat Pump Operation

Since a large share of the emissions is related to indirect emissions from electricity consumption, it is critical to consistently model the energy demand of the buildings and the corresponding heat pump operation. The heat pump operation is driven by the building's heat demand, which is determined via TEASER [18]. TEASER is a framework for data enrichment of building performance simulation models to simplify simulating the heat demand of buildings, neighborhoods, and city districts. Based on the location, building type, building area, year of construction, and modernization standard, TEASER approximates the building's envelope area and insulation standard. In this paper, a two-story single-family house in Aachen is considered. The building has a living area of 150 m$^2$ and an insulation standard according to the 2nd Thermal Insulation Ordinance of 1984.

As the building model’s boundary condition serves a weather data set (Test Reference Year (TRY), 2015) representing an hourly resolved annual temperature profile. The TRY data set used represents Aachen to match the building location and was published by the German Weather Service. In general, TRY data sets exist for each square kilometer in Germany. Thus, spatially-resolved temperature profiles can be used in further studies to exploit the change of environmental impacts depending on the location.

TEASER enriches a parameterized building performance simulation model with data sets and a weather data set to create a simulation model. Then, the energetic performance is calculated based on the heat demand, which is required to balance heat losses to the environment while maintaining an indoor air set temperature,
which is 21 °C in our case study (cf. Figure 3). In total, the annual heat demand of the considered building is about 20,400 kWh with a maximum heat load $Q_{\text{max}}$ of 7.5 kW.

To meet the building’s heating demand based on the outdoor air temperature, a heating system is required. We use an air-to-water heat pump model to provide heat that meets the hourly resolved demand. Outdoor air temperature and heating demand serve as the boundary condition for the calculation procedure. The nominal flow temperature is calculated using a conventional heating curve. The heat pump model includes a fluid dependency and calculates the fluid behavior in a basic refrigeration cycle, according to Figure 4. The model is used from Hoeges et al. and covers fluid dependence with a validated loss-based compressor model.

Based on the boundary conditions, the heat pump model optimizes the pressure levels in the evaporator and the condenser. In addition, the degree of subcooling at the condenser outlet and the degree of superheating at the compressor inlet is maximized for each operating point subject to maximum Coefficient of Performance (COP). For more details on the heat pump model we refer to Hoeges et al. [2]. Using the heat pump model, the heat demand profile, and the outdoor air temperature profile, the required electrical power for space heating is determined for each refrigerant.

2.3. Data Sources and Calculation of Environmental Impacts

This work uses the LCA database ecoinvent [10] to obtain the environmental impacts of material and energy used for the production of refrigerants, the construction and operation of heat pumps. (cf. Table 1). The ecoinvent datasets already contain the characterization models and, thus, the environmental impacts of each material or energy flow needed in this study. When using the ecoinvent datasets, the environmental impacts must be scaled by the amount of material or energy flow necessary to supply the functional unit. The characterization factors for elementary flows representing refrigerants are used to estimate the impact of refrigerant leakage. The characterization factors indicate the extent to which the refrigerant leakage contributes to an impact category.
3. Life Cycle Impact Assessment

In this section, we provide the general Life Cycle Impact Assessment and conduct a sensitivity study with respect to the grid mix.

3.1. General Assessment

The electricity demand from heat pump operation accounts for the largest share of the total environmental impacts in most categories (orange, Figure 5). The only exception is ozone depletion of fluorine-containing refrigerants due to leakage of intermediates during the refrigerant production. In all other categories, refrigerant production is negligible, and heat pump production is the second largest contributor to environmental impacts. In particular, heat pump production results in significant environmental impacts in ecotoxicity, human toxicity, and resource consumption for all refrigerants except the R717 due to not involving copper (see Section 2.2.2).

![Figure 5: Environmental impacts of a heat pump for each environmental category and each refrigerant (normalized to R410A). Considered is heat supply over 20 years using the German electricity mix (2018) (521 gCO₂/kWh). The shares of the individual phases are color-coded.](image)

Refrigerant leakage during the operation (red) is the smallest contributor and depends on the refrigerant and the environmental category: The high-GWP refrigerants R410A and R32 lead to an increase in GHG emissions and leakage of the toxic refrigerant R717 leads to minor environmental impacts, in particulate matter formation, acidification, and terrestrial eutrophication.

Across all refrigerants, R717 causes the lowest environmental impacts in all categories due to the high efficiencies. Due to the high SCOP that can be achieved with R717, the electricity required to operate the heat pump is lower, resulting in lower environmental impacts. In addition, the production of the R717 heat pump causes lower environmental impacts. Since the environmental impacts are lowest for a heat pump with R717, the refrigerant R717 is recommended in the context of a purely environmental evaluation. After R717, the environmental impacts are lowest for the hydrocarbons R290 and R1270. The use of R290 and R1270 allows high efficiencies and thus lower environmental impacts due to electricity demand than the HFOs and R600a. The next efficient refrigerant is R32. A disadvantage is the high GWP, so the leakage of R32 significantly
increases GHG emissions. Using R600a and R1234yf causes high environmental impacts due to the lower efficiencies. The highest environmental impacts in all environmental categories are caused by using R410A with the lowest efficiency. Moreover, R410A leakage significantly increases GHG emissions. The production of R410A also causes the highest environmental impacts in the ozone depletion category. Since the electricity demand and the grid mix have the highest influence on all environmental impacts, we analyze its sensitivity.

3.2. Influence of Grid Mix

The environmental impacts of the heat pump (Figure 5) were calculated assuming the German electricity mix from 2018 (GE) for the heat pump’s entire lifetime. However, the share of renewable energies in electricity production is forecast to increase while the share of fossil fuels is forecast to decrease. Thus, in the following, we assume a dynamic electricity mix (GE-to-SDS) that changes over the heat pump’s lifetime to account for the influence of possible decarbonization. We assume a linear progression between the German electricity mix from 2018 and the European electricity mix from the Sustainable Development Scenario (SDS) of the International Energy Agency (IEA) for 2040 [19]. The Sustainable Development Scenario models the measures needed to achieve the goals of the Paris Climate Agreement. The resulting environmental impacts of the heat pump considering the GE-to-SDS electricity mix (Figure 6).

The environmental impacts of the heat pump decrease in most environmental categories due to a higher share of renewable energy sources and nuclear energy compared to the German electricity mix. Only ionizing radiation and water demand increase due to the higher proportion of nuclear and hydro energy in the SDS electricity mix. Not only do the environmental impacts in most environmental categories decrease due to the change in the electricity mix, but the ranking of refrigerants is also affected. For example, for the static German electricity mix, the R32 heat pump produces lower GHG emissions than the heat pumps of the low-GWP refrigerants R1234yf and R600a due to good efficiency despite leakage (see Figure 6). For the GE-to-SDS electricity mix, this statement is no longer valid, as GHG emissions are higher for the use of R32.

Furthermore, changing the electricity mix does not affect the environmental impacts from production of heat pump and refrigerant, even though these phases require electricity. This is because the production is based
on aggregated datasets from ecoinvent, which does not directly allow to exchange the electricity mix, e.g., for the upstream copper production. The refrigerant leakage is also unaffected since no electricity is involved.

4. Discussion

To evaluate whether changing from a gas condensing heating system to an air-to-water heat pump increases or decreases the environmental impact we show a list of all impact categories and different grid mixes in Table 2. A heat pump with R410A refrigerant is used for the comparison to conservatively assess potential GHG environmental impacts in one or more impact categories when the heat pump performs in an environmental comparison with a gas condensing heating system. The SCOP of 3.1 used comes from the research project WPSmart in the inventory of Fraunhofer ISE. The gas condensing heating system is modeled using an ecoinvent dataset. Table 2 shows that the heat pump’s potential to reduce environmental impacts depends on the electricity mix and the impact category. If the heat pump would use the current German electricity mix (GE) throughout its entire life cycle, GHG emissions decrease by 30% compared to the gas condensing system.

Further reductions are expected in ozone depletion, photochemical ozone formation and energy resources. All other environmental categories increase significantly. The GE-to-SDS electricity mix approximates the electricity mix of a heat pump installed in 2020 that has a 20-year lifetime. In the GE-to-SDS electricity mix, the environmental categories increase or decrease in the same environmental categories. In the climate change categories, the changing electricity mix achieves a higher reduction in GHG emissions (-54%). Further significant savings are also possible in the ozone depletion, and energy resources. In the remaining environmental categories, except for ionizing radiation and water consumption, the environmental impacts decrease less for the GE-to-SDS electricity mix than for the GE electricity mix.

While the environmental impacts of switching to a heat pump with the GE-to-SDS electricity mix can only be reduced in 4 out of 16 environmental categories, the number increases to 9 out of 16 for the static SDS electricity mix. Using the SDS electricity mix, a heat pump reduces GHG emissions by 79% down to one-fifth of the GHG emissions that would be caused by providing space heating through gas heating. By switching to the SDS electricity mix, the environmental impacts of a heat pump can be significantly reduced compared to the GE electricity mix in all environmental categories except ionizing radiation and water consumption. Furthermore, the less environmental impact caused by the generation of the purchased electricity, the better the air-to-water heat pump performs in an environmental comparison with a gas condensing boiler. In addition to the three electricity mixes, the comparison between gas heating and heat pumps is listed for electricity supply by wind power and photovoltaic (PV) technologies. The data sets for both technologies come from ecoinvent [10]. The use of wind power can reduce GHG emissions by 89%, and environmental impacts are reduced in 11 of 16 environmental categories. With the use of PV, a reduction of 81% is possible, or in 8 of 16 environmental categories.

To summarize, in the categories of climate change, ozone depletion, photochemical ozone formation, and energy resource consumption, environmental impacts can be reduced for all five electricity mixes. However, in the categories of eutrophication, freshwater, and human toxicity, the environmental impacts of carcinogenic, resource consumption, and water consumption increase when switching to a heat pump for all five electricity mixes. The environmental impacts cannot be reduced in all environmental categories, even if renewable energy sources, wind power, and photovoltaics provide electricity.

When switching from a gas condensing heating system to a heat pump, burden-shifting always occurs. Burden shifting describes the increase of environmental impacts in one or more impact categories when reducing environmental impacts in another category. For example, when switching from a gas condensing heating system to an air-to-water heat pump, GHG emissions can be saved, while environmental impacts increase in other environmental categories.

The extent to which burden-shifting is acceptable depends on the environmental categories affected. Reducing GHG emissions is currently a high priority, so burden-shifting could be acceptable. The Planetary Boundary framework provides an initial guide for assessing whether burden-shifting compromises the overall sustainability. Planetary Boundaries are boundaries in nine categories, the crossing of which threatens the stability of the Earth’s ecosystem. Climate change is one of the nine categories. Other categories address the biogeochemical cycles of nitrogen and phosphorus, freshwater use, and land use. However, an exact mapping between the EF environmental categories used in this study and the Planetary Boundaries is only partially possible. Five of the nine boundaries have already been transgressed so that burden-shifting to these categories should be avoided. These categories among others include climate change, land-system change (similar to land...
use), and the biogeochemical cycles of nitrogen and phosphorus (similar to eutrophication), which are also addressed in the EF environmental categories.

Table 2: Changes of the environmental impact when switching from a gas condensing heating system to an air-to-water heat pump depending on the electricity mix. The gas heating system is used as a reference. (R410A, n = 20 a, SCOP = 3.1)

</table>

Burden-shifting occurs in land use and eutrophication when switching from a gas condensing heating system to a heat pump. However, further assessment is needed to determine the magnitude of the burden-shift compared to the boundary value. If the shift is low enough, other sectors might be able to efficiently reduce impacts in these two categories and compensate for the burden-shift from switching to heat pumps, for the cause of overall GHG mitigation without pressuring already transgressed planetary boundaries. Ultimately, all sectors in sum need to comply with the planetary boundaries to be sustainable and the strength of heat pumps lies in comparably energy-efficient GHG mitigation [20].

Another criterion besides the immediate environmental impacts that influence the refrigerant selection is the F-Gas regulation [21]. The F-Gas regulation restricts the distribution of high-GWP refrigerants containing fluorine. This restriction can negatively affect the supply and price of refrigerants such as R410A and R32. Another aspect that has to be considered is the degradation of refrigerants in the atmosphere. The refrigerant R1234yf degrades to TFA within a few weeks [22]. TFA belongs to the group of PFAS chemicals that have been reported to be carcinogenic. Therefore, there are efforts to ban the distribution of PFAS chemicals [23] in the next years which in turn could restrict the option of using R1234yf.

These two criteria are among many that further restrict the possible choice of refrigerants for heat pump applications. In summary, achieving overall sustainable domestic heating will comprise environmental, social, and economic aspects, such as health and refrigerant price.

5. Conclusion

This work performs a life cycle analysis (LCA) for air-to-water heat pumps for use in German residential buildings. Particular focus is put on the influence of refrigerants, which can potentially be used in heat pumps. The refrigerants investigated are the hydrofluorocarbons R410A and R32, the hydrofluoroolefin R1234yf, the
hydrocarbons R290, R1270, and R600a, and the inorganic refrigerant R717. The LCA results can be used to estimate which of these refrigerants leads to the lowest environmental impact over the entire life cycle and should be used in heat pumps for residential buildings.

The LCA is divided into four steps according to DIN EN ISO 14040. First, the objective and the scope of the LCA are defined. Then, the life cycle of the heat pump is modeled, consisting of the production and operation of the heat pump and the production and leakage of the refrigerant. Based on these four life cycle phases, a heat pump's environmental impacts are estimated in 16 environmental categories recommended by the ILCD. The LCA results show that the largest share of environmental impacts in the life cycle is due to electricity demand. Therefore, the lowest environmental impacts are achieved by using refrigerants that enable high heat pump efficiency and reduce the required electricity demand. These include R717, R290, and R1270. In contrast, using R410A, R1234yf, and R600a result in the highest environmental impacts, as only low efficiencies are achieved through these refrigerants. Other phases of the life cycle have only a secondary impact. Sensitivity analyses confirm the high significance of the electricity demand for the total environmental impact also until mid-century. Simultaneously, impacts from production become more important with increasingly renewable electricity generation.

One possibility to reduce the environmental impacts due to electricity demand is to increase the efficiency of the heat pump which reduces the electricity demand. A second possibility is reducing the specific environmental impacts of electricity generation by using more renewable energy sources. The expected increase of renewable energy sources in the German electricity mix would decrease the environmental impacts of a heat pump significantly. Therefore, the current electricity mix should not be used for the environmental assessment of a newly installed heat pump. Instead, a possible change in the electricity mix during the heat pump's lifetime should be considered.

Based on the results of the LCA and other selection criteria, such as the F-Gas regulation, a recommendation for action is made, and the use of R290 in residential heat pumps is recommended. The use of R290 leads to low environmental impacts due to its high achievable efficiency. In addition, R290 is non-toxic, has a low GWP, and is already used in heat pumps for residential buildings. The disadvantage of R290 is its high flammability and classification in safety class A3. In addition, DIN EN 378 [3] restricts possible installation sites for R290 heat pumps. If R290 is not possible, alternative refrigerants must be used.

With the environmental impacts of a heat pump determined, an ecological comparison is then made between a heat pump and a gas condensing boiler. As mentioned before, the efficiency of the heat pump and the origin of the purchased electricity significantly influence the environmental impact of a heat pump and, thus, also the ecological comparison. For example, with a SCOP = 3.1 and a predicted increase in the share of renewable energies in the German electricity mix, a heat pump decreases greenhouse gas emissions over the entire life cycle by 54% compared to a gas condensing boiler. However, the environmental impacts can only be reduced in 4 of the 16 environmental categories investigated; in the remaining 12 environmental categories, a heat pump causes higher environmental impacts than gas condensing heating. Therefore, reducing greenhouse gas emissions is achieved by shifting the environmental impact to other categories, i.e., burden shifting. By increasing the heat pump's efficiency, the environmental impacts can be further reduced, but burden-shifting can still not be avoided. Thus, further research has to assess the relevance of the identified burden-shifting, while either way heat pumps offer an opportunity for significant greenhouse gas mitigation.

Abstract
Phase change material heat exchangers (PCM-HX) can be used as a latent heat thermal energy storage (LHTES) component in heat pump applications to further enhance the efficiency of a heat pump as well as to yield financial savings by peak-load shifting. In this paper, a low-cost commercially available aluminum serpentine heat exchanger with louvered fins was experimentally investigated to check its thermal performance as a PCM-HX. A transparent rectangular box fabricated from acrylic plates served as a PCM container. Two cameras were used to capture the phase change process of the PCM on the front and top sides of the container during the experiment. A total of 88 installed temperature sensors throughout the test setup and a mass flow meter enabled a quantitative analysis of the PCM-HX as well. The energy balance deviation between the estimated theoretical and experimentally calculated PCM storage was ±14% considering the often-neglected heat loss and thermal mass of the PCM-HX. PCM temperature profiles, charge and discharge rates, and energy densities under different test conditions were also investigated.

Keywords: Phase change material; Serpentine; Thermal energy storage; RT35HC; Experimental investigation; Louvered fins;

1. Introduction

The demands for energy-efficient heat pump technology have been steadily increasing worldwide with the goal of decreasing carbon footprints. A latent heat thermal energy storage (LHTES) integration into heat pump systems can potentially help shave the peak load demand of the residential and commercial energy sectors while using off-peak electricity, ultimately realizing both financial and energy savings. Phase change material heat exchangers (PCM-HXs) can be excellent candidates for LHTES as they can utilize the latent heat during the charging and discharging processes. When integrating LHTES into heat pump systems, heat exchanger should be designed to overcome the challenge of low thermal conductivities of PCMs. Hence, it is essential to explore different heat exchanger configuration options and expand the list of high-potential candidates that are economical and easy to implement [1]. In this paper, a commercially available serpentine tube heat exchanger with louvered fins was experimentally investigated as the first-order analysis revealed that this type of heat exchanger has a very competitive compactness and a material utilization value as compared to the other commercially available configurations such as crimped fin, wire fin, and spine fin heat exchangers. A comprehensive thermal performance analysis including PCM temperature profiles, charge/discharge rates, energy densities, and energy balance of the PCM-HX under different operating conditions are presented in this study. Often-neglected visual observation and heat loss and thermal mass calculations were experimentally

considered in the study for more of an in-depth analysis as well as to capture the practical side of the experiments. There are a number of existing literature for experimental investigations of compact PCM-HXs [1]–[4]. However, the experimental study regarding the selected heat exchanger configuration in this paper is scarce. Therefore, this study will provide one of the initial experimental data for this heat exchanger configuration when used as a PCM-HX.

2. Experimental Setup

2.1. PCM properties

RT35HC from Rubitherm [5] was chosen as a PCM for the experiments as it is known to be stable in terms of cyclic durability and has a relatively high heat storage capacity (HSC) for an organic-based PCM. Its nominal phase change temperature, thermal conductivity, specific heat, and volume expansion ratio are around 35 °C, 0.2 W/m-K, 2 kJ/kg, and 12.5%, respectively. Choosing a specific PCM with an actual hot storage applicable phase change temperature was not the main concern for this study as the main focus was to assess the thermal performance of the heat exchanger configuration itself. This statement can be further supported by the PCM heat sink topology optimization results from Ho et al. [6] where the optimization runs with PCMs with different melting temperatures yielded nearly identical optimized designs for conduction-dominated cases. Hence, the use of RT35HC in this study can be justified because if the heat exchanger showed a good performance with certain PCM, it would also show a good performance with other PCMs with different melting/solidification points for conduction-dominated cases. The original equipment manufacturer (OEM) claims that the nominal HSC within the selected temperature range is 240 kJ/kg with ±7.5% accuracy. It is important to mention that a separate differential scanning calorimetry (DSC) test was conducted to have additional reference to the enthalpy information of the PCM. The HSC values from the DSC results with a 5 °C/min heat rate yielded 180.6 kJ/kg and 203.7 kJ/kg for melting and solidification, respectively. Lastly, the total amount of PCM mass that was charged into the PCM-HX container was 3.979 kg.

2.2. PCM-to-HTF (Heat Transfer Fluid) Test Facility

An in-house test facility was used to conduct PCM-to-HTF experiments. As shown in Fig. 1, the test facility was placed inside the temperature- and humidity-controlled environmental chamber for reliable test conditions. The facility consists of main components such as Coriolis mass flow meter, gear pump, resistance heater, air-to-HTF heat exchanger with a fan, and the PCM-HX test section. T-type thermocouples and resistance temperature detectors (RTD) were installed for PCM and HTF-side temperature measurements. For HTF, deionized water was chosen for this study. The National Instruments (NI)’s data acquisition (DAQ) system together with the LabVIEW software was used for controls and data collection. It is worth mentioning the test facility could function bi-directionally using the 3-way valve and ball valves depending on the orientation of the PCM-HX. However, only one HTF direction was investigated in this study since the PCM-HX was oriented horizontally. For melting experiments, heater proportional-integral-derivative (PID) control was used to stabilize the inlet temperature of the HTF, while the air-to-HTF heat exchanger with a fan was used to control the HTF inlet temperature during the solidification experiments. The mass flow rate (MFR) was controlled by the PID control using the Coriolis mass flow meter and the pump driver during both experiments.
Sub-components such as the orifice-type turbulator inserts, 3D printed RTD guides with multi-cord grips, and 90° elbows were installed near the PCM-HX’s inlet and outlet side for accurate HTF-side temperature measurement. The elbows and turbulator inserts allow the HTF to be well-mixed before the measurement points whereas the RTD guides prevent the RTD end tips from touching the tube wall and keep them concentric. Hence, the systematic uncertainties of the HTF side measurement could be minimized even with flows in a laminar regime.

2.3. Serpentine Heat Exchanger and Thermocouple Positions

A commercially available serpentine tube heat exchanger was selected as a PCM-HX candidate. A single-path serpentine tube heat exchanger consisted of 21 individual rectangular channels. The detailed dimensions and its configuration are shown in Fig. 2 – (a).
In total, 78 T-type calibrated thermocouples with ±0.5 K absolute uncertainty were installed in and around the test section. After calibration, the measured maximum temperature deviation across all thermocouples was about 0.15 K when a few test points were measured. First, as shown in the top left corner of Fig. 2 - (b), six thermocouples were attached to the surfaces of the 1st and 3rd U-bends on the front side of the heat exchanger. From the bottom, the thermocouples were attached to the outer surfaces of the 3rd, 11th, and 20th rectangular channels for both U-bends. Next, as shown in the bottom left corner of the same figure, four thermocouple pairs were evenly distributed in each quadrant of the acrylic plate’s inner and outer surfaces. These heat loss and thermal mass measurement thermocouples were installed on all six container surfaces. Lastly, two levels of twelve thermocouples were installed in between the fins to measure the PCM temperatures, as shown in Fig. 2 - (b). The thermocouples were installed every 52.5 mm from the front to back surfaces. The 1st and 2nd levels are 43 mm and 77 mm from the bottom surface of the container.

2.4. Container Configuration

Clear high-strength acrylic plates were used as container walls. The acrylic plates were cut to the designed dimensions using the laser cutting machine. Modified acrylic plates were later assembled with screws and acrylic epoxy for the container construction. The detailed dimensions of the container’s inner volume are shown in Error! Reference source not found.. A 10 mm gap between the heat exchanger surfaces and the inner wall of the container was given around all heat exchanger surfaces except for the top surface. For the bottom gap, small 3D-printed blocks were attached to the bottom surface of the heat exchanger. The height of the container’s inner volume was designed to have at least a 15 mm air gap at the top to prevent any unexpected PCM leakage through the top plate. The front and top surfaces used for visual observation angles were double-plated to increase the thermal resistance while maintaining transparency. The rest of the single acrylic plates were later covered with 1” thick insulation sheets.

Fig. 3. A 3D model of a container and heat exchanger assembly dimensions
3. Data Reduction

The theoretical storages of the PCM-HX with the given initial and final PCM temperatures along with PCM properties were estimated using the average value of the PCM-side thermocouples temperature readings. The sensible and latent portions of the theoretical storages during both phase change processes were calculated using the temperature range that was specified by the OEM. Also, the thermal mass of the aluminum heat exchanger was considered as a part of the theoretical storage as shown in Equations (1) and (2).

\[
Q_{m,\text{theor}} = \sum M [C_{p,s}(27 - T_{\text{init}}) + L_{\text{PCM}} + C_{p,s}(T_{\text{fin}} - 42)] + \sum TM_{\text{HX}}
\]

\[
Q_{s,\text{theor}} = \sum M [C_{p,s}(T_{\text{init}} - 42) + L_{\text{PCM}} + C_{p,s}(27 - T_{\text{fin}})] + \sum TM_{\text{HX}}
\]

The accumulated HTF energies during melting and solidification were calculated using Equation (3). The time step of 10 sec was chosen as a data collecting interval.

\[
Q_{\text{(m/s), HTF}} = \int_{\tau_{\text{in}}}^{\tau_{\text{fin}}} \dot{m}C_{p,\text{HTF}}(T_{\text{RTD(in/out)}} - T_{\text{RTD(out/in)}}) d\tau
\]

For estimating the actual charged and discharged energies, the heat loss and thermal mass considerations of the test section were necessary. Hence, Equations (4) and (5) were used. Importantly, the heat loss sum and thermal mass sum terms each contain different equations inside for charging and discharging scenarios. This was to avoid heat loss or thermal mass double counting depending on the directions of the heat transfer during each process and the defined control volumes. As this test setup only consisted of flat rectangular surfaces, a simple 1-D flat heat flow approach was assumed as shown in Equation (6).

\[
Q_{\text{charged}} = Q_{\text{(m/s), HTF}} - \sum \text{Heat Loss} - \sum \text{Thermal Mass}
\]

\[
Q_{\text{discharged}} = Q_{\text{(m/s), HTF}} + \sum \text{Heat Loss} + \sum \text{Thermal Mass}
\]

\[
\text{Heat Flow}_{\text{flat}} = \int_{\tau_{\text{in}}}^{\tau_{\text{fin}}} U \cdot A \cdot \Delta T \, d\tau
\]

Moreover, Equations (7) and (8) were used to calculate the systematic uncertainties of the measured HTF side energies. The systematic uncertainties were minimized by using two sets of three 1/8-inch diameter RTDs with ±0.03 K absolute uncertainty and a Coriolis mass flow meter with ±0.2% relative uncertainty.

\[
U_{q_{\text{water}}} = \sqrt{\sum \left(\frac{\partial Q_{\text{water}}}{\partial x_i}\right)^2} \, U_x^2 \quad U_{q_{\text{water, total}}} = \sum \left(U_{q_{\text{water}}}\right)_x
\]

Two dimensionless numbers, the Reynolds number, a ratio of fluid inertial to viscous forces, and the Stefan number [7] and [8], a ratio of sensible to latent heats were calculated using Equations (9) and (10).

\[
Re = \frac{\rho u D_H}{\mu} \quad Ste = \frac{C_{p,\text{PCM}}(T_{\text{fin}} - T_{\text{phase change}})}{L}
\]

4. Results and Discussion

4.1. Test Conditions

The summary of the test matrix is described in Table 1. The [M] and [S] in the table represent the melting and solidification cases. The test matrix was designed to test a combination of two melting inlet temperatures and three mass flow rates. The ambient temperature for all test conditions was within the range of 25.0–25.1 °C. The Reynolds numbers for a single rectangular channel for all chosen test conditions were under a laminar flow regime due to a slow flow velocity in each channel as the main flow diverges into 21 channels. Compared with the melting cases, the solidification cases had lower Reynolds numbers as the dynamic viscosity of water increased as the water temperature decreased. The Stefan number for each test condition was also calculated.
to have a dimensionless parameter as a reference. The melting process was considered finished when all the heat loss and thermal mass measurement thermocouples that were installed on the inner surfaces of the acrylic plates reached 40 °C. Similarly, the solidification process was thought to be completed when the same group of thermocouples all reached 27 °C. For melting, the thermocouples located at the inner surface of the bottom acrylic reached 40 °C at last. For solidification, the thermocouples installed at the inner surface of the back-side acrylic took the longest to reach 27 °C. Importantly, the test condition 2 was repeated three times to check the test facility’s repeatability before completing the test matrix, and excellent repeatability results were obtained.

The test durations and average charge and discharge rates of the PCM-HX for each test condition are shown in Table 1 as well. The higher mass flow rates yielded both faster melting and solidification and higher average charge and discharge rates. The higher average HTF inlet temperature for melting yielded faster melting, as expected. Test conditions 1 through 3 have slightly longer solidification durations than the lower average inlet T group with same MFRs as the only difference was the initial PCM temperature that was affected by the higher HTF inlet temperature for melting. Finally, the energy densities had negligible differences among the test conditions within the same melting HTF inlet temperature group.

4.2. HTF inlet Temperature, PCM Average Temperature, and ΔT

Test condition 2 from Table 1’s HTF inlet temperature, PCM average temperature, and heat exchanger temperature difference between inlet and outlet are shown in Fig. 4. The HTF inlet temperature was controlled within ±1 °C during the melting process. The heater was switched off when the melting process was considered completed, then the HTF inlet temperature was brought down to the room temperature for the solidification process. The PCM average temperature was plotted using the average value of all PCM-side thermocouples. Lastly, as shown in the plot, the ΔT was measured the highest during the beginning of both melting and solidification processes, then both decreased towards to zero as the PCM absorbed and discharged most of the HTF’s energy and its absorbed energy, respectively.
4.3. Visual Observation

As mentioned in section 2.4, the front and top angles were selected to visually observe the experiments. In Fig. 5, the front and top angles images of test condition 2 from Table 1 are displayed for both the melting and solidification processes. For melting, it was shown that the melting progression was from right to left and top to bottom from the front angle. It is essential to mention that the front angle view shows only the outer boundary of the PCM that touches the inner surface of the container wall. Therefore, for a more complete observation, top angle images could be investigated for comparison. The top-angle images show that the PCM in close contact with the heat exchanger surfaces quickly melted as compared with the PCM close to the container’s inner walls. This could be verified by checking the ΔT plot of the heat exchanger inlet and outlet from Fig. 4 where the slope became less stiff around the 15 min mark. The charging rate slowed as only the outer PCM was left to melt. Hence, it was observed that the major portion of the PCM near the heat exchanger melted almost uniformly regardless of the height with the help of louvered fins, then the outer PCM that was closer to the container’s inner walls took longer to melt due to the higher thermal resistance in the PCM layer without fins. Thus, the outer PCM melting front was from top to bottom as the melted PCM’s natural convection effect was the dominant driver of heat transfer. For solidification, since conduction became the main mode of heat transfer, the solidification fronts showed more of a uniform trend that followed the serpentine path, as shown in the bottom images of Fig. 5 - (TOP) and (BOTTOM). Additionally, the PCM volume change was observed near the top section of the container as PCM solidified and increased its density, as shown in the front angle images.
4.4. PCM Temperature Profiles

Fig. 6 – (TOP) shows test condition 2’s temperature profiles for the selected PCM locations during the melting process. As shown in the image and the naming convention, the front four pairs (locations 1, 4, 7, and 10) of thermocouples were chosen for a temperature profile comparison. As mentioned in the previous section, the thermal conductivity of the PCM was largely enhanced by the louvered fins. Hence, the temperature delays between the bottom- and top-level PCM locations were relatively smaller than the vertically oriented finless PCM-HX test results from the literature [9]–[11]. The top-level PCM thermocouples started to increase the temperature gaps from the bottom-level thermocouples as the PCM around them were fully melted and the natural convection effect kicked in. Then as most of the PCM melted and their temperatures nearly reached the HTF temperature, the gaps were reduced. For all top-level PCM thermocouples, there were minor temperature dips right before they started to get flattened out, reaching the HTF temperature. This was due to the solid PCM at the top surface melting and traveling down the cracks between the fins as they became small enough to fall through. This was verified by comparing the timing of the recorded images from the top-angle camera. Also, the temperature delays across the horizontal PCM thermocouple locations were clearly shown from right to left as they followed the serpentine path.

Test condition 2’s temperature profiles for the same PCM locations during the solidification process are presented in Fig. 6 – (BOTTOM). As mentioned previously, conduction became the dominant mode of heat transfer during solidification. Therefore, the temperature gaps between the bottom and top thermocouples were relatively smaller than the temperature gaps of the melting test results throughout the test. Furthermore, the temperature delays across the horizontal PCM thermocouple locations following the serpentine path were shown again during the solidification process. Lastly, a minor supercooling phenomenon was observed near 31 °C for all PCM locations.

The temperature profile data of the U-bends in different locations were also collected as well. However, for the sake of brevity, such information was not included in this study.
Fig. 6. Test condition 2’s temperature profiles for the selected PCM locations during (TOP) melting and (BOTTOM) solidification

4.5. Energy Balance

The summary of the energy balance results for each test condition’s melting [M] and solidification [S] process is presented in Table 2. The energy balance deviations were calculated using the data reduction approach in section 3. The energy balance deviation was calculated by comparing the theoretical storage and the estimated charged/discharged energy values. The average of the systematic uncertainties of the HTF (water) side energy for all test conditions was calculated to be 0.5% for melting and 1.4% for solidification, while the maximum uncertainties were 0.7% for melting and 2.1% for solidification.

Initially, although not shown here for brevity, when the nominal HSC value (240 kJ/kg) given from the OEM was used, the $Q_{\text{water}}$ values for test conditions 2, 3, 5, and 6 during melting were smaller than their theoretical storage values which is unintuitive. The $Q_{\text{water}}$ values contain the information of heat loss and thermal mass of the test setup on top of the PCM-HX charging process. Hence, the $Q_{\text{water}}$ values for melting should always be larger than the theoretical storage values. Furthermore, existing literature [12]–[14] show that their in-house DSC analysis yielded 11.9%, 6.3%, and 13.8% fewer HSC values compared with the nominal value from the manufacturer’s datasheet. Therefore, the HSC values from the DSC results and the lower bound of the HSC value from the OEM’s datasheet were used for energy balance estimation.

As shown in the grey energy balance column, all test conditions’ energy balances were within ±14% deviation when using the HSC values obtained by the DSC results. On the other hand, as presented in the green energy balance column, the melting energy balance deviations were improved significantly while the solidification energy balance worsened when the theoretical storages were calculated using the lower bound of the HSC range. For more accurate energy balance estimation in the future, the DSC test should be conducted.
with multiple heat rates to get the best result as they are highly dependent on different heat rates as well as the sample size and test temperature range.

4.6. Practical Considerations

One should not only pay attention to the theoretical considerations but also carefully look into the practical considerations when implementing or designing the PCM-HX-based thermal energy storage. From this study, several practical issues were identified. One of the most common challenges with PCM-based storage is a pressure build-up in the container as the PCM undergoes a phase change process. This is caused by the volume expansion of the PCM as its density decreases as it undergoes the melting process. In this test setup, a portion of liquid PCM squirted onto the ceiling plate could be observed around the 7.5 min mark of the melting process shown in Fig. 5 – (BOTTOM) due to the pressure build-up. Additionally, the PCM container even experienced a minor leakage issue after a number of cycles due to the repeating rounds of volume expansion and contraction cracked the acrylic epoxy adhesion. Hence, in a case where one can control the HTF direction, the HTF direction should be carefully chosen with the effort of minimizing the pressure build-up in the container. For example, one can flow the HTF downwards when the straight tube PCM-HX is oriented vertically, promoting the downwards melting trend so that the melted PCM would have a free space to expand to right away.

Another consideration that stems from the PCM volume change that one should beware of is the changing boundary condition. In a scenario where the container is narrow and long, the PCM level change during the phase changes will be relatively large. Hence, one should make sure to have the PCM-HX surfaces always submerged in the PCM during both charging and discharging modes to take full advantage of the heat transfer area.

Moreover, when initially charging the PCM liquid into the container, extra effort should be made not to create or trap any air bubbles in the container, especially in between the fins. These air bubbles can negatively affect the heat transfer between the PCM and the heat exchanger surfaces.

5. Conclusions

Overall, a PCM-HX assembly from a commercially available serpentine heat exchanger with louvered fins was embedded in RT35HC and experimentally investigated to check its thermal performance. A test matrix consisted of six test conditions with varying inlet HTF temperature and MFR. According to the obtained test results, particular conclusions were derived and can be summarized as follows:

- Increase in both Re and Ste had considerable effects on reducing the test durations while increasing the average charge and discharge rates in a laminar regime.
- For test conditions 1 to 3, the melting test durations were decreased by 15% and 20%, respectively when increasing the MFR from 5 g/s to 10 g/s and 15 g/s, whereas the solidification test duration decreased by 13% and 17%, respectively.
For test conditions 4 to 6, the melting test durations were decreased by 15% and 19%, respectively when increasing the MFR from 5 g/s to 10 g/s and 15 g/s, whereas the solidification test duration decreased by 12% and 16%, respectively.

For test conditions 1 to 3, the average charge rates were increased by 16% and 23%, respectively when increasing the MFR from 5 g/s to 10 g/s and 15 g/s, whereas the average discharge rates were increased by 14% and 22%, respectively.

For test conditions 4 to 6, the melting test durations were decreased by 18%, 18%, and 19%, respectively when the melting HTF inlet T was increased by 5 K.

For test conditions 4 to 6, the average charge rates were increased by 15% and 20%, respectively when increasing the MFR from 5 g/s to 10 g/s and 15 g/s, whereas the average discharge rates were increased by 17% and 24%, respectively.

The energy balance deviations were within ±14% and ±9%, respectively when the HSC values from DSC results and the lower bound of the OEM datasheet were used.

In the future, for constructing a various types of PCM-HXs’ performance database, the operating conditions and applications should be clearly defined so that meaningful comparisons could be made when using useful comparison approaches like rate capability and Ragone plots [15] and ε-NTU method [3], [4], [7], [16].

TECH Clean California: Paving the Way to Heat Pump Market Transformation

Evan Kamei* and Teddy Kisch

*Energy Solutions, 449 15th Street, Oakland, California, 94612, United States of America

Abstract

In the United States, over 90 percent of direct residential carbon emissions come from fossil fuel-fired space and water heating [1]. A critical strategy to decarbonize this sector is scaling adoption of high-efficiency, electric heat pumps for space and water heating. However, the market share for heat pumps for both is less than 10 percent in most states in the U.S. and will need to scale exponentially over the next decade to meet greenhouse gas (GHG) reduction goals. TECH Clean California is a $120 million, multi-year market transformation initiative focused on accelerating adoption of heat pump technology by driving down costs, finding new value streams, and scaling successful approaches through market and policy changes. The initiative includes three concurrent efforts: 1) motivating the supply chain through midstream incentives, providing accessible workforce training, and driving consumer demand; 2) demonstrating scalable solutions to key market barriers; and 3) using data from TECH installations to create a public database that can inform policy. This paper provides an overview of the initiative’s theory of change and illustrates the relevancy of its results to resiliency, efficiency, and the heat pump industry at large.

1. Overview

TECH Clean California (TECH) is a market transformation initiative aimed at driving market adoption of zero-emissions space and water heating technologies for existing single family and multifamily residential homes to help achieve California’s goal of six million installed heat pumps by 2030 and carbon neutrality by 2045 [2]. In 2022, the California Air Resources Board (CARB) finalized their State Implementation Plan proposed a zero-emission standard for space and water heaters effective 2030 [3]. The initiative was created through the passage of California Senate Bill 1477 and is funded by revenues collected through California’s Cap-and-Trade program.

TECH is designed to be a centralized flagship implementation program for all existing and potential heat pump HVAC (HP HVAC) and heat pump water heater (HPWH) programs and to create best practices to inform statewide consistency. To achieve lasting scale, the initiative will pave a path for favorable decarbonization policy and make heat pumps cost-competitive with incumbent technologies.

There are three main pillars to the initiative. First, to meet California’s aggressive decarbonization goals, there must be a significant increase in market scale and a rapid shift towards clean heating technologies. To achieve this, TECH provides a combination of market incentives, supply chain engagement, workforce development, and consumer education. The second pillar of TECH leverages regional pilots and Quick Start Grants to address specific barriers to scale within specific markets, such as low income or multifamily, as well as and explore ways to push through existing barriers such as with identifying customers, project finance, streamlining permitting, and load control. Lastly, the third pillar of TECH informs long-term, building decarbonization policy frameworks by collecting, analyzing, and publicly publishing energy and GHG impacts.
and detailed program case studies, results and processes that can be used to inform long-term decarbonization planning.

2. Initiative Description

2.1. The initiative framework

2.1.1. Pillar One: Spur the clean heating market for electrification through statewide strategies

Focus on contractors to prime the market: TECH Clean California employs several strategies to prime the market throughout the supply chain. TECH actively coordinates with manufacturers, distributors, contractors, and consumers to holistically support market transformation. TECH Clean California concluded that contractors would have the greatest impact on market transformation since they directly influence the sales process for most heat pump installations, including customer decisions on fuel substitution. To impact heat pump sales in the near-term, engaging these supply chain actors is critical. However, contractors are often hesitant to break away from their existing profitable sales model and invest time and effort to sell and install nascent technologies with yet-to-be proven demand [4]. Given these findings, this initiative is designed to train contractors on the technology, value proposition, and business model aspects of electrification; and to motivate contractors to sell heat pump technologies by providing contractor incentives, sales rewards, and bonuses.

Provide incentives for both single-family and multifamily residences: Providing incentives for both residence types helps ensure demand is supported across the market, including customer segments that can be hard to reach. TECH provides both HPWH and HP HVAC installation incentives for single-family residences, while encouraging best installation practices associated with each project. TECH also provides incentives installed in multifamily properties, thus reaching renters who may not be in charge of infrastructure upgrade decisions. Incentives are available for various equipment types that serve residential apartments as well as communal spaces used by residents and multifamily building staff.

Leverage existing marketing infrastructure to drive consumer demand: The Building Decarbonization Coalition (BDC) has played a prominent leadership role in consumer education, outreach, and engagement thus far. To drive demand, TECH integrates with and enhances their consumer inspiration campaign, the Switch Is On, which has been a key means of engaging in mass market communications for the initiative and has also been supported by heat pump manufacturers. This resource provides information for every step of the customer journey, such as guides to electrification, as well as resources that enable them to take direct action such as finding qualified contractors and available incentives.

2.1.2. Pillar Two: Create scalable models for market transformation through regional pilots and focused outreach

Test strategies through regional pilots and Quick Start Grants: Six regional pilots are designed to address key barriers to heat pump adoption, in a small-scale targeted fashion. The focus for two of the six pilots is to address adoption barriers within particular market segments — low-income households and multifamily housing — important for supporting an equitable transition. The remaining four pilots address key barriers along the customer journey: identifying the customers most likely to save money by switching to heat pumps, enabling high-volume project finance structures, streamlining equipment installation, and managing the new electrical load once the appliance is installed. TECH Clean California launched these pilots and also funded seventeen Quick Start Grants. Pilot details are discussed further in section 2.5 below.

Target low-income, hard-to-reach, disadvantaged communities (DACs): Investments in impacted communities help fuel economic recovery and respond to the needs of those hit hardest by historical environmental and social inequities as well as the ongoing COVID-19 pandemic. TECH Clean California has deployed targeted strategies and localized investments to enable equitable, impactful decarbonization. The initiative has a goal to invest 40 percent of program incentives in low-income households and DACs. To promote program collaboration, with advise of the California Public Utilities Commission (CPUC) Low-income Oversight Board (LIOB), TECH Clean California assembled a Low-Income Ambassador Panel, consisting of low-income regional representatives from across the state. The objective of these activities is to gather the requisite data and market experience to inform policies and program designs that will transition low-income weatherization programs towards electrification, ensuring that low-income households have access to the health and safety benefits associated with decarbonization.
2.1.3. Pillar Three: Inform long-term building decarbonization framework

Public reporting drives policy: As a market transformation program TECH Clean California’s role is to support structural shifts through policy and market mechanisms, and create sustained, long-term impacts. The initiative provides a single source of heat pump market data for California through its public reporting website, www.techcleanca.com, offering market transparency with program information on installation details, project prices, deployment progress, and meter-based impacts.

Quantify the value of decarbonization: A key barrier to decarbonization is the existing deficiency of the market to monetize grid and climate value. Many of the primary benefits of decarbonization are grid- and climate-related (bill savings are generally secondary), and thus a key near-term opportunity is using installation data from the initiative to quantify these values and support the development of more formal markets. Achieving zero carbon homes by 2045 will require significant public and private capital investment and robust project finance that supports this investment. By rigorously quantifying GHG impacts and all other decarbonization value streams for heat pumps by means of interval meter data, TECH Clean California hopes to achieve an actuarial level of impacts quantification required for large-scale project finance, similar to the wind and solar industry.

2.2. Demonstrating scalability

Like many other states, decarbonization efforts in California need to balance multiple priorities: 1) maximizing GHG reductions, 2) maintaining grid reliability, 3) ensuring equity and minimizing consumer bill impacts, and 4) achieving project cost declines and mature business models so that a large-scale transition is economically feasible. Programs like TECH Clean California can support scale to help pave the way for market transformation by demonstrating market demand and supporting a scalable process that can accommodate the high project volume needed to achieve California’s heat pump goals. Within California, energy reliability remains an ongoing concern with respect to peak electricity demand in the summer. The California Independent System Operator (CAISO) conducted analyses and concluded that additional resources are needed to ultimately achieve long term reliability margins and need to consider growing risks of more extreme events stemming from climate change and supply chain disruptions. This stresses the need for approaches that support reliability and resiliency, such as HPWHs with load-shifting capability or customer targeting that maximizes peak load reductions [5].

In the United States, the Inflation Reduction Act is set to infuse approximately $300 billion into energy and climate reform measures, including $9 billion for rebates on efficient equipment — including HP HVAC and HPWH — and corresponding contractor training and education. The information gained from TECH Clean California will be invaluable in guiding other programs within California and nationwide as others create their own programs in response to the Act. The statewide initiative coordinates directly with the CPUC to deliver results across the four investor-owned gas utilities: Pacific Gas & Electric (PG&E), San Diego Gas & Electric (SDG&E), Southern California Gas (SoCalGas), and Southwest Gas (SWGas). TECH Clean California has also layered $5.4 million in incentives funded by partner utility programs, adding to the $31.7 million paid through the Cap-and-Trade funding that directly supports the initiative. These partner utility programs include those offered by community choice aggregators such as Central Coast Community Energy, municipal utilities such as Sacramento Municipal Utility District (SMUD), and regional energy networks such as BayREN. This incentive layering strategy is especially important as the Inflation Reduction Act will soon launch new programs such as the High-Efficiency Electric Home Rebates Program (HEEHRA) and the Whole-Home Energy Efficiency Program (HOMES) throughout the United States. These programs will need to coordinate and layer with local, existing energy efficiency programs. The lessons learned from TECH Clean California and the data available through our public reporting site offer unparalleled value to state energy offices and implementers and will guide and support the future of the industry.

2.3. Incentive design

TECH Clean California is designed to provide a simplified and consistent statewide incentive structure that integrates with existing local heat pump programs. A large-scale, statewide initiative brings significant benefits by simplifying two key areas: contractor participation and general program communication. To support this, TECH developed the Incentive Clearinghouse to layer incentives across integrated programs. This approach enables multiple organizations to provide funding for a single product type. TECH Clean California has now integrated its application process with five additional heat pump programs.
TECH Clean California’s single-family incentive structure was designed with two goals in mind: 1) stretch the incentive budget by encouraging layering with local programs, and 2) provide a baseline set of incentives everywhere to ensure an equitable rollout. TECH concluded that the best approach would be to provide a statewide level of baseline incentives focused on overcoming the financial barriers associated with fuel switching, while coordinating with local energy efficiency programs to enhance incentives.

Facilitating a truly seamless experience for the contractor requires that all programs adopt consistent eligibility rules and application processes. In the first phase of incentive layering integration, each program still had its own rules, which caused contractor confusion and uncertainty. TECH Clean California and the other programs continue to work to streamline requirements and processes.

In addition to single-family incentives, TECH Clean California provides incentives for HPWH and HP HVAC equipment installed in multifamily properties for both retrofit and new construction applications. Incentives are available for various equipment types that serve residential apartments and communal spaces. For multifamily dwellings or properties with five or more dwelling units, TECH opted for a single incentive structure available throughout the investor-owned utility (IOU) gas territories to make the program simple and consistent for building owners and property managers.

2.4. Progress-to-date

2.4.1. Single-family incentives

TECH Clean California launched statewide, single-family incentives on December 7, 2021, and enrolled contractors ramped up participation quickly and enthusiastically. This is evidenced by the month-over-month growth in submissions shown in Fig. 1 below. Within six months, TECH enrolled over 900 contractors (3.5% of total California HVAC and water heating contractors) and received over 20,000 completed projects or reservations.[6]

Incentive spending in certain gas IOU territories gained momentum much more quickly than others, resulting in program suspensions due to budgetary limits required by the California Air and Resources Board funding allocations. These suspensions started with SDG&E on April 26, 2022, and extended to PG&E and SoCal Gas (HVAC only) on May 13, 2022.

To address the potential for exceeding the amount of available incentives, TECH Clean California introduced an incentive reservation system in May 2022 which allowed contractors to reserve incentives prior to project completion to ensure that funding would still be available when they were ready to submit applications for reimbursement. The team worked with participating contractors and energy raters to develop the reservation process and obtain feedback. The team sent out several communications to stakeholders to ensure that contractors were aware of the new system and in the span of a single week TECH received over 5,000 incentive claims, which quickly exhausted the remaining incentive budget and forced the program to suspend further incentive reservations.

Overall, both HPWHs and HP HVAC show significant growth, but initial sales were dominated by HVAC projects in single family homes: market-rate single-family TECH incentives applications had a 7.1:1 ratio of HP HVAC heat pump installations to those for HPWHs. This dramatic success of HP HVAC is likely due to selling on increased comfort and a combined heating and cooling solution, and the additional infrastructure
and complexity involved with HPWHs. For HPWHs, most installs took place in the Bay Area and Sacramento regions, which had existing programs and a more mature installer network. This suggests that HPWH programs in new areas should include robust investment in supply chain engagement and training, requiring time to build up a set of qualified and motivated contractors.

2.4.2. Multifamily incentives

TECH Clean California launched multifamily incentives with an incentive reservation system to accommodate the long pre-construction and construction timelines, the need to track incentive budgets, and the need for a contractor to provide property owners and managers with firm pricing proposals prior to decision-maker approval.

The TECH Clean California incentives enabled owners to move forward with heat pump projects that they could not otherwise fund themselves. To date, reservations have been made for over $12 million in multifamily incentives representing over 7,400 housing units, with the majority set aside for disadvantaged communities and affordable housing. In addition to the reserved incentives, about $7 million worth of incentives are on the multifamily waitlist, representing projects in the pipeline that can be completed if funding becomes available from new sources, such as IOU energy efficiency programs and state funding, or from projects that do not materialize. These incentive reservations were mostly for projects in SoCalGas and PG&E territory with a smaller portion in SDG&E territory (see Fig. 2 for breakout).

For multifamily installations, HPWHs comprised roughly 60 percent of projects. Of HPWH installations, 85 percent were in-unit installations, with 15 percent of units being served by central HPWHs. These heat pump investment decisions were often driven by project economics, or property owners looking to electrify to manage long-term fuel costs, decrease GHG impacts, and integrate with solar.

2.5. Overcoming barriers

The six TECH Clean California regional pilots, summarized in Table 1, are designed to test potential solutions to discrete market barriers, including impediments to widespread technology deployment and meeting California’s GHG reduction goals. The solutions that prove effective will be incorporated into the TECH Clean California framework and scaled into statewide approaches where feasible.

Two of the six pilots address adoption barriers for market segments that are particularly important for supporting equitable transition: low-income households and multifamily housing. The remaining four pilots address key barriers along the customer journey: identifying the customers most likely to save money by switching to heat pumps, financing the project, streamlining equipment installation, and managing the new electrical load once the appliance is installed.

2.5.1. Inclusive Utility Investment Program

The Inclusive Utility Investment Pilot aims to demonstrate and expand the Tariffed On-Bill (TOB) or Inclusive Utility Investment (IUI) model through a partnership with a Load Serving Entity (LSE). TOB/IUI programs allow utilities to pay for cost-effective energy improvements, such as home heating and cooling units, at a specific residence. TOB/IUI also recover costs for improvements over time through a dedicated charge on the utility bill less than the estimated savings from the improvements. TOU and IUI are not forms of debt or lending, and cost recovery survives across successor occupants, making it more inclusive and allowing longer cost recovery terms. TOB/IUI is a new concept and exact impacts of a larger program are unknown. Results from this pilot can be used to inform the statewide framework to support future programs.

2.5.2. Low-Income Integration Pilot

The Low-Income Integration Pilot aims to expand access to building decarbonization technologies among low-income households by partnering with existing energy efficiency or income-based retrofit programs to ensure heat pumps are available in more programs and to more customers.

In 2019 the CPUC initiated the San Joaquin Valley Disadvantaged Communities (SJV DAC) Pilots, seeking to increase access to affordable energy sources and reduce use of fossil fuels for generators. A key focus is on creating pathways to electrification for low-income households. The TECH Clean California Low Income Integration Pilot team collaborated with this program to address issues in low-income homes that must be remediated before electrification can proceed. The SJV DAC program had a limited budget for pre-existing homes that was proving inadequate to cover unforeseen repair needs. The goal of the TECH Clean California collaboration pilot is to address 70 single-family homes that were not originally able to participate in the SJV DAC program, by providing each home with additional funding for remediation. As of June 2022, TECH Clean California has funded remediation on 13 homes in the San Joaquin Valley, with more in the pipeline. A central learning of the pilot is that the initial costs for retrofitting and repairs that are essential before installing heat pumps are often underestimated and the bill impacts of heat pumps are uncertain due to variables unique to each installation site. The lessons learned from this pilot will inform other equity-based programs throughout the state.

2.5.3. Multifamily Housing Pilot

The Multifamily Housing Pilot seeks to address barriers associated with electrification and energy efficiency upgrades in multifamily properties specifically by reducing the perceived risk of heat pump systems, by providing deep technical support in building system design. The strategy is to increase market familiarity with technologies and build capacity within design teams at multiple levels: from owners and architects to mechanical, electrical, and plumbing engineers. By accelerating the learning curve, the pilot will reduce the time and cost for developers to transition to all-electric buildings. The pilot has three tracks of activity:

- Project Specific and Portfolio Level Electrification Advising
- Central Heat Pump Water Heater Technical Support
- Property Electrification Readiness Plan

By addressing these multifamily housing barriers, this pilot can help provide a framework to support future efforts to transition properties to all-electric service.
2.5.4. HPWH Load-Shifting Pilot

This pilot aims to establish market readiness and ensure that the full load-shifting benefits of HPWHs can be realized. It addresses this by motivating contractors to set up a HPWH to load-shift upon installation and encouraging them to sign customers up for demand response (DR) programs.

The initial focus of the pilot through 2021 and early 2022 was to educate contractors about the value of load shifting. The pilot team created an HPWH load-shifting training curriculum, and as of May 2022, more than 700 contractors had begun to enroll. Of these contractors, more than 150 had viewed the training video, and 75 percent of those who responded to the post-training survey reported that they had a positive view of the training, with only six percent being less than satisfied.

Initially, the pilot team also offered a $200 incentive to contractors who installed a thermostatic mixing valve (TMV), a component that greatly expands the load-shifting potential of an HPWH. The pilot received and paid 209 TMV incentive claims, and early results from the launch of general TECH Clean California incentives revealed that about 70 percent of installs were already including TMVs as a matter of course. In the fall of 2021, the Self Generation Incentive Program (SGIP) announced HPWH incentives with requirements that included the inclusion of TMVs for all installations. To align the TECH Clean California requirements with SGIP, and after consultation with contractors to ensure the market was ready to include TMVs as a standard part of installations, TMVs were made a requirement for receiving standard TECH Clean California incentives, and TMV bonus incentives were discontinued on June 20, 2022.

With the discontinuation of TMV incentives, the pilot team expanded the portion of this pilot that encourages contractors to enroll customers in DR programs by providing an additional $50 incentive for each customer enrolled. Originally, the HPWH Load Shifting Pilot focused on collaboration with PG&E’s WatterSaver DR program; however, standard TECH Clean California incentives were exhausted in PG&E territory in May 2022. The team expanded its focus and now offers the $50 incentive for enrollment in DR programs statewide and is currently collaborating with WatterSaver, SMUD’s PowerMinder program, and OhmConnect, and open to other collaborations in the future. The pilot team will continue to educate contractors – and through them, customers – on the benefits of DR enrollment for both the grid and customer savings and will collect data on the barriers and challenges that dissuade contractors and their customers from enrolling in these programs.

2.5.5. Streamlining Permitting Pilot

This pilot aims to close the gap in permitting times between natural gas water heaters and HPWHs, by adopting a single-day HPWH permitting process within single-family homes where code compliance could be demonstrated easily and effectively. The permitting process for HPWHs can currently span multiple days, deterring both homeowners and installers from making the switch from gas water heating to electric HPWHs. In emergency replacement scenarios, longer installation periods due to permitting delays are an even more significant barrier.

Throughout the second half of 2021 and into 2022, the pilot team convened numerous meetings with stakeholders to identify permitting challenges and solutions and help shape the potential goals of the pilot. Incorporating feedback from these sessions, the group reviewed a permit guidance package intended to aid building permit offices and contractors in creating a more expedited HPWH permitting process.

2.5.6. Customer Targeting Pilot

This pilot seeks to identify and test outreach strategies to drive demand among customers for whom the value of electrification is most compelling. It addresses two key market barriers hindering adoption of heat pumps in California:

- A lack of large-scale data demonstrating which customers are most likely to benefit from upgrading to a heat pump, and how to motivate those customers to buy a heat pump instead of an alternative.
- Poor outcomes from recruitment of customers with low potential to save, which can have an outsize effect on adoption in early-stage technology markets. This highlights the need to recruit customers whose energy profiles indicate high potential to save.

This work transitioned from planning to implementation in early 2022 after receiving the necessary customer data from the utility. Working with SCE, the team devised an email campaign to be sent to SCE customers with a high likelihood of energy bill savings from installing HP HVAC systems. The pilot will compare the effectiveness of a general message about the efficiency and benefits of heat pumps to a specific
message stating that a customer’s energy use indicates their household is a particularly suitable candidate. The lessons learned from this comparison will demonstrate the value of targeting customers based on energy use, which may be leveraged by future programs.

2.5.7. Quick Start Grants

Along with other TECH pilots, the Quick Start Grant (QSG) program aims to identify and fund targeted, innovative pilots that test approaches to overcome market barriers to heat pump deployment. The QSG program has funding for two solicitations annually. With these, the QSG program aims to promote the development and refinement of interventions that meet our solicitation criteria:

- Test solution to a barrier to residential building decarbonization.
- Have the potential to scale up to become statewide solutions.
- Ensure feasibility within the budget proposed and can be implemented within one year.

The first solicitation sought QSG pilots in the fall of 2021, received 35 grant applications and selected 11 projects for funding. Of the winning projects, 73 percent of overall funding went to projects expected to serve low-income households or historically underserved populations. The projects launched in early 2022. Since then, each of the grants has made progress in hitting individual milestones.

Fig. 3 provides a summary of the Quick Start Grants from the first solicitation.

The second solicitation was completed in the fourth quarter of 2022 and selected six projects for funding. Several changes were made to the second solicitation to reflect input from stakeholders as well as the implementation team’s experience. These include expanding stakeholder outreach, extending the open time of the solicitation, adding an interview stage for grant finalists, and increasing the focus on projects addressing barriers in historically underserved communities.

Fig. 3. Quick Start Grant summary

TECH will analyze the collected data, review the gained experience, and make the findings known to key decision makers through the public reporting website.

2.6. Public reporting

The vision for TECH Clean California public reporting is to bring a variety of data sources together and layer them into a robust and scalable data pipeline that offers novel visibility into the California heat pump market as shown in Fig. below. In the first year of implementation, TECH focused on building a core infrastructure to collect useful, actionable data. First-year accomplishments include building a robust incentive application data collection pipeline, unlocking access to historical meter data via CPUC to measure key participant outcomes, and launching the public reporting website to collect data and key findings, including anonymized project-level data and evaluation data as of July 2022.
The primary data pipeline starts with the Incentive Clearinghouse, where contractors submit incentive applications and data about project installation. An early focus area has been to outfit the Incentive Clearinghouse with all the features needed to fulfill TECH Clean California’s ambitious goals — programs for two distinct technologies, each with high data quality requirements, and each capable of layering with other partner programs — while making the combined incentive consistent enough for contractors to understand and predict. Once this functionality was in place, incentives for thousands of projects could be quickly deployed in just a few months, layered with four partner programs, each with a distinct layering structure. The Incentive Clearinghouse can continue to serve as a processing and layering center for new incentive programs anywhere in the state.

Concurrently, TECH worked with CPUC and California Energy Commission to gain access to statewide residential historical electricity and gas meter data (approximately 11 million meters) to understand the impacts of heat pump installations on the utility bills and GHG emissions of TECH Clean California participants. After collaborating with CPUC to resolve unforeseen legal barriers preventing access to the necessary meter data, TECH was able to start auditing the database that stores statewide residential electricity and gas meter data. TECH has started building a baseline understanding of residential gas and electricity consumption throughout the state and using this data to inform customer targeting and regional pilots. Meter-based results for TECH Clean California participants will become available starting one year after heat pump installation – the third quarter of 2023 for most TECH Clean California participants.

Finally, TECH has established regular data exchange with our evaluators, Opinion Dynamics, to further our understanding of customers’ and contractors’ experience with TECH Clean California and heat pumps in general. For example, Opinion Dynamics’ participant surveys [n=596] found that the TECH incentive was at least somewhat important to their purchase decision for 93% of customers, and that over 90% of respondents were satisfied with their contractor experience. This rapid feedback significantly helped inform ongoing program decisions. TECH is also working on data sharing arrangements with key market actors to obtain sales and product price data for the overall California heat pump market. Given the importance of this data to these companies’ business models, traction on this is still in progress and obtaining the data requires persistent and attentive negotiation.

With a data pipeline built atop the Incentive Clearinghouse, and integrated meter-based impacts and TECH Clean California participant surveys, TECH will publish data-driven insights to catalyze market transformation. These will be hosted on our public reporting website, which launched in July 2022. Hosting downloadable data and interactive data visuals, the public reporting site makes data engaging and impactful for both casual visitors as well as researchers. The site currently hosts application data from the several thousand market rate single-family projects that received TECH Clean California incentives since December 2021, and this data is updated monthly as more incentives are paid.

3. Key Lessons Learned

3.1. Balancing the need for scale with consistent funding streams

A key challenge for TECH was balancing its market transformation mandate to drive adoption and send clear market signals, with its incentive funding limitations. The enthusiastic overall response led to incentive
funding being suspended in much of the state by May 2022, well ahead of schedule but still at a pace far below the annual installation numbers and growth rates required to achieve the state target of six million heat pumps by 2030. While TECH funding provided incentives to over 20,000 projects and exhausted funds relatively quickly, over 500,000 water heaters and 500,000 furnaces or air conditioners are installed each year in California. The inherent trade off was that high incentives were needed to initially attract contractor attention and create the market shifts necessary to rapid uptake, yet, given the scale of the California market TECH did not have sufficient funding to move the market alone. To achieve the level of scale needed, incentives per project need to decrease over time and long-term sources of private and public investment are needed to sustain significant transformation. The 20,000 projects deployed through TECH data should provide a robust data set to inform development of a longer-term funding approach that aligns with California’s 2030 heat pump goals. As TECH integrates additional funding, the initiative will refine its offering by lowering incentives to match growing customer demand in support of market transformation.

As the number of incentivized technologies grows, and TECH gathers empirical data on their energy use, an analysis of what is driving — or impeding — heat pump adoption will become available. The first year of the program has produced key process-based lessons on the essential components of program design necessary to meet heat pump goals at the scale set by California.

3.2. Robust heat pump incentives drive the market

A market shift toward heat pumps will require large-scale shifts in equipment production towards lower emissions products. To ensure there is sufficient equipment supply and manufacturers are incorporating these decarbonization goals into their product roadmaps, it is critical that the state outline investment strategies commensurate with these goals to send a clear signal to supply chain actors. California has recently begun to step up its public investment in decarbonization: through equipment incentive programs like TECH and SGIP which will provide $80 million in incentives for HPWH; through incentives for all-electric new construction like the Building Initiative for Low-Emissions Development; and through the proposed $1 billion investment from the legislature to support equitable building decarbonization. However, the state should establish a clearer, long-term funding roadmap.

3.3. Consumer education and outreach is an important complement to incentives

TECH’s consumer education website and outreach efforts, through www.SwitchIsOn.org and its Ambassador Program, played a crucial role in supporting consumers at each point of the customer journey. The website achieved over 326,000 unique visitors and facilitated over 4,500 contractor quotes. Website visits scaled with project installations, with the most popular pages being the Rebate Finder tool and the Find a Contractor tool. Anecdotal evidence from contractors suggests that the website provided critical support for contractors to help educate prospective customers. In addition, the Ambassador Program, which focuses on individuals sharing their heat pump and home electrification journey with others, received over 100 initial ambassador volunteers throughout the state to promote and offer their experience as a resource to other prospective customers. These resources are particularly important when considering broader community engagement campaigns.

3.4. Providing statewide support and creating consistency among the many heat pump programs

There are many heat pump programs within California, and a project may be eligible for multiple programs based on its location. A large-scale, statewide initiative brings significant benefits by simplifying two key areas: contractor participation and general program communication. To simplify the contractor experience and eliminate the need for applying separately for multiple programs, TECH integrated its application process with other five additional heat pump programs. This layering approach enables multiple organizations to provide funding for a single product. This approach is particularly important for decarbonization measures, since the NOx, GHG, energy efficiency, and peak demand benefits may have different funders or organizations interested in those respective values. For example, an air quality management agency may be interested in NOx reductions, while a utility is focused on efficiency and peak load reduction. Additionally, incentive layering equips programs with funding that can tackle key barriers seen through the TECH pilots, such as remediation costs, bill impacts, or cost effectiveness for low-income programs or split incentive challenge for multifamily programs.
While streamlining multiple incentives provided benefits to create standardized incentive amounts across the state, there were significant implementation challenges due to differences in eligibility criteria. These differences made it difficult for contractors to understand which programs they qualified for. The difficulty in communicating consistent eligibility requirements across programs was a sufficient barrier that the TECH program decoupled incentives from multiple programs. That made it easier to communicate flat amounts provided by each program. Ultimately, TECH believes the best approach is having a robust statewide baseline incentive, sufficient to move the market, with as-needed supplemental incentives in areas to drive specific adoption. Numerous contractors noted that the statewide simplicity across utility borders was a major benefit and made participation more straightforward. Scaling heat pump adoption is a statewide priority and thus it makes sense to have a statewide initiative rather than a patchwork of smaller efforts. It also requires significant non-incentive market development efforts, such as workforce education and training, consumer education and data reporting, all of which benefit from economies of scale at the statewide level.

4. Conclusion

TECH Clean California has launched a combination of market incentives, supply chain engagement, workforce development, consumer education, regional pilots, and Quick Start Grants. TECH Clean California has resulted in the rapid deployment of heat pumps and has established data infrastructure to inform statewide consistency. Through these efforts, TECH Clean California has identified key lessons learned, including the effectiveness of incentives, importance of consumer and contractor engagement, and value of consistency among heat pump programs.

During the next year of TECH Clean California implementation, the focus of data reporting efforts will shift from building new infrastructure to scaling and improving the initiative. As the depth and breadth of the data increases over time, TECH will continue to refine its ongoing strategies to maximize impacts as well as conducting analyses that inform statewide decarbonization policies and investments. The initiative’s goal is to make application data and meter-based results for every TECH-funded project easily accessible and comparable, in one place, to showcase important differences between the various TECH Clean California programs, such as single-family versus multifamily projects. In addition to public data, TECH has also initiated a process of customized quarterly reporting for key heat pump manufacturers, giving them critical insight into TECH Clean California participation. Manufacturers are just one key consumer of TECH Clean California data, though, and it will be critical for TECH to strategize where and how the initiative focuses its analysis and outreach to meet the most important needs for decarbonization policymakers and investors.

Funded with an additional $50M through the California State budget, TECH Clean California will continue to enable the installation of zero-emissions space and water heating technologies and will collect and publish energy and GHG impacts with market data to inform California’s long-term decarbonization framework and beyond.

Abstract

The heat pump (HP) system is one of the environmentally friendly solutions to reduce the carbon footprint of buildings due to its high efficiency and low added initial cost from the cooling-only systems. This paper presents a literature review of the recent advances in HP systems applied in cold climate regions categorizing the systems into two major types depending on energy source types. The first type is the systems with an air source without additional energy sources, i.e., Air Source HP (ASHP) systems, which use various working fluids and configurations. However, several issues impede their widespread applications. When the systems are used for space or water heating in cold climates, ASHP systems suffer a high discharge temperature and pressure ratio at low ambient temperature, which leads to low efficiency and heating capacity. Furthermore, some researchers reported that the defrost penalty reduced the energy efficiency by up to 30\%, leading to a degradation of heating capacity by 43\%. The second type is the systems with additional energy sources, like solar-assisted HP systems, which can partly improve energy performance but have difficulties in coupling different sub-systems to achieve increased operational time and are limited to locations with enough solar radiation. This study identifies the future research directions as (1) developing multi-source heat pumps with efficient control; (2) utilizing waste heat for defrosting; and (3) optimizing HP configurations and minimizing refrigerant charge while achieving higher efficiency.

1. Introduction

A number of researchers have reported that the high energy consumption of the building sector is among the significant global challenges for sustainable human development [1]. Space and water heating take up more than half of residential energy consumption [2]. This ratio increases significantly in cold climate regions [3]. Over the last two decades, residential buildings have widely adopted Heat Pump (HP) systems due to their simple structure and low added initial cost [2]. Several different HP technologies exist. Air Source Heat Pump (ASHP) systems take low-grade heat from the air and produce high-temperature heat for domestic heating or other purposes [4]. Solar Assisted Heat Pump (SAHP) systems, which combine solar thermal panels with heat pumps, have been widely used to provide residential hot water owing to their simple structure, low cost, stable operation, and effective solar energy collection [5]. Ground Source Heat Pump (GSHP) and Water Source Heat Pump (WSHP) systems use heat energy naturally stored in either the ground or water, taking advantage of the

relatively constant temperatures of the earth or waterbody throughout the seasons [6]. However, there are many challenges when people are using HP systems in cold climate regions. This paper groups the so-called cold climate heat pump (CCHP) systems into two major types depending on energy sources for clear discussion. The first type is the systems with an air source only without any additional energy sources, i.e., ASHP systems. The second type is the systems coupled with additional energy sources, like GSHP or SAHP systems. This study summarizes the challenge of different HP types to penetrate the cold climate region application.

2. Challenges of Heat Pump Application in Cold Climates

Challenges exist for almost all current CCHP systems. First, typical ASHP systems work under a high discharge temperature and pressure ratio at low ambient temperature, which leads to low efficiency and heating capacity [7]. For instance, with a decline in ambient temperature, a decreased heating capacity of the ASHP system may be insufficient for the building’s heating load requirement, and the high compression ratio may lead to an extremely high discharge temperature and system shutdown. Furthermore, frost on the outdoor heat exchanger coil surface degrades thermal performance by reducing airflow area due to the blockage caused by the layer of frost [8]. Also, an insulating area is built up over the evaporator coils, thereby reducing their ability to absorb heat from the outdoor environment [8]. Defrost is a non-eligible problem in cold climate region. The heating COP would decrease by 30% if the heat exchanger was fully frost [9].

SAHP systems face challenges as well. The constant operation of the heat pump in the systems usually leads to a large carbon footprint, significant electrical energy use, and an energy inefficient operation [10]. However, owing to the fluctuation of solar radiation during the day time, the SAHP system may have a low efficiency without a proper control strategy or energy storage device [10]. As for the GSHP and WSHP systems, the installation region is restricted.

3. Air Source Heat Pump

Zhang et al. (2018) [2] reviewed the literature on vapor compression ASHP systems from 2005 to 2017 and classified the systems into single-stage, dual-stage, and multi-stage compression systems. They concluded that the quasi-two-stage compression system showed enormous potential for heating performance and initial cost. No similar study exists after Zhang’s work summarizing new CCHP techniques based on the authors’ knowledge. This section mainly focuses on reviewing the experimental studies conducted in the recent five years while comparing the new works with three old studies [11–13].

Table 1 summarizes the authors and some features of the target studies. In the “cycle type” column, “cascade” refers to two-stage systems using two separate compressors [14,15], while “VI” refers to the systems using the Vapor Injection (VI) technique. “-” in this column refers to single-stage systems. In the “discharge temperature” column, “-” means the information is not given in the related studies. Among the studies, Zhang et al. (2017) and Fan et al. (2022) [16,17] highlighted the need to reduce defrosting process power consumption in cold climates. Zhang et al. (2019) developed and investigated a novel thermal storage refrigerant-heated radiator coupled with an ASHP heating system. Zhang et al. (2017), Wei et al. (2020), and Wu et al. (2022) [16,19,20] examined the long-term performance of the ASHP system in the field test.

Fig. 1 plots these studies using the ambient temperature as the x-axis and COP as the y-axis. All points were tested under the same indoor condition (21 °C). The linear regression line of the data points shows that most of the ASHP systems can reach 1.5 COP under extreme conditions. One outstanding piece of research was carried out by Bertsch and Groll (2008) [11,12]. They applied a special low-pressure stage compressor with an oil tap in the VI system and mentioned that this compressor with a suction volume of approximately 90 cm³/rev was not commercially available, which might explain the impressive performance.

First, the data suggest that VI using R410A is the primary trend technique applied for cold climate ASHP system. However, the discharge temperature of the upper stage cycle typically exceeds 90 °C. Except for some limited studies, the COP limitation exists under the extreme ambient conditions of -20 °C to -30 °C. Second, frost-caused performance degradation is non-negligible [9]. Supplying an auxiliary heat source, e.g., an electric heater, seems necessary for cold-climate ASHP systems.

In summary, from the existing studies, the maximum COP of the advanced system under low ambient temperature conditions based on the published literature is still low from the viewpoint of the primary energy ratio. Secondly, its heating capacity deserves to be further enhanced to satisfy building heating loads, especially under extreme conditions. Finally, more research on the technology about system start-up at low ambient temperature and year-round control strategy is required to ensure the reliability of the advanced system.

4. Systems with additional energy sources

Some researchers identified the merits of SAHP systems as flexibility, efficiency, and stability in cold regions [23]. Others argued that cold regions in winter usually lack solar energy [7]. Many studies exist to improve the thermal performance of SAHP systems. Ji et al. (2008) and Fu et al. (2012) [24,25] optimized the structure of the solar thermal panels and evaporator; Zhang et al. (2014) [26] studied the optimal geometrical sizes and capacity; Gorozabel Chata et al. (2005) and Kong et al. (2017) [27,28] concentrated on the refrigerant type; Chaturvedi et al. (1998) and Kong et al. (2018) [29,30] focused on the control strategy for compressor and electronic expansion valve, and Chaturvedi et al. (2009) [31] combined the cascade structure with Thermal-SAHP water heater to reach higher supply temperature. Nevertheless, none of the research mentioned how their proposed system could match the requirements under low ambient temperature or radiation conditions. Qiu et al. (2018) [32] investigated a low-temperature heat-collecting system and got a simulation COP result of only 1.6 at -25 °C ambient temperature and 200 W/m² solar radiation intensity. Only limited scholars studied combined photovoltaic-thermal (PV/T) SAHP (air-source). Li et al. (2015) [33] developed a mathematical model of a PV/T-SAHP system and optimized the flow distribution and velocity to reach the COP as high as 4.6 at 10 °C ambient conditions. However, this result was given with 400 W/m² radiation, and the authors also mentioned that the performance could reduce to 21% when the outdoor air temperature was -5 °C. Cao et al. (2016) [34] simulated a PV/T-SAHP performance using Computational Fluid Dynamics (CFD). The COP could reach 3.5 when the ambient temperature was around 0 °C. However, they did not study the performance under further lower temperature conditions.
A comparative study of different seasonal Thermal Energy Storage (TES) systems using HPs with solar collectors identified the heat pump’s COP and the solar fraction as the main factors that influenced the efficiency of the system, with both factors being a function of the collector area and storage volume [35]. Pensini et al. (2014) [36] undertook an economic analysis of using excess renewable energy for heating purposes, and reported that HPs with centralized thermal storage met heat demand at lower costs than conventional systems even if there was a charge for producing excess renewable energy. Kapsalis and Karamanis (2016) [37] considered solar TES and heat pumps with Phase Change Materials (PCMs) and concluded that further investigation and experimental work were necessary to determine the combined effect PCMs in building components and HP operation within different climates.

This section discussed the merits and limitations of SAHP systems in cold regions. Several studies have been conducted to improve the thermal performance of SAHP systems. SAHP could improve the COP in cold regions with high solar radiation, but the benefit is limited in low solar radiation regions.

4.2. Ground Source Heat Pump

It was reported that Ground Source Heat Pump (GSHP) systems have relatively stable performance throughout a year but can only be installed at specific locations [38]. One study shows that such systems are 40% more energy efficient than ASHPs [39]. Huang et al. (2019) [40] reported that the GSHP system had higher installation costs but higher energy efficiency and 10% lower costs across 10 years. Direct expansion GSHPs, a variant of the common GSHP that uses a buried copper piping network through which refrigerant is circulated, can deliver superior performance relative to GSHPs and ASHPs in Canadian and Chinese locations [41,42], Mattinen et al. (2015) [43] compared carbon emissions across direct electric heating, ASHP, and GSHP systems and found that GSHPs perform better in colder climates due to higher COP at lower outdoor temperatures. Carbon emissions in ASHP systems were 40% lower than direct electric heating and 70% lower in the GSHP system. From an emissions perspective, this makes GSHP systems the best option; however, reducing emissions is only possible if the heat pumps are integrated with low-carbon power systems. Otherwise, deploying large quantities of heat pumps in a power system where there is a low level of decarbonization of electricity generation merely results in shifting emissions from one sector to another. Wu compared ASHPs with GSHPs and concluded that GSHPs have the advantages of higher efficiency; lower life cycle cost; lower impact on environment; and better reliability [44]. Safa et al. got a result that for cooling mode, the COP of ASHP ranged from 4.7 to 5.7 at an outdoor temperature of 33 °C and 16 °C respectively, while the COP of GSHP ranged from 4.9 (at an ELT of 8.5 °C and EST of 19.2 °C) to 5.6 (at an ELT of 12.4 °C and EST of 17.8 °C) [45]. Garber et al.’s results of the analysis show that potential savings from a full-size GSHP system largely depend on projected HVAC system efficiencies and gas and electricity prices [46].

This section summarizes that GSHP systems can be more efficient than ASHP systems. However, their emissions benefits are only realized if they are integrated with low-carbon power systems.

4.3. Water Source Heat pump

Water source heat pumps (WSHPs) use lakes, ponds, rivers, groundwater, and other water sources, as a source of heat. They convert low-grade heat from the water source to a higher grade. The temperature of the waterbody fluctuates less than that of air; thus, the performance of WSHP is relatively stable. Bach et al. (2016) [47] from Denmark found the seasonal variation of COP had little or no impact on the transmission and distribution networks of the district heating system, as COPs of WSHPs did not vary much throughout the year. Thus, such systems can work well in cold weather. However, WSHP applications are limited due to the requirement of large water bodies or storage tanks near dwellings. Moreover, the need to adhere to specific environmental regulations may further result in a low uptake rate of WSHPs.

5. Discussion

5.1. Existing studies

First, based on existing literature for ASHP systems, the two-stage compression system shows tremendous potential for performance and cost [2]. Furthermore, Table 1 suggests that VI systems using R410A are the main trend technique. However, the discharge temperature of the upper stage cycle was usually high. In addition, the COP of all the systems is still a bit small from the viewpoint of the primary energy ratio. The
defrost power consumption, low-temperature start-up technology, and year-round control strategy are significant but are seldom mentioned in current published literature.

Some studies concluded that SAHP and GSHP systems are better options than ASHP systems in colder regions [4]. However, the type of heat pump to be installed is location and application specific. This is due to the concern that ASHPs may not be able to meet the thermal comfort and energy efficiency requirements when ambient temperatures are immensely low. The requirement of solar radiation, ground thermal sources, and other environmental concerns limit SAHP, WSHP, and GSHP systems’ overall uptake rate.

5.2. Current Barriers

Several issues that impede the widespread of above applications still exist: 1) the lack of clear decarbonization pathways, technology acceptance, and funding are the primary sources of barriers to cold climate heat pump uptake [48]; 2) public acceptance and awareness issues, i.e., emanate from unwarranted fear, misperception, misinformation, and previous experiences on the reliability, also pose significant challenges in adopting the new technology [49]; 3) existing market structures combined with public perception can also hinder the penetration of cold climate heat pumps [50]; 4) barriers related to lack of standards and mandatory policies can also considerably constrain some special HP systems deployments, like GSHP and WSHP [51]; 5) an essential barrier to widespread adoption of heat pumps in cold climate is the limitation of the electrical network, which may be further increased at peak periods and in turn may require additional electricity grid infrastructure investment to satisfy the demand [52]; and 6) proper sizing and installation of a heat pump is essential in order to achieve the desired design objectives and overcome the barriers to widespread adoption.

5.3. Future work

The future research directions were identified: (1) multi-source heat pumps, for example, the systems using both solar energy and ground source energy, could be proposed; for these systems, an efficient control to coordinate each part is necessary; (2) waste heat or low-grade heat shall be used for heat pump defrosting in cold climate regions; identification of more heat source other than the ground source or water source could be investigated; (3) people may also study advanced heat storage technology and heat exchanger design strategies; and (4) researcher may continue to optimize the configuration and refrigerant usage to achieve low discharge temperature in cold climate heat pumps.

6. Conclusions

Due to the great efficiency and minimal added initial cost compared to cooling-only systems, HP systems are one of the ecologically sustainable ways to lower the carbon footprint of buildings. In this research, the HP systems are divided into two main categories depending on supplementary energy sources, and current HP system developments for cold climate regions are thoroughly assessed. Following is a list of the conclusions:

The two-stage compression system shows tremendous potential for performance and cost, and VI systems using R410A are the primary trend technique for ASHP systems. However, the discharge temperature of the upper stage cycle was usually high. In addition, the COPs of all the systems are still a bit low from the primary energy ratio viewpoint.

Some researchers reported that the defrost penalty reduced energy efficiency by up to 30%, leading to further degradation of heating capacity by 43%. Thus, defrost is a non-negligible factor for CCHP application.

Low-temperature start-up technology and year-round control strategy are significant but are seldom mentioned in published literature.

Some studies concluded that SAHP and GSHP systems are better options than ASHP systems in colder regions. However, the type of heat pump installed is location and application specific. This is due to the concern that ASHPs may not be able to meet the thermal comfort and energy efficiency requirements when the ambient temperature is immensely low. The requirement of solar radiation, ground thermal sources, and other environmental concerns limit SAHP, WSHP, and GSHP systems’ overall uptake rate.

Current barriers to CCHP systems include policy limitation, public acceptance, economic reasons, a lack of standards and funding, and insufficient studies on an electronic network.
Future research should focus on the following topics: (1) multi-source heat pump with effective control; (2) heat pump defrosting capability utilizing waste heat; (3) advanced Heat Storage and Heat Exchange Unit technology; and (4) optimized structure and refrigerant usage to obtain low discharge temperature.

Abstract

Gas absorption heat pumps (GHP) are an emerging class of high efficiency heating equipment that upgrade low-quality ambient heat via an ammonia-water absorption process. This technology can reduce fuel consumption of space heating systems served by furnaces or boilers by 35\%-55\%, with rated seasonal heating efficiencies of 140\% AFUE or greater, based on the application and climate region. GHPs are commercially available, but the commercial space conditioning market adoption is low due to the upfront investments and a lack of installation and maintenance experience. Drawing from multiple case studies, the authors explored the implementation of heat pumps in cold climates for water heating and / or hydronic space conditioning applications. This paper summarizes important design considerations, installation best practices, controls, commissioning and lessons learned from successfully integrating GHPs into hot water plants, often with existing equipment to boost overall plant efficiencies.

Keywords: Gas Absorption Heat Pumps; Reversible Cycle; Space Heating; Space Cooling; Chilled Water; Service Hot Water; Ammonia Absorption Cycle; Combination Heating Systems;

1. Introduction

Commercial space conditioning (heating, cooling and ventilation) accounted for about 7.0 quads per year, or about 40\% of total commercial energy use, in terms of primary energy consumption, in the United States [1]. Per a 2018 survey of commercial buildings [2], total number of buildings increased 6\% from 2012 to 2018 or about 11\% increase in floorspace. By 2050, commercial building floor space is estimated to reach 124 billion square feet, or a 33\% increase from 2020 [3]. Natural gas or electricity was the primary fuel source for commercial space heating, while electricity was primarily used for cooling. Packaged heating units and furnaces were used to condition 50\% of commercial floor space, boilers accounted for 30\% and heat pumps accounted for 15\%. For commercial space cooling, packaged A/C units conditioned 58\% commercial floor space, central chillers accounted for 19\% and heat pumps accounted for 12\%.

EIA forecasts short term commercial electricity pricing to increase from 11.27 cents / kWh in 2021 to 12.23 cents in 2023. Natural gas spot pricing is expected to remain high into early 2023, due to lower than average natural gas inventories. Rapid electrification of buildings to achieve decarbonization and sustainability goals may increase grid reliance from 20\% to 50\% [4]. As systems decarbonize and shift towards pumped hydroelectric, wind, solar, battery storage, etc., there will be a renewed reliance on natural gas to provide peak load balancing to allow for this transition to be seamless. The above factors may contribute to higher prices for commercial space conditioning.

Conventional fuel fired heating systems such as gas fired furnaces and boilers have approached their thermodynamic limit over the past few decades. Electric heat pumps are highly efficient and have been growing in popularity (where electrification for existing buildings is economically feasible), but their heating performance in cold climate retrofits is low [5]. Additional barriers include high capital and maintenance costs of equipment [7] and associated electric infrastructure upgrades, and challenges in maintaining SHW supply temperatures at peak winter conditions.

Gas absorption heat pumps (GHPs) are an emerging class of high efficiency Thermally Driven Heat Pump (TDHP) equipment that upgrade low-quality ambient heat via an ammonia-water absorption cycle process. This technology can reduce fuel consumption of space heating systems served by furnaces or boilers by 35%-55%, with rated seasonal heating efficiencies of 140% AFUE or greater, based on the application and climate region [8]. GHPs also employ internal heat recovery for coil defrost such that the Coefficient of Performance (COP) and output capacity reduction at low ambient temperatures is less significant when compared to other heat pump technologies. In a study of ammonia absorption cycle heat pump installs across multiple types of commercial buildings in the US Midwest and Canada, TDHPs have shown a consistent Coefficient of Performance for Gas Consumed (COPg) of >1 in cold climate installs. Despite the benefits outlined above, and the commercial availability of GHPs, integration and adoption of GHPs in the commercial space conditioning market is low.

2. A Summary of GHP Integration Strategies with Water Heating, Space Heating, Combination, and Space Cooling Systems

This section aims to assess and summarize key aspects of a hybrid GHP-Boiler integration into water heating and/or space conditioning systems. The term ‘Hybrid’ here refers to a combination of 2 heating sources. Information such as the site selection process, capacity sizing and storage design considerations, construction and commissioning, controls integration, and operational lessons learnt are also discussed.

2.1. Hybrid GHP-Boiler Integration in Combination SHW Systems

The Toronto Atmospheric Fund’s case study [9] in association with a local utility selected a social housing complex in Toronto, ON, Canada to demonstrate GHP integration into a gas-fired SHW and space heating system to maximize emissions reductions.

Existing Conditions: The existing oversized boilers provided both space and SHW heating at an average of 54% TE (thermal efficiency) baselined through a 12,133-liter SHW storage tank.

System Design and Sizing: Two (2) heating only GHPs with a heating capacity of 36.2 kW were selected through a SHW system modelling approach to provide 58% of the overall SHW capacity, while also being able to handle 100% of the baseload non-peak demand at a 54 °C SHW setpoint. A brazed plate and frame double-walled heat exchanger (PFHX) separated the glycol and potable water systems, and supplemental SHW and space heating demand was met by a pair of high-efficiency condensing boilers. Since GHPs are installed in unconditioned or exterior spaces exposed to weather elements, a water-glycol mixture was used as a heat transfer medium to prevent freezing of pipes. The equipment manufacturer provided performance correction factors which were utilized during the design and selection process. Although, these correction factors were developed only under an ambient temperature of 35°C and a supply water temperature of 6.6°C. It would be helpful to explore capacity correction factors under a range of glycol operating temperatures in the future.

Modelled seasonal efficiency of the condensing boiler and GHP system providing SHW and space heating was expected to reach 110%. The study restricted the GHP sizing to two (2) units only due to space constraints in the mechanical room, and to reduce construction costs required to install equipment on the roof. In addition, utilization of the ‘N’th unit would be limited to peak SHW load conditions only. The installed system configuration and associated monitoring devices is shown in Figure 1.
System Performance: GHP performance was represented using the COP measure as shown below.

\[
COP = \frac{\text{usable heat supplied by GAHP}}{\text{natural gas consumed} + \text{electricity consumed by GAHP}}
\]

The study achieved a mean (averaged during cooler weather operation) COP of 1.14 and at an average GHP Supply Water Temperature (SWT) of 46.6 °C. When the Outside Air Temperature (OAT) fell below -12 °C, COP fell below 1.0. It is important here to understand the GHP’s cold climate performance to contextualize its COP. This heating only GHP (36 kW, 6°C ambient, 50°C outlet temperature) is a commercially available product developed by Manufacturer A and works on a Generator-Absorber Heat Exchange (GAX) cycle and does not modulate in capacity. Figure 2 shows the performance impact of manufacturer A’s product due to OAT under laboratory test conditions. The mean COP achieved in this case study was realistic due to variabilities in the field such as glycol percentage, system flowrates, cyclic operation, etc, which may impact performance. Also shown is the laboratory tested performance of a product from Manufacturer B. This was a prototype operating on a single effect direct fired ammonia absorption cycle with capacity modulation, but was not commercially available at this time.

Figure 2. Comparison of Laboratory Performance of two GHPs at different Ambient Temperatures [10]
Operational Challenges and Lessons Learned:

1. Boilers were manually operated for two weeks which resulted in high Return Water Temperatures (RWT) that were close to or exceeded the GHP RWT limit of 50 °C. This error in sequencing impaired the operation and performance of the GHPs.

2. During periods of no SHW demand, or when the RWT exceeded 50 °C, the GHPs and their associated glycol circulation pumps were sequenced to shut down. Unfortunately, the GHP flow switches would trip due to premature stopping of the circulation pumps thereby transferring SHW heating load to the backup boilers. This issue was resolved by sequencing the pumps to shut down only after the GHPs stopped consuming electricity.

3. SHW use at the site resulted in fluctuating utilization of the GHP capacity with peak SHW use occurring between 8-10am, and a second peak occurring between 4-6pm. Hourly average capacity utilization was 40% and peaked to 61% at 9am. Capacity utilization of the GHP was lower than pre-installed modelling where it was expected to meet 100% of the daily-off peak loads. To address this underutilization, the GHP will be prioritized when there is an SHW demand instead of calling for heat from the GHPs and boilers simultaneously. This is expected to increase GHP utilization in summer, but not during the shoulder and winter seasons since the boilers will be operational at colder ambient temperatures.

4. When specifying equipment, it is important to determine the % glycol in the glycol-water mixture and apply performance correction factors. An optical refractometer is recommended for this purpose.

2.2. Hybrid GHP-Boiler Integration with a Re-designed Buffer Tank in Combination SHW Systems

GTI Energy’s (GTI) study in association with NEEA [11] selected a multifamily residential site in Evanston, IL to demonstrate GHP integration into a gas fired SHW and space heating (or combination) system. The GHP was a prototype developed by manufacturer B (see Figure 2 above) and tested under laboratory conditions [8].

Existing Conditions: One (1) existing oversized non-condensing 80% TE boiler (123 kW) provided both space and SHW heating to six (6) housing units. Daily SHW load is approximately 757-946 liters/day.

System Design and Sizing: Analysis of past utility bills estimated the baseline boiler to have only 6-8 equivalent full load hours (EFLH) during peak winter conditions. During summer with SHW loads only, peak load was estimated as 879.3 kW/day. One (1) heating only GHP with a heating capacity of 23.4 kW, 4:1 modulation, a peak delivered temperature of 73.8 °C and active defrost was selected. If the GHP was expected to meet 40% of SHW load assuming a COPg of 1.10 during peak winter conditions, it yielded 20 EFLH which indicates the GHP may be well sized for this application. A brazed plate double walled PFHX separated the glycol and potable water systems. A buffer tank was designed and installed as a ‘volume’ where the GHP loop and the main return loop mixed to preheat cold service makeup water through a coil, to avoid cyclic GHP operation. The existing oversized boiler was replaced with two (2) 84% AFUE and 58.6 kW boilers. One boiler was installed in series with an indirect storage tank to handle SHW loads, and both boilers can provide full redundancy to the GHP. A dedicated Plant Controller was installed and configured to stage the GHP and Boiler operation based on RWT, Space or SHW demand, and OAT reset. Details of the control strategy were published [8] and the installed system configuration is shown in Figure 3.
**System Performance:** At steady state operation under laboratory conditions (50% fire, ambient 0°C, 49.4°C RWT), COP was measured at 1.20. This demonstration saw a COP of 1.24 under steady state field conditions. During a 13-day continuous operating period between February and March 2020 of the GHP, where RWT is above 51.6 °C and close to maximum operating capacity, the GHP’s efficiency was close to the laboratory measured COPs of 1.12 at -10 °C and 1.32 at 8 °C [8]. The system efficiency formula is below:

\[
\text{System Efficiency} = \frac{\Sigma (Q_{\text{Hydronic,THP}} + Q_{\text{Hydronic,Boiler1}} + Q_{\text{Hydronic,Boiler2}})}{\Sigma (Q_{\text{NG,Boilers}} + Q_{\text{NG,THP}} + Q_{\text{Elec,Pumps}} + Q_{\text{Elec,Boilers}} + Q_{\text{Elec,THP}})}
\]  
(2)

\[
\text{COP}_{\text{gas}} = \frac{\Sigma (Q_{\text{Hydronic,THP}})}{\Sigma (Q_{\text{NG,THP}})}
\]  
(3)

Despite this room for optimization, the projected annual therm savings and GHG emissions reductions were estimated to be 43% for SHW mode and 41% for combined space heating and SHW mode for the GHP/boiler system over the original equipment, or 24% for the compact boiler only architecture. Using the rated 80% TE as the baseline, this corresponds to a hybrid GHP/boiler system delivered efficiency of 136%. On financial payback for the 2835 therms saved/year, at $0.76/therm this system as installed with two compact boilers would have a 4-year payback, or 1.3 years for an optimized system with a single boiler.

**Operational Challenges and Lessons Learned:**

1. This was a 1st of its kind demonstration of GHP-Boiler integration to multifamily hybrid combination systems with a new product developed by the manufacturer and GTI and tested through this field demonstration. The GHP underwent repairs and a full replacement due to unique failure modes caused by excess wear and tear of the prototype GHP leading to service interruptions. Subsequent design improvements were undertaken on key components (such as the solution pump). The project team recommissioned the system as of spring 2022 and will monitor performance for one (1) year.

2. A parallel study by GTI to utilize GHPs for SHW in full-service restaurants identified a sweet spot for sizing the GHP to carry 30%-60% of peak water heating demand.

3. Capacity and efficiency loss are often a strong function of higher RWTs. High RWTs also lead to high-limit shutdowns, thereby reducing utilization of the GHP. Use of variable speed circulation pumps and a reduced boiler reset temperature setting can help with lowering RWTs.

4. Design and sizing of buffer tanks is critical to manage the high thermal inertias associated with GHPs, variable SHW loads and to smooth out cyclic GHP operation. Depending on GHP size, technology and setpoints, GHPs can require between 5 – 15 minutes to reach steady state capacity and efficiency.
5. The original piping scenario was designed so that the backup boilers would be installed to serve the main space heating loop and the indirect water heating tanks. The GHP would still be installed outdoors and the glycol and service hot water loops would be separated by a PFHX. The first zone is the higher priority water heating tank, and the return is mixed with the main return line. The second zone is the buffer tank, which allows the GHP to preheat return water to the boilers. An alternate layout includes all the above but includes a second PFHX that allows the GHP to heat the SHW directly and is shown in Figure 4. The team identified pitfalls with both layouts:
   a. Combination operation could lead to warming up the RWT as the indirect SHW tank warms up, which would lead to premature shut downs.
   b. In space heating only mode, as the circulation pumps cycle, adverse mixing on the hot and cold sides of the PFHX would hurt the GHP performance due to temperature swings in the buffer tank.
   c. For SHW only, since the feed water to the indirect water heater tank is a mix of cold water and building recirculation, RWTs to the GHP PFHX would be warm / hot

These issues led the team towards the piping design described under “System Design and Sizing”.

**TDHP-Based System (Alternative)**

Figure 4. Preliminary Integrated GHP-Boiler Combination Piping Layouts

### 2.3. Hybrid GHP-Boiler Integration in SHW Systems, with future Space Heating Considerations

Building Energy Solutions Ltd. (BES) and Fortis BC collaborated on a measurement and verification study to investigate the performance of GHPs integrated into SHW systems at five (5) multi-unit residential buildings in Canada. This paper reviews the work performed at site #4 (site numbers designated by the study). The results of the study will be published by the authors at a later date.

**Existing Conditions:** The SHW system consists of one (1) existing standard efficiency (80%) boiler with a 296 kW capacity, a separate standard efficiency (80%) SHW boiler with a 116.9 kW capacity, and a 435-liter SHW storage tank. The project team estimated that the actual boiler operating efficiency of both boilers was between 65% - 79% based on a number of factors including submetering of boiler input and output parameters, independent flue gas analysis, age and condition of the boilers, and losses in efficiency due to cyclic operation.

**System Design and Sizing:** Historical gas utility data was weather normalized over a 10-year period (2008-2018) to determine baseline SHW consumption. Since natural gas is used for space and SHW heating, a baseline average of historical gas consumption during summer months was calculated for sizing considerations. The design team developed and built a prefabricated skid that housed the double wall heat exchanger, pumps and control valves, and the skid was installed within the mechanical room. Two (2) heating only GHPs from manufacturer A with a combined capacity of 76.2 kW were installed on the roof with reinforcement. One of the existing SHW storage tanks was replaced with a similarly sized preheat buffer tank.
with an internal heat exchanger. Per local building codes, SHW must be heated to 60 °C prior to consumption to eliminate harmful bacteria. A 3-way control valve was installed to bypass the existing hot water boiler when the GHPs were operational to prevent internal corrosion of the standard efficiency boiler’s tubes. The project team installed advanced controls to automatically sequence, schedule and change setpoints of the integrated systems to boost energy savings and efficiencies. The installed system configuration is shown in Figure 5.

![Figure 5. GHP Integration into an existing combination system](image)

**System Performance:** The GHP was able to operate efficiently in heating mode between 15 °C - 17 °C ambient air temperatures due to the high heating load requirement of the building below these temperatures. i.e., the output of the GHPs was approximately 25% of the output of the existing SHW boiler. A 15.7% reduction in the site’s SHW natural gas consumption and a 8.9% reduction in space heating natural gas consumption from baseline was achieved when test results were extrapolated over a full year. The project team attempted to right-size the GHP capacity by using one of the two installed GHPs to handle SHW demands. A 19.0% SHW gas consumption savings was achieved through this effort. In addition, with a differential temperature of greater than 2°C across the GHP, the average COP was measured at 1.14. At differential temperatures greater than 8°C, the GHP can achieve a COP of 1.2 to 1.4.

**Operational Challenges and Lessons Learned:**

1. The project team installed two (2) gas meters to measure consumption for the site versus the GHPs respectively. There were inconsistent readings between the site versus GHP gas flowrate measurements which pointed to data collection and instrumentation errors. In a similar vein, a few sites within the demonstration’s portfolio of test sites had 0.1-meter diameter SHW flow meters installed, which was unable to record flowrates below 227 liters/min. Unfortunately, these factors limited calculation of the system efficiency. For critical parameters, it is important to use high accuracy sensors with the right measurement ranges and calibration certificates.

2. Standard efficiency boilers are on average 80% efficient per their nameplates. Based on the age and condition of the boilers, the baseline efficiency of the boilers at full fire was determined to be between 70% - 78%.

3. Efficiency of the GHP is strongly tied to the SHW load profile, which is typically intermittent. Maintaining a large and sustained temperature differential across the GHP (greater than 2 °C) helps boost efficiencies. Right sizing of the GHP is also very important to improve response times and the temperature differentials.

4. The project estimated a 3.7% thermal efficiency loss occurs across the heat exchanger between the glycol loop and SHW loop. Other sources of efficiency loss included the use of glycol in the loop and...
the inadvertent effect of short cycling of the existing boiler under reduced load (~>10%) due to introduction of the GHP for SHW heating. Short cycling significantly reduces efficiencies especially for boilers with limited turndown ratios.

5. The project determined that replacing the existing standard boiler with a minimum 5:1 modulating condensing boilers and improving system sequencing controls as detailed on point #6 could achieve an overall system COP of above 1.0. Introducing condensing boilers can eliminate corrosion concerns thereby modifying the system to a hybrid configuration where the GHP can meet stage 1 demands. In addition, integrating GHP operation with smaller and more consistent heating loads such as Make-Up air handling unit coils or swimming pool heating could allow the GHP to operate for longer periods, thereby improving the COP. This would require additional system design / controls considerations which BES and Fortis BC are exploring in the next phase of their pilot study.

6. Important control parameters for the GHP system are the heating temperature setpoint and the deadband. ‘Deadband’ is the difference between the supply water temperature when the system cycles off, and the return water temperature when the system cycles on and can vary between products and for a given product-based controls. The heating outlet temperature limit of a GHP is generally between 55 °C – 58 °C. The GHP would shutoff due to internal limits before it approaches 60 °C supply water temperature.

2.4. Hybrid GHP-Water Heater Integration with a Space Cooling Application

GTI in association with the California Energy Commission [6] demonstrated a low-cost gas-fired heat pump integrated with existing commercial water heating and air-conditioning at two (2) restaurants in Los Angeles. The commercial restaurant sector consumes more natural gas per square foot than other commercial building types, with water heating being the largest thermal load. With condensing efficiencies being the ceiling for water heating technologies, the project looked towards deploying gas-fired GHPs. GHPs had the ability to operate at 140% or greater efficiencies and reduce gas consumption by 43% [12]. In addition, GHPs could displace up to 20% electricity demand for air conditioning providing greater operational savings. The project team assumed that an added 0.5 – 2.2 tons of cooling capacity could be useful in all instances with the range dependent on the GHP modulation. Los Angeles has only 1,200 heating degree days per year on average and the internal loads in the kitchen are expected to demand cooling year-round.

Existing Conditions: Depending on SHW loads and redundancy requirements, typical restaurants have one or two hot water heaters with integrated or external storage tank(s) and a recirculation loop to provide 60 °C SHW for kitchen operation. HVAC equipment should be sized to handle high ventilation loads and internal heat gain totalling to 5-7 times greater energy consumption than other commercial building types. This paper reviews the work performed at site #1 (site numbers designated by the study). Site #1 has two identical storage type 82% TE gas-fired water heaters (79.1 kW input) with 378 liters of storage each. Site #1 consumed 10,290 liters on average of SHW per day, with a peak of 14,142 liters, and a peak flowrate of 45 lpm. The annualized gas input was 875.5 GJ at an average delivered efficiency of 70%. Space conditioning is provided by five heat pumps of 17.5 kW capacity each and one RTU of 44 kW capacity. Weather normalized power demand for the RTU was estimated to be 79 MWh.

System Design and Sizing: A 23.4 kW output GHP, a 427.7-liter indirect storage tank, associated piping and controls were assembled on a 1.2 m x 2.4 m skid to allow for ease of install and maintenance. The GHP skid was installed to act as a preheater for the existing gas fired water heaters. This system was sized and controlled to be SHW demand led, with the GHP carrying most of the SHW load and the gas fired water heaters handling peak loads. For space conditioning, an indoor fan coil unit was sized to deliver 9.3 kW/h and installed in the kitchen which typically experiences year-round cooling requirements. The installed system configuration is shown in Figure 6Error! Reference source not found.
System Performance: The GHP system operated for 4,790 hours and 1,150 cycles through a 1-year monitoring period. The project recorded a heating only COPg range of 1.10 - 1.30, and a heating / cooling COPg range of 1.30 - 1.70. Figure 6 shows the projected delivered efficiencies of the GHP system and the integrated system (GHP + Existing Gas Water Heaters). Ambient temperatures for the site varied between 1.6 °C - 43.8 °C. Use of the retrofit space conditioning system yielded a 14% electric saving (10,820 kWh/year). The GHP carried most of the SHW load through the day, which was approximately 30-60% of the total SHW load.

Operational Challenges and Lessons Learned:
1. Skid assembly and pre-shipment preparations included development of contractor training materials and instructions to ensure a smooth install and on-site commissioning.
2. The GHP skid was to be installed beside an exterior parking space or on the rooftop due to the lack of extra space within the mechanical room or the roof. To minimize hot water piping to the indirect storage tank and chilled water lines to the FCU, an alternate location closer to the water heaters was chosen. Although, the manufacturer required clearance / setback to install a portion of the evaporator coil was not achieved which limited the airflow thereby reducing performance of the GHP.
3. The GHP and FCU were integrated with glycol and chilled water lines respectively. The host site expressed concerns with the glycol mixture’s proximity to the cooking areas due to potential leaks. Unfortunately, the final placement of the FCU was less useful in improving thermal comfort of restaurant employees as they were not directed at portions of the cookline and food preparation areas. Although, as discussed in the “system performance” section, there was a 14% reduction in AC kWh usage for a year-round cooling requirement. In addition, the chef and cooks provided positive feedback on the retrofit AC’s functionality.
4. The length of and restrictions within the FCU Chilled Water loop prevented the installed system from reaching its designed chilled water flowrates as recommended by the manufacturer. Supplemental A/C effectiveness was further reduced due to a lack of effective air removal from the hydronic loops during routine service. Site #1 achieved only 55% of the target CHW flowrate.
5. Nuisance “blocked vent” errors caused early interruptions of GHPWH operation. Issue was resolved when vents were properly sloped for condensate disposal.
6. Due to prototype status of this product from manufacturer B, hardware / software issues were identified during operation and resolved. The first issue was with a faulty startup capacitor which stopped condenser fan motor operation. The fan motor was replaced, and the issue did not recur. Second, the solution pump showed signs of wear on the bearing which required a pump replacement. Third, over the course of the 12-month study, the evaporator coil had accumulated excessive dust /
lint due to site conditions. Exterior fouling was addressed by simply hosing down the coil. Each issue was identified and rectified with the manufacturer, and design improvements were recommended.

3. Conclusion

With the push towards electrification and decarbonization in a steadily growing commercial building market, it is important to integrate high efficiency heating technologies such as GHPs into water heating or space conditioning systems. Utilities are already using natural gas fired plants to meet increased electricity demand due to electrification of water and space heating systems. Extreme cold and hot weather events can also trigger unexpected spikes, grid instability, and power outages. Depending on the geographic fuel mix for electricity generation, the consumer may pay more for electricity consumption and demand. GHPs can help flatten peak electricity demand especially during the heating season and maintain efficiencies above conventional heating systems. GHPs can also serve as a drop-in replacement for conventional boilers / water heaters and require minimum updates to existing infrastructure. However, attention must be paid to critical design considerations and integration strategies for a successful deployment of GHPs.

This paper summarizes key design considerations and operational lessons learned from four (4) field demonstrations across North America, with a few aspects highlighted below:

- Existing SHW or Combination systems typically have an oversized 80% TE non-condensing boiler with redundant capacity. SHW systems also have large storage tanks and variable demand through the day which lead to the boilers cycling and hence reduce overall system efficiency.
- A retrofit GHP system can be sized to meet baseload non-peak demand with supplemental heating provided by existing boilers. Design and right-sizing can also consider analyses of past utility bills, sub metered / monitored data for a range of OATs and building loads, results from system modeling, capacity correction factors when using a glycol-water mixture and utilization of a heat exchanger internal or external to a buffer tank (review manufacturer published recommendations for buffer capacity). OAT reset controls for space conditioning systems must consider the GHP’s SWT limit of 60°C and RWT limit of 50°C. GHPs must be installed exterior to the building with adequate access and clearances provided.
- A majority of lessons learned are from implementation of control parameters / limits used to stage the hybrid heating plant. GHPs must be prioritized to handle baseload and to maximize runtime (reduce cycling). Controls for ancillary equipment such as 3-way control valves and circulation pumps must be commissioned on a system level to prevent premature shutdown of GHPs. Other mechanical and plumbing considerations are to maintain appropriate slope for condensate vents, clean condenser coils prone to fouling due to dust, and install air removal vents at high points of hydronic systems.

The authors hope to provide a roadmap to design, install and operate hybrid heating systems with heat pumps, which would ultimately increase adoption of this emerging technology.

Abstract

Residential space conditioning and hot water loads in the US are typically decoupled and served by separate equipment. A residential home in four and above IECC climate zones can have two to three systems, typically a gas furnace for space heating, a gas-fired storage water heater, and an electric air conditioning (A/C) unit for space cooling. The decoupled nature of these individual systems prevents the units from working in a tandem nature, limiting the benefit of shared system costs and internal heat recovery. In addition, gas-fired furnaces and water heaters operate at less than 100% thermal efficiencies, insufficient for most CO2 emission reduction schemes. This manuscript summarizes data and key findings from the laboratory evaluation of a hybrid heat pump, a packaged Thermal Heat Pump (THP), and an Electrical Air Conditioning (EAC) unit for the combined operation of space conditioning and water heating. The packaged heat pump prototype achieved an AFUE of 121.6% and SEER of 8.

Keywords: Gas Absorption Heat Pump; Electric Air Conditioning, Space Conditioning, Water Heating, Packaged Heat Pump

1. Introduction

The annual heating needs are more significant than the yearly cooling needs for residential buildings in most climate regions in the US [1]. Gas-fired appliances predominantly provide US residential space and water heating. As of the 2018 EIA report [2], more than 26 million homes in the cold climate regions of the US are heated by gas-fired furnaces, water heaters, and boilers. These gas-fired appliances have approached their thermodynamics limits in terms of efficiency (<100%), and any further improvements will have diminishing returns. The most recent residential energy consumption survey data highlighted that the total natural gas consumption for residential space and water heating is 38 billion therms, 68% of all residential heating in the US [2]. Natural gas is primarily consumed in cold and very cold climate regions, with more than 5,400 heating degree days (HDD) and more than 9,000 HDD, respectively.

Electric Heat Pumps (EHP) have recently grown in demand and popularity due to policy changes and push for electrification and low-carbon initiatives. EHPs, primarily as air-source heat pumps (ASHP), are in demand in milder climates for new retrofit homes, where local electricity rates are competitive (namely in the south and the pacific northwest). The significant advantages of ASHPs are (a) the ability to reduce heating costs and (b) the integration of cooling and heating with a reversible heat pump. Improvements in ASHP technology and new constructions have driven the adoption of ASHP further. As of 2015, more ASHPs are being shipped than gas furnaces and electric resistance heating [3].

In cold climates, where gas heating is well established, ASHP adoption has been slow because: (a) highly efficient condensing gas-fired appliances are well established and can be cost-effective, (b) drop-off in
Coefficient of Performance (COP) and capacity at cold ambient temperatures, and the requirement for supplementary resistance heating, and (c) the initial cost of owning a cold-climate ASHPs (ccASHPs).

Therefore, the current market and changes in regulatory requirements have created the pathway and need for gas heating equipment with COPs higher than 100%, namely Gas Heat Pumps (GHP). The air-source Gas-Fired Absorption Heat Pump (GAHP) uses natural gas as energy input to extract heat from the outdoors to a conditioned indoor environment. GAHP products and prototypes in the market use the vapor absorption cycles where the sorbent is in the liquid phase and work on the principle that by combining refrigerant/working fluid with a sorbent, significantly less input energy is required to raise refrigerant pressure. During these cycles, thermal energy input is necessary to "desorb" the refrigerant/working fluid from the sorbent to yield a high-pressure vapor. At the core of the GAHP is a group of heat exchangers, vessels, and a pump that comprise the "thermal compressor." LiBr/H2O (chilling) and NH3/H2O (heating) are common absorptions working fluid pairs. GAHP for heating is a developing technology with a notable advantage in heating performance in cold climates that exceeds ASHPs performance. In a single-effect vapor absorption cycle, approximately 40% of the heat delivered to the building is from the ambient ("heat pumping effect" and the remaining is from internal heat recovery [4]. For this reason, GAHP's in heating mode is much less sensitive to cold conditions and commonly do not require supplementary heating.

In the majority of residential applications in the US, space conditioning and hot water loads are typically decoupled and served by different types of equipment. A residential home in four and above IECC climate zones can have two to three types of equipment, typically a gas furnace for space heating, a gas-fired storage tank for water heating, and an electric air conditioning (A/C) unit for space cooling. The decoupled nature of these individual systems prevents the units from working in a tandem nature, limiting the benefit of shared system costs and internal heat recovery. Previous studies have described developing and demonstrating gas-fired "combi" systems for space and water heating, achieving a projected 140% AFUE while reducing water heating energy consumption and emissions by up to 50% [5–7]. One approach to address these challenges is an optimized and cost-effective packaged heat pump unit for combined space conditioning and water heating. The packaged unit offers advantages by coupling the space conditioning and water heating with a single unit to reduce the overall equipment and installation cost and operate at efficiencies of more than one.

This manuscript summarizes data and key findings from the lab evaluation of a hybrid heat pump, a packaged Thermal Heat Pump (THP), and an Electrical Air Conditioning (EAC) unit for the combined operation of space conditioning and water heating.

2. Concept

This effort is to take a pre-commercial GAHP product that only provides whole-house heating and domestic hot water (DHW) and add a cost-effective cooling function to provide space conditioning and water heating in a single packaged unit. Figure 1 illustrates the 4-pipe configuration of the hybrid GAHP–EAC (system for space conditioning and water heating. The GAHP–EAC systems consist of (1) an air handling unit (AHU), (2) a DHW storage tank, and (3) an outdoor unit. The outdoor unit is a four-pipe hydronic system that provides heating and cooling with two independent systems, a 3:1 modulating GAHP and a standard two-stage EAC system through a refrigerant/water heat exchanger. The outdoor unit heating and cooling streams are connected to an indoor hydronic coil AHU with internal pumps and three-way valves to independently manage space conditioning and water heating processes. The AHU system provides heating or cooling based on two-stage 24 VAC thermostat calls and water heating via a separate recirculating loop connected to the indirect storage water heater controlled by an aquastat.
The GAHP is based on an economical single-effect, ammonia/water absorption cycle. With previously estimated Annual Fuel Utilization Efficiency (AFUE) of >140% [7,8]. Acknowledging that a reversible GAHP product is neither novel nor efficient compared to modern electrically-driven Air-Conditioning (A/C) technologies, this effort sought to add a vapor compression module using R410a as the refrigerant to provide cooling. Table 1 highlights the hybrid GAHP-EAC system specifications. The prototype system is illustrated in Figure 2.

Table 1: The hybrid GAHP-EAC specifications.

The hybrid GAHP-EAC system relies upon the logic built into the system that responds to a 2-stage 24VAC thermostat and aquastat demand calls. This logic monitors the outdoor ambient temperature (OAT) and indirect storage water heater temperature, amongst other variables, to appropriately respond to space conditioning and water heating demands.

The hybrid GAHP-EAC system provides space and water heating with the GAHP. A configurable outdoor reset curve for space heating is based on the OAT and supply water temperature to modulate the GAHP between the maximum and minimum heating capacity as a function of OAT. During a heating call, hot glycol/water Heat Transfer Fluid (HTF) from the GAHP is delivered to the AHU at a constant water flow rate, with the AHU increasing the airflow as a function of the time of actuation at thermostat stages. The GAHP operation is centered around maximizing run-on-time and efficiency. In DHW mode, after receiving a call from the aquastat, the GAHP will turn on and supply water at 120-125°F until the aquastat is satisfied. The control will prioritize water heating if both space and water heating are being called.

The hybrid GAHP-EAC can simultaneously provide space cooling from the EAC and water heating from the GAHP. Since the EAC is a two-stage compressor air conditioner, it provides space cooling based on 1st
and 2nd cooling stage calls from the thermostat. The second stage cooling call will be triggered if the thermostat is 3.0°F above the set point. The AHU will start at medium speed and increase the airflow as a function of time.

3. Experimental Procedures

The hybrid GAHP-EAC system's performance for residential space conditioning and water heating applications was evaluated in a laboratory environment. The seasonal performance and capacities for space heating and cooling were characterized using standardized steady-state testing based on the North American rating method (ANSI Z21.40.4) and (AHRI 210/240), respectively. In addition to standardized testing, extended 24-hour Simulated Use Tests (SUT) on GTI Energy's Virtual Test Home (VTH) were conducted for real-world operation.

Both standardized steady-state test methods comprised a series of steady-state rating points under static conditions at full and partial loadings, including considering defrost modes and cycling degradation. Data from test rating points were used to calculate the seasonal performance metrics for the GAHP and EAC. The test conditions for the steady-steady testing can be referenced in the following standard's manual for ANSI Z21.40.4 [9] and AHRI 210/240 [10].

The hybrid GAHP-EAC system for space conditioning and water heating performance was evaluated in a simulated environment over 24 hours. In SUT testing, one space heating and cooling profile was implemented to present the heating and cooling season. One daily water heating profile was superimposed onto the space heating or cooling profile to simulate DHW usage for these two operating seasons. The SUTs space conditioning and water heating load profiles were based on yearly EnergyPlus modeling of a 3,016 sq-ft Vintage IECC 2012 home in Chicago, IL, as illustrated in Figure 3.
The SUTs implemented thermostat DHW simulators to evaluate the hybrid GAHP-EAC system performance and logic features to as-installed operating conditions. The thermostat simulator for simulating-use space conditioning evaluation is an algorithm based on a whole-home lumped heat capacity approach to simulate space conditioning part-load operation with HVAC equipment. This approach has been well documented in literatures [11,12].

A purpose-built test stand with instrumentation and the environmental chamber was used to evaluate the hybrid GAHP-EAC system, as illustrated in Figure 4. A National Instrument was used to record all data continuously throughout the data collection period with a maximum data sample interval of 5 seconds. The instrumentation list with make model and accuracy are summarized in Table 2.

</table>

The electrical input at the System Boundary is the total power measurement of the indoor and outdoor units as:

\[ E_{Sys} = E_{AHU} + E_{OU} \tag{1} \]

Where:
- \( E_{Sys} \) = accumulated electrical power at the System Boundary (kWh)
- \( E_{AHU} \) = accumulated electrical power at the AHU (kWh)
- \( E_{OU} \) = accumulated electrical power at the outdoor unit (kWh)

The following basic equation is used to calculate the gas consumption by the system:

\[ Q_f = \sum HHV \cdot \dot{V}_f \cdot \Delta t \cdot \rho_{fs}/\rho_{fa} \tag{2} \]
Where:

- \( Q_f \) = accumulated HHV fuel energy input (Btu)
- \( HHV \) = fuel higher heating value (Btu/ft³)
- \( \dot{V}_f \) = flow rate of fuel (lbm/h)
- \( \Delta t \) = testing period (h)
- \( \rho_{fs} \) = fuel standard density (lbm/ft³)
- \( \rho_{fa} \) = fuel actual density (lbm/ft³)

Thermal output at AHU is determined by measuring the airflow rate, supply and return temperature, and relative humidity. The enthalpy difference was computed using the measured temperatures and relative humidity in Engineering Equation Solver. The heating and cooling output was calculated with the following equation for heating:

\[
Q_{SH} = \dot{V}_a \cdot \rho_{as} \cdot -\Delta h \cdot t \cdot \sqrt{\frac{\rho_{as}}{\rho_{ss}}} \quad (3)
\]

Where:
- \( Q \) = accumulated heating/cooling output of the AHU, (Btu)
- \( \dot{V}_a \) = AHU airflow, (acfm)
- \( \Delta h \) = enthalpy difference between leaving and entering air temperatures at the AHU, (°F)
- \( \rho_{as} \) = dry-air density based on the fluid temperature at the flow meter (lbm/cF)
- \( \rho_{ss} \) = dry-air density at standard at 14.69psia and 70°F, (lbm/cF)
- \( t \) = data collection time step, (min)

The DHW output was measured and calculated with the direct measurement of the water flow rate, city water, and DHW supply water temperatures at the indirect storage tank as:

\[
Q_{DHW} = \dot{V}_w \cdot \rho_w \cdot c_{pw} \cdot \Delta T_{DHW} \cdot t \quad (4)
\]

Where:
- \( Q_{DHW} \) = accumulated DHW output, (Btu)
- \( \dot{V}_w \) = city water flow rate, (gpm)
- \( \Delta T_{DHW} \) = temperature difference between city water and DHW temperatures at the indirect storage water heater, (°F)
- \( \rho_w \) = water density based on the fluid temperature at the flow meter (lbm/gal)
- \( c_{pw} \) = specific heat based on average entering and leaving water temperatures across the indirect storage water heater (BTU/lbm · °F)
- \( t \) = data collection time step, (min)

The coefficient of performance (COP) at the GAHP is calculated by the accumulated heat produced by the GAHP over the gas consumption as:

\[
COP_{gas} = \frac{\sum_{t_o}^{t_f} (Q_{SH} \cdot \Delta t) + \sum_{t_o}^{t_f} (Q_{DHW} \cdot \Delta t)}{\sum_{t_o}^{t_f} (Q_g \cdot \Delta t)} \quad (5)
\]

Where:
- \( COP_{gas} \) = coefficient of performance at the GAHP, gas only
- \( \Delta t \) = data collection time-step
- \( t_o \) = start of steady-state measurement
- \( t \) = data collection time step, (min)

The COP for the system is calculated by the accumulated heat produced by the GAHP over the gas and electric consumption as:

\[
COP = \frac{\sum_{t_o}^{t_f} (Q_{SH} \cdot \Delta t) + \sum_{t_o}^{t_f} (Q_{DHW} \cdot \Delta t)}{\sum_{t_o}^{t_f} (Q_g \cdot \Delta t) + E_{Sys}} \quad (6)
\]

Where:
- \( COP \) = coefficient of performance at the GAHP
Figure 4: The purpose-built test stand and instrumentation.
4. Results and Discussion

The results of the steady-state heating and cooling test are summarized in Figure 5 and Figure 6, respectively. Using the data from Figure 5, the seasonal AFUE for US average climate bin conditions per ANSI Z21.40.4 was 121.6% for the US average climate bins based on a cycling degradation coefficient (Cd) of 0.25 as per the standard of ANSI Z21.40.4 based on air-water evaluation at a water return temperature of 95°F.

At lower and intermediate firing rates, the air-air GAHP was maintained close to 95°F return hydronic temperature (RHT), similar to an air-water GAHP. Whereas, at level 2 firing rate, the performance and capacity of the air-air GAHP are 9 to 12% lower than an air-water GAHP. At a higher firing rate, the air-air GAHP RHT was 13 °F higher than the air-water GAHP.

Using the data from Figure 6, the Seasonal Energy Efficiency Rating (SEER) was 10.1 (EAC only) and 8.24 (EAC + AHU) with a cycling degradation coefficient (Cd) of 0.59. As per standard Cd of 0.2 as per AHRI 210/240, the SEER was 12.4 (EAC only) and 10.1 (EAC +AHU). The EAC’s cycling degradation coefficient and electric consumption were considered high in this prototype due to (1) an additional refrigeration/water heat exchanger and (2) an additional pump needed for the water loop.

Figure 7 summarizes and compares the supply air temperature of hybrid GAHP and EAC to other manufacturers’ state-of-the-art technology. The GAHP supplied air at a higher temperature than ccASHPs in the market. At level 2 firing rate, the GAHP supplied air above 100°F. The EAC with hydronic loop provided supply air at ±2°F of manufacturer A’s 16 SEER system.
The GHAP’s flue gas composition and emissions were measured during steady-state tests. Table 3 summarizes the average measurements of flue gas composition on a dry basis. Compared to the 40 kBtu/hr gas furnaces, the hybrid's GAHP-EAC carbon monoxide (CO) in free air is 3 - 4 times lower. The NOx emission of 7.8 ng/J is roughly 45% lower than the requirement per Rule 1146 and SCAQMD requirements for residential and commercial space heating of 14 ng/J. Therefore, the hybrid GAHP-EAC can be classified as a low-NOx system.

Figure 8 summarizes the hourly heating load, COP gas, OAT, and the indoor temperature during the simulated use testing over 24 hours. As outlined in Figure 8 (Left), the hybrid GAHP – EAC mainly operated in the intermediate firing rate region at a heating rate of 15 to 20 kBtu/hr. During the cyclic operation, the GAHP took about 25-30 minutes to reach steady-state operation, of which 6-10 minutes of initial load were used to heat the system's mass. Therefore, during the 24-hour duration, the GAHP only operated on the first stage of the heating call. The heating call's second stage was programmed to be triggered only when the indoor temperature is 3°F above the thermostat set point. The GAHP took an average of 60 minutes to 145 minutes to raise the home's temperature by 2°F from 69°F to 71°F, as shown in Figure 8 (Right).
Table 4 summarizes the average space, water, and combi performance of GAHP when operated at an average OAT of 39.3 °F over 24 hours. The electric load made up 9% of the total energy used in a combi operation, and heat loss from the tank was 0.57 kBtu/hr (0.86 °F/hr), with a 24-hour standby electrical usage of 0.623 kWh. The combined system COP was 1.08. The significant electrical load due to the additional pumps and blower affects the system COP, as these are roughly 50% of the total electric load.

An approximately 13% performance degradation between the GAHP performance rating and an optimized GAHP system can be found. This degradation percentage is anticipated with other technologies such as furnaces and ASHPs. Figure 9 shows the resulting performance of a 96% AFUE furnace at the same testing conditions implemented for the SMTI 40k hybrid GAHP system at 36 °F ambient temperature day. This testing condition was used for comparison since it represents the majority of load hours of heating equipment in the US national average climate. The 96% AFUE furnace sized per Air Conditioning Contractors of America (ACCA) Manual S scored 89% daily gas efficiency. The difference between AFUE and installed performance was about 7%, similar to the difference observed between air-to-air configuration ANSI Z21.40.4 testing and SUT evaluation in the 40k hybrid GAHP system.
Similarly, Table 5 summarizes the average space cooling with EAC and water heating with GAHP performance over 24 hours. The average COP of EAC for space cooling was 2.56 at average OAT of 92.2 °F. Similarly, the average system COP of water heating with GAHP was 1.3, and the heat loss from the tank was similar to the heating test at 0.62 kBtu/hr. Compared to the heating test, the 24-hour standby electrical load was 0.36 kWh; the lower standby electrical load in the cooling test was due to the EAC’s extended long-time over the 24 hours.

5. Conclusion and Future Work

A series of laboratory evaluations were conducted to map the performance of the Hybrid GAHP-EAC system for residential HVAC and water heating applications. The seasonal heating and cooling performance of the Hybrid GAHP-EAC system were: (1) AFUE: 121.6%; (2) SEER: 8. In the SUT testing for space and water heating, the system performance degraded by 6-11% in comparison to the steady-state testing. The average system COP, including the gas and the electrical load, was 1.10 (space heating), 1.02 (water heating), and 1.08 (combined) at an average OAT of 39.3 °F. The electric consumption was 9% of the energy consumption.

In the SUT testing for space cooling and water heating, the system performance degraded by less than 7% due to the long runtime of the EAC. The EAC operated at extended periods in stage 1, as the trigger from stage 1 to stage 2 was ±3 °F above the thermostat set point. The average COP was 2.56 for space cooling and 1.3 for water heating at an OAT of 92.2 °F.

Future work for space heating are:
- Improvement in controls for the time taken for space heating to maintain comfort. The 3 °F trigger for the next stage seems high to keep the required comfort in the home.

Figure 9: Daily efficiency of a 96 AFUE furnace at VTH 36 °F ambient test used for the SMTI 40k hybrid GAHP system.
• The electric load should be considered in the design phase. The electric load makes up 9% of the energy usage. As observed in the SUT testing, the combined COP of the system was 1.08 at 39.3°F. Future work for space cooling are:
• Like space heating, a 3°F trigger for the next stage seems high to maintain the required comfort in the home and reduce the EAC’s performance. Therefore, the motivation for the next step should be a combination of time-based and OAT reset.

Abstract

Cooling systems are a necessity of modern civilization that have greatly enhanced our standard of living and enabled the development of large population centers in harsh climates. However, a key shortcoming of the existing prominent cooling system i.e., vapor compression system is the need for overcooling of air to condense its moisture content. This limitation often leads to implementation of reheat to bring the air to a desired supply temperature to maintain comfort and indoor air quality (IAQ). Liquid desiccant absorption systems have been considered to handle the latent load such that need for reheat is eliminated. However, a low energy efficiency, high cost, and operational and maintenance complexities have prevented such systems from becoming a mainstream product. Here, we report progress on development of ionic liquid desiccant dehumidification systems with a membrane-based absorber that promise to overcome shortcomings of the existing desiccant dehumidification systems. We compare performance of the system operating with adiabatic and internally cooled membrane-based absorbers. The studies are conducted at Integrated Seasonal Moisture Removal Efficiency (ISMRE) inlet air conditions. Effect of dew point temperature on system capacity and coefficient of performance (COP) is studied. A maximum COP of 0.82 is reached, showing promise in terms of energy efficiency. The studies also suggest that further enhancement in dehumidification level is required to meet the needs of HVAC systems.

1. Introduction

Cooling systems are responsible for nearly 10\% of the global electricity consumption [1]. This energy use is steadily rising due to the increase in the number of installed cooling systems and climate temperature. Currently, only 8\% of the 2.8 billion people living in the hottest parts of the world possess an air conditioner [1]. As the living standard in these areas rises, the number of air conditioners is expected to increase [2]. It is projected that the global energy consumption associated with cooling could reach 6,200 TWh by year 2050 [1]. The use of dedicated outdoor air systems (DOAS) for applications with large ventilation loads have shown reduction in the overall building energy use and improvements in the indoor air quality (IAQ). A DOAS is designed to handle the outdoor ventilation air latent load. However, to remove moisture from air, vapor compression systems must overcool air to saturation conditions. The use of a more thermodynamically efficient process to remove moisture from air has the potential to improve energy efficiency in HVAC systems.

In this study, an experimental analysis of a membrane-based ionic liquid (IL) desiccant dehumidification system is presented. This work builds upon our invention of specific aspects of this absorption cycle [4,5] and demonstration of its performance using ILs [5–7] as well as characterization of a membrane-based absorber for dehumidification [8,9]. In the following sections, the system configuration, and its components, including...
the absorber, desorber, and the implemented IL are introduced. The experimental system is presented, and measurement uncertainties are discussed. The system dehumidification performance is measured at the Integrated Seasonal Moisture Removal Efficiency (ISMRE) inlet air conditions used to establish dedicated outdoor air systems (DOAS) performance characteristics.

2. Experimental System

2.1. Process and instrumentation diagram

A single-effect liquid desiccant absorption dehumidification system was fabricated and integrated into a test suite (Figure 1). This system operates in a cycle in which water vapor is absorbed from the airflow in the absorber and is subsequently liberated in the desorber (via heating). Within the absorber, the concentrated desiccant solution flows down the absorber plate while interfacing with the airflow through the membrane. The water vapor is absorbed by the solution. The dilute (i.e., water-rich) solution then exits the absorber and is pumped to the desorber where it is regenerated. A heat exchanger (i.e., solution heat exchanger, SHX) recovers heat of the desorber outbound solution to elevate temperature of the desorber inbound solution. This internal energy recovery stage plays a key role in energy efficiency of the system as well as absorber performance, as it lowers the absorber inlet solution temperature. The water vapor liberated from the solution is condensed, metered, and drained.

This experimental test setup consists of two primary flow loops including the solution and air flow loops as well as three secondary flow loops; the heating oil loop, the condenser/absorber cooling water loop, and the air-cooling loop (cf. Figures 1 and 2). The IL solution exiting the absorber is pumped to the desorber by a small variable speed gear pump. The absorber is located within the closed air loop (cf. Figure 2). To control the humidity level within the air loop, a steam generator in conjunction with a custom-made steam distribution manifold are utilized. To control the air temperature, a secondary water loop is connected to a heating/cooling coil installed within the air duct. A variable speed axial fan is used to circulate air through the air loop. The heating oil loop, which powers the desorber, utilizes a heating oil bath and synthetic oil SIL 180. An additional water chiller is used to cool the absorber (in inter-cooled operation) and the condenser. Temperature, relative humidity, and flow sensors (Figure 1) are installed throughout the system to enable components and system level characterizations.

2.2. Absorber

A schematic of an absorber panel showing the desiccant solution, cooling water, and airflow is shown in Figure 3. The absorber is fabricated from Acrylonitrile Butadiene Styrene (ABS) sheets. Each absorber plate has an internal cooling water core containing water channels and distribution manifolds. The desiccant solution flows on the two outer surfaces of each plate. The plate surfaces are machined to include features designed to slow and spread the solution flow to “wet” the entire surface (front and back) of each sheet \([10,11]\). A membrane is then bonded over the surface features to constrain the solution. Lastly, manifolds are bonded on the top and bottom of each side of the ABS sheet-membrane assembly (i.e., a panel) to direct the IL flow through the gap formed in between the ABS surface and membrane, and the water to the internal water cavity. Air flows across the panels (cf. Figure 3) through 3 mm gaps formed in between them within the absorber assembly. Geometrical characteristics of the absorber is listed in Table 1.
## 2.3. Desorber and Condenser

Figure 4 depicts the desorber, showing the dilute solution supplied by a distribution manifold over the desorber surface. To ensure uniform supply of solution over the surface (Figure 4A) and enhancement of the desorption rate, surface structures described in our earlier studies are utilized here [12]. The desorber surface is heated using silicone oil in a counter flow heat exchange configuration (Figure 4A). To capture and condense the vapor, a condensing surface is built adjacent to the desorber surface, separated by a porous polytetrafluoroethylene (PTFE) membrane (Figure 4B). A critical function of this membrane is to eliminate IL carryover from the desorber while permitting water vapor migration to the condensing surface. The condensing surface is cooled using a water loop.

![Figure 4](image)

**Figure 4.** A schematic of the desorber and condenser assembly showing solution falling film flow configuration (A) and the desorption of water vapor, its flow through a PTFE membrane, and subsequent condensation in the condenser (B).

## 2.4. Measurement System

The solution flow rate is measured using a positive displacement flow meter. Due to the elevated temperature of the oil flow loop, a high-temperature positive displacement flow meter is used to measure the oil flow rate. The water flow rate is measured using a turbine flow meter. All flow meters were calibrated in house using a bucket-stopwatch method. The airflow rate is measured using a pitot tube sensing element mounted within the air loop duct. Multiple sensing ports along the length of the sensing element are used, and internally averaged to ensure accurate airflow rate measurement. All liquid temperatures were measured using T-type thermocouples. The process air temperature and relative humidity are measured using thin-film capacitive sensors. The absorber solution inlet and outlet concentrations are measured using two inline refractive index (RI) sensors. RI instead of Coriolis effect is used because the variation in density for ILs is insignificant over a wide concentration range, making accurate measurement of the concentration infeasible. Curve fits have been developed to establish RI values as a function of IL concentration and temperature. The primary system temperature, flow rate, RI, and air velocity are recorded using a data acquisition system. A second data acquisition system is used to record the air temperature and relative humidity. Time stamps are used to combine the data collected by each data acquisition system to enable a system level data analysis.

## 2.5. Data reduction and uncertainty analysis

The system performance presented in the results and discussion section is calculated based on the measured data described above. The system latent capacity is calculated using Eq. (1).

---

2.6. Test Conditions

The test conditions listed in Table 3 represent the ISMRE [14] inlet air conditions used to establish DOAS performance characteristics. The inlet air, IL solution, and oil flow rates as well as the oil inlet temperature have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, and 148 °C, respectively.

3. Results

Figure 5 shows results of a typical run conducted at the ISMRE A test condition operating with an intercooled absorber at an air inlet temperature of ~35 °C and ~52% relative humidity. It is noted that due to the low thermal mass of the system, the system quickly reaches steady state conditions. In these steady state conditions, the difference in the inlet and exit air absolute humidity remains constant (Figure 5A), resulting in an essentially constant moisture removal rate (Figure 5B).

![Figure 5. System inlet and exit air conditions (a) and water removal (b) with an intercooled absorber at ISMRE A conditions. The inlet air, IL solution, and oil flow rates as well as the oil and water inlet temperatures have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, 148 °C, and 10 °C, respectively.](image)

3.1. Dehumidification performance

The dehumidification performance of the system was experimentally evaluated at each of the four ISMRE test conditions, with the absorber operating in both adiabatic and intercooled configurations. In these flow configurations, the water flow rate was varied between 0 lpm (no flow) and 0.82 lpm for the adiabatic and intercooled configurations, respectively. The absorber inlet water temperature for the intercooled condition was held constant at 10 °C. The dehumidification performance of the system is plotted on the psychometric chart shown in Figure 6. In the adiabatic configuration, the heat associated with condensation of the water vapor into the solution is returned to the air stream. As a result, the air is dehumidified and heated in a nearly isenthalpic process. In the intercooled configuration, the absorber heat energy is removed by the cooling water enabling latent and sensible cooling of the process air.

Typically, in DOAS applications, outdoor ventilation air is dehumidified and conditioned to a room or neutral state (Figure 6). As can be seen, dehumidification of the process air to neutral conditions was not achieved during these tests. For ISMRE conditions C and D, it is believed that slight changes in the water and airflow rates will enable the existing system to deliver neutral air. For ISMRE conditions A and B, in addition to changes to air and water flow rates, a larger absorber is required. This experiment demonstrated that this absorber configuration, with proper air/water flow control can provide a wide range of air conditioning (above isenthalpic to constant relative humidity cooling). This range of air conditioning is enabled by the dehumidification capacity of the solution and the heat transfer between the absorber fluids. This is exemplified by performing above isenthalpic dehumidification because of the additional sensible heat transfer from the solution to the air emanating from high temperature of the solution entering the absorber.

The absorber implemented for this test, was approximately 35 cm tall, 35 cm long, and 8 cm wide with an active surface area of 3.3 m² (Table 1). The dehumidification capacity, in latent cooling (W) and the moisture removal rate (kg/hr) of the absorber in the two configurations is shown in Figure 7. As shown in Figure 7, the dehumidification performance of the intercooled configuration is significantly better than that of the adiabatic configuration. The water absorption process is driven by the difference in vapor pressure between the process air and the desiccant solution. As the desiccant solution is heated its vapor pressure increases, reducing the absorption rate. As the cooling water in the intercooled configuration cools the solution, it is intuitive that under the same physical conditions (size, surface area, flow rates, etc.) the intercooled configuration will have a greater dehumidification capacity than the adiabatic configuration. As the architecture of both the absorber and desorber are modular, the addition of plates serves to increase system capacity.
Figure 6. System inlet and exit air conditions for the system operating in the adiabatic and intercooled configurations at the four ISMRE conditions. The inlet air, IL solution, and oil flow rates as well as the oil and water inlets temperature have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, 148 °C, and 10 °C, respectively.

Figure 7. System latent capacity and moisture removal rate as a function of inlet air dewpoint temperatures which approximate the ISMRE conditions for the adiabatic and intercooled absorber configurations. The inlet air, IL solution, and oil flow rates as well as the oil and water inlet temperatures have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, 148 °C and 10°C, respectively.

3.2. Coefficient of performance (COP)

As the primary function of the system is dehumidification, its COP (calculated using Eq. 3) represents the system’s dehumidification (latent cooling) efficiency. This COP is plotted in Figure 8 as a function of the inlet
air dew point temperatures representative of the four ISMRE conditions. As shown in Figure 8, the COP of the system with the intercooled absorber (chilled water inlet temperature of 10 °C) is greater than that of the adiabatic configuration at higher dewpoint temperatures. The highest COP is associated with the maximum latent load, as dew point temperature is an indicator of the air moisture content. Although the system performance is presented in Figure 8 as a function of the inlet air dew point temperature, the inlet water and air drybulb temperatures also impact system performance. For the intercooled absorber, the inlet chilled water temperature has been maintained as 10 °C, which cools the solution within the absorber, ultimately resulting in the absorber inlet temperature being held essentially constant across the four test conditions. In contrast, the solution inlet temperature of the adiabatic absorber increases with increasing air inlet dewpoint/drybulb temperatures, such that for ISMRE A (22.1 °C T_{DP, air inlet}) it is 15 °C higher than its intercooled counterpart. While the cooling water dominates the heat transfer characteristics of the absorber, cooling both the solution and the air, the air inlet dry bulb temperature increased the solution temperature within the adiabatic absorber. The resulting increase in solution temperature decreased the latent capacity of the adiabatic absorber relative to the intercooled absorber at the higher inlet air dewpoint/drybulb conditions.

As shown in Figure 8, the system COP declines, regardless of absorber configuration, as the inlet air dewpoint temperature decreases. The system performance at these low dewpoint conditions was negatively impacted by maintaining a constant solution flow rate. The COP is expected to improve by lowering the solution flow rate such that change in the solution concentration between the absorber inlet and outlet is maximized. In other words, the solution flow rate should match the air dehumidification requirement.

![Figure 8](image)

**Figure 8.** System COP as a function of air inlet dew point temperatures that approximate the ISMRE condition for the adiabatic and intercooled absorber configuration. The inlet air, IL solution, and oil flow rates as well as the oil and water inlet temperatures have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, 148 °C, and 10 °C, respectively.

### 4. Conclusions

A lab scale IL dehumidification system was experimentally tested in two configurations, adiabatic and intercooled, at the inlet air conditions representative of the four ISMRE test conditions, while the system internal operating conditions were maintained constant. The use of IL demonstrated the robustness of the system in providing dehumidification across a wide operational range, without control equipment for mitigating crystallization. An all polymer plate-and-frame membrane-based absorber effectively demonstrated dehumidification of the airflow in a small volume format. The measured system latent performance and system COP ranged from ~265 W to ~820 W, and 0.30 to 0.82 respectively across the test conditions. These tests demonstrated that this absorber configuration, with proper air/water flow control can provide a wide range (beyond isenthalpic to constant relative humidity cooling) of air conditioning, which when properly sized can deliver ventilation air at neutral air conditions.
Nomenclature

ABS  acrylonitrile butadiene styrene

Abstract

Drying, an energy-intensive process that is indispensable to many industries, accounts for 10–20\% of the total industrial energy use in most developed countries. Thus, there are great incentives to reduce energy use in drying to lower its carbon footprint and improve process economics. However, challenging thermodynamic barriers have limited the opportunities to reduce energy consumption in the drying industry. The vapor compression system heat pump (VCSHP) has been established as a promising technology to improve the drying process efficiency. Fuel-flexible heat pump systems (operated by waste heat, solar-thermal, biomass, and green hydrogen) provide an off-grid alternative to VCSHP with attractive efficiency and economics. Here, two configurations of a thermally-driven ionic liquid semi-open absorption heat pump drying system are studied. Both systems utilize an adiabatic absorber to remove latent heat (moisture) from the process air and return its latent energy content as sensible heat to the process air (i.e., latent to sensible energy exchange takes place in the absorber). The systems’ condenser heat is then recovered to further increase the process air temperature prior to its entry into the drying kiln. Test results show that our semi-open ionic liquid absorption heat pump approaches a moisture removal efficiency (MRE) of \(\sim1.2\ \text{kg H}_2\text{O/kWh}_{\text{primary}}\) comparable with the VCSHP drying systems (available products have an average MRE \(1.4\ \text{kg H}_2\text{O/kWh}_{\text{primary}}\)). This level of performance, coupled with its fuel-flexibility, demonstrates the viability of the ionic liquid absorption heat pump technology in industrial drying.

1. Introduction

Drying is an indispensable technique for large-scale food preservation and lumber production. Dried foods offer numerous benefits including storage stability, ease of packaging, and reduction in transportation cost. Lumber is dried to enhance its stability and strength. However, drying is one of the most energy-intensive processes, accounting for 10–20\% of the total industrial energy use in most developed countries [1]. The main reason for this is the high latent heat of evaporation of water and the relatively low energy efficiency of industrial dryers [2]. Thus, there are clear incentives to reduce energy use in drying to lower its carbon footprint and improve process economics. However, challenging thermodynamic barriers have limited the opportunities to reduce energy consumption.

Current vapor compression system heat pump (VCSHP) drying has been demonstrated as a state of the art, low energy drying technology applicable to the food and lumber industries [3]. VCSHP drying is a technology in which an air-to-air heat pump is used to dehumidify and heat air as the convective medium for drying of food and lumber materials [4]. Since the system is entirely re-circulatory, food and lumber products are dried in environmentally friendly conditions in an operation that is independent of outside ambient weather.

\footnote{Corresponding author. E-mail address: saeedmog@ufl.edu}
conditions. Energy consumption is significantly reduced with respect to other commonly used industrial drying technologies [5].

Recent work has demonstrated the dehumidification capability of a thermally driven semi-open absorption heat pump [6–9]. The semi-open absorption cycle operates at near ambient pressure, eliminating complexities and costs associated with conventional absorption cycles. An ionic liquid (IL) has been successfully implemented enabling the system operation at cycle conditions not possible with conventional salts and operation with inexpensive and passive controls. Herein, two configurations of the system are studied to establish their moisture removal efficiency (MRE). The performance of these two configurations is compared with VCSHP technology.

2. System

Single- (Figure 1a) and double-effect (Figure 1b) semi-open heat pump absorption cycles with heat recovery are studied at conditions representative of lumber drying kilns. These systems operate in a cycle in which water vapor is absorbed from the warm and humid air of the drying kiln. The water vapor is absorbed in the absorber and is subsequently liberated in the desorber(s) via heating. Within the absorber, the concentrated desiccant solution flows down the absorber plates while interfacing with the air flow through a porous membrane. The water vapor is absorbed by the solution. The dilute (i.e., water-rich) solution then exits the absorber and is pumped to the desorber where it is regenerated. Depending on the configuration, one or two heat exchangers (SHXs) are used to recover heat of the solution exiting the desorber to elevate the temperature of the solution entering the desorber. In this application, the heat of the desorbed vapor/condensate is used to heat the process air. This enables the cycle to dehumidify and reheat the process air, prior to its reentry into the drying kiln.

![Figure 1](image_url)

Figure 1. The semi-open absorption single-effect (a) and double-effect (b) heat pump drying system configuration schematics.

2.1. Instrumentation Diagram

To validate performance of the single- and double-effect semi-open absorption cycles, and their associated moisture removal efficiencies, two systems were studied. Each experimental test setup consisted of two primary flow loops including the solution and air flow loops as well as three secondary flow loops; the heating oil loop, the condenser/absorber cooling water loop, and the air-cooling loop (Figure 2). The IL solution exiting the absorber is pumped to the desorber by a small variable speed gear pump. The absorber is located within the closed air loop (cf. Figure 2). In the single-effect configuration (Figure 2a), the solution exiting the desorber returns to the absorber to complete the solution flow loop. In the double-effect configuration, the solution exiting the upper desorber is pumped to the lower desorber by a second variable speed gear pump. The solution exiting the lower desorber returns to the absorber to complete the solution flow loop. To control the humidity level within the air loop, a steam generator in conjunction with a custom-made steam distribution manifold are utilized. To control the air temperature, a secondary water loop is connected to a heating/cooling coil installed...
within the air duct. A variable speed axial fan is used to circulate air through the air loop. The heating oil loop, which powers the upper desorber, utilizes a heating oil bath and synthetic oil SIL 180. As the test setups only validated the cycle performance, they did not contain a heat recovery exchanger (Figure 1) to sensibly heat the air prior to its exit back into the drying kiln. As such, a water chiller is used to maintain the lower condenser at the desired temperature.

The solution and water flow rates are measured using positive displacement and turbine flow meters, respectively. Due to the elevated temperature of the oil flow loop, a high-temperature positive displacement flow meter is used to measure the oil flow rate. The air flow rate is measured using a pitot tube sensing element mounted within the air loop duct. Multiple sensing ports along the length of the sensing element are used, and internally averaged to ensure accurate air flow rate measurement. All liquid temperatures were measured using T-type thermocouples. The process air temperature and relative humidity are measured using thin-film capacitive sensors. The absorber solution inlet and outlet concentrations are measured using two inline refractive index (RI) sensors. RI instead of Coriolis effect is used because the variation in density for ILs is insignificant over a wide concentration range, making accurate measurement of the concentration infeasible. Curve fits have been developed to establish RI values as a function of IL concentration and temperature. The primary system temperature, flow rate, RI, and air velocity are recorded using a data acquisition system. A second data acquisition system is used to record the air temperature and relative humidity. Time stamps are used to combine the data collected by each data acquisition system to enable a cycle level data analysis.

2.2. Absorber

In the HP drying application, humid warm air is removed, dehumidified, heated, and returned to the drying kiln. To support this process, an adiabatic absorber fabricated from Acrylonitrile Butadiene Styrene (ABS) sheets is used. The desiccant solution flows on the two surfaces of each absorber plate. The plate surfaces are machined to include features designed to slow and spread the solution flow to “wet” the entire surface (front and back) of each sheet [10,11]. A membrane is then bonded over the surface features to constrain the solution. Lastly, manifolds are bonded on the top and bottom of each side of the ABS sheet-membrane assembly (i.e., a panel) to direct the IL flow through the gap formed in between the ABS surface and membrane. Air flows across the panels (cf. Figure 3) through 3 mm gaps formed in between them within the absorber assembly. To support our modelling efforts, an absorber was fabricated and tested. Geometrical characteristics of the absorber are provided in Table 1. The test data was used to validate the absorber model [12].

2.3. Desorbers and Condensers

In the double-effect configuration, the desorber/condenser module contains upper and lower desorbers and condensers (Figure 4a). In this configuration, heat is added to the dilute solution in the upper desorber using silicone oil in a counter flow heat exchange configuration. The desorbed vapor is then condensed in the upper condenser. The heat released from the vapor is used to heat the solution in the lower desorber. The solution leaving the upper desorber is cycled back to the low desorber after it passes through a heat recovery heat exchanger (Figure 1). The vapor desorbed in the lower desorber is condensed in the lower condenser. In the single-effect configuration (Figure 2a), heat is only used once in the desorption process. Thus, only a single desorber and condenser are contained in the module. The heat from the lower condenser (double-effect) and the condenser (single-effect) are used in a steam/air heat exchanger to heat the process air. A single- and a double-effect desorbers/condensers module (Figure 4b) were fabricated and have been used to test the performance of the single and double-effect test systems.
2.4. Ionic Liquids

ILs are broadly defined as low temperature molten salts composed of large asymmetric organic cations and inorganic or organic anions that are moisture and air stable at room temperature [13], [14]. ILs exhibit properties required for absorption dehumidification systems including thermal stability, negligible vapor pressure, high solubility in water, and low corrosion towards metals, making their use promising in absorption systems [15]. In liquid desiccant absorption systems, the dehumidification capability of the desiccant is considered its most critical thermo-physical property. This characteristic of the desiccant is best represented by its water vapor pressure at a given concentration and temperature.

Another key factor that dictates the dehumidification system design and whether an IL-based system can be successfully built is the IL viscosity. Our studies [9], [7], [16], have shown that the IL viscosity impacts the design of middle and low temperature components of the system the most, consisting of the absorber and solution heat exchanger. The high operating temperature of our desorber greatly reduces the IL solution viscosity such it is not the prominent factor in design considerations. Viscosity is a key constrain in design of the solution heat exchanger when the IL flow from the desorber to absorber is driven by gravity. Furthermore, design of the IL flow distribution within the absorber is impacted by the IL viscosity. Hence, assessing utility of one IL versus another involves comparing their viscosity.

Table 2 compares viscosity of the IL used in this study and LiBr, LiCl, and [EMIM]OAc. While viscosity of both ILs is similar, it is 2-3 times higher than that of the LiBr and LiCl.

2.5. Data reduction and uncertainty analysis

The system performance presented in the results and discussion section is calculated based on the measured data described above. The system latent capacity is calculated using Eq. (1).

\[ Q_{\text{latent}} = \dot{V}_{\text{air}} \rho_{\text{air}} h_{\text{fg}} (\omega_{\text{air,in}} - \omega_{\text{air,out}}) \]  

where \( \dot{V}_{\text{air}} \) is the absorber air flow rate; \( \omega_{\text{air,in}} \) and \( \omega_{\text{air,out}} \) are the absorber air inlet and exit absolute humidity, respectively; \( \rho_{\text{air}} \) is the air density as calculated from standard tables using the measured air inlet conditions; and \( h_{\text{fg}} \) is the water latent heat of evaporation. The desorber heat input is calculated using Eq. (2).

\[ Q_{\text{oil}} = \dot{V}_{\text{oil}} \rho_{\text{oil}} c_{\text{p,oil}} (T_{\text{des,oil,in}} - T_{\text{des,oil,out}}) \]  

where \( \dot{V}_{\text{oil}} \) is the desorber oil flow rate; \( T_{\text{des,oil,in}} \) and \( T_{\text{des,oil,out}} \) are the desorber oil inlet and outlet temperatures, respectively; \( \rho_{\text{oil}} \) is the oil density; and \( c_{\text{p,oil}} \) is the oil thermal capacity calculated using curve fits derived from data provided by Clearco for their SIL 180 silicone oil. The system latent heat capacity along with the desorber heat input are used in Eq. (3) to calculate the system dehumidification COP.

\[ \text{COP}_{\text{dehumidification}} = \frac{Q_{\text{latent}}}{Q_{\text{oil}}} \]  

The moisture removal efficiency (MRE) was estimated using Eq. (4).

\[ \text{MRE} = \frac{\dot{V}_{\text{air}} \rho_{\text{air}} (\omega_{\text{air,in}} - \omega_{\text{air,out}})}{Q_{\text{oil}}} \]  

The uncertainty was calculated using an engineering equation solver (EES) uncertainty propagation subroutine. The subroutine is based on NIST guidelines [17] and assuming that the individual measurements are uncorrelated and random, the uncertainty in the calculated quantity can be estimated using Eq. (5).

\[ U_Y = \sqrt{\sum_i \left( \frac{\partial Y}{\partial X_i} \right)^2 U_{X_i}^2} \]
Table 2 below lists all the relevant measurement errors and uncertainties in this experimental study.

### 3. Results and discussions

The experimental test loop was run to validate the dehumidification performance of the two different configurations of the semi-open absorption cycle as a heat pump dryer. The absorber implemented for this test was approximately 35×35×8 cm (H×W×D) in size with 3.3 m² of active surface area (Table 1). It is noted that the absorber and desorber architectures are modular, enabling the increase in capacity through the addition of plates, without loss in efficiency. In typical drying applications, it is desirable to dehumidify the process air and elevate its temperature within the absorber. As shown in Figure 5, the system latent capacity is a function of the inlet air dewpoint temperature because the air moisture increases with increasing the dewpoint temperature. Within the absorber, the primary difference between the single- and double-effect system configurations is the inlet solution concentration and temperature. In this study, across the spectrum of single-effect experimental data, the absorber solution inlet concentration was kept constant at ~88%. The absorber inlet solution concentration in the double-effect experimental is maintained constant at ~92%. As the water absorption process is driven by the difference in vapor pressure between the process air and the desiccant solution (solution vapor pressure decreases with increasing concentration), the latent capacity of the double-effect system at these same conditions (Figure 5) is expected to be greater.

![Figure 5. Single- and double-effect system latent capacity as a function of inlet air dewpoint temperatures. The inlet air, IL solution, and oil flow rates as well as the oil inlet temperatures have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, and 148 °C, respectively. The solution flow rate for the two double-effect data points is 125 mlpm.](image)

In the drying application it is also beneficial to raise the temperature of the process air at the absorber exit. This limits the amount of condenser heat recovery required to achieve the desired exit air temperature conditions. The amount of sensible heat transferred to the process air is a function of the absorber inlet air dry bulb temperature and the inlet solution temperature. As shown in Figure 6, as the difference between the solution and air inlet temperatures increases (the solution is hotter than the inlet air) the process air dry bulb temperature rises. At large solution/air inlet temperature differences, the process air is heated up to ~6 °C. It is
noted that although the same solution and air inlet temperature difference can be observed at different operating conditions, leading to a range of absorber air temperature increases, there is a general trend of increasing absorber with increasing solution/air inlet temperature difference. The low air temperature rise in the double-effect system is attributable to the low solution flow rate (125 mlpm). At this low flow rate, the heat transfer resistance between the solution and the air flows increases due to an increased air gap between the membrane and the solution.

![Graph showing process air dry bulb temperature increase as a function of the single- and double-effect absorber inlet solution/air temperature difference.](image)

Figure 6.1 Process air dry bulb temperature increase, as a function of the single- and double-effect absorber inlet solution/air temperature difference. The inlet air, IL solution, and oil flow rates as well as the oil inlet temperature have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, and 148 °C, respectively. The solution flow rate for the two double-effect data points is 125 mlpm.

The MRE of the single- and double-effect systems as calculated on a primary energy basis is shown in Figure 7. To convert the MRE as calculated by Eq. 4, a burner efficiency of 0.85 and a site-to-source ratio of 1.05 (natural gas) has been used to adjust the amount of energy (Q\textsubscript{oil}) required to drive the system. As this system can use solar thermal, biomass, waste heat, etc., it is believed that this burner efficiency/natural gas site-to-source ratio provides a representative estimate of the system’s primary energy consumption. As can be seen in Figure 7, the single-effect primary MRE approaches 1.25 kg/kWh\textsubscript{primary} with increasing inlet air dewpoint. At the same conditions, the estimated theoretical performance of the double-effect system (Figure 7) approaches an MRE of 2.35 kg/kWh\textsubscript{primary}. As the testing has just begun, the MRE performance of the double-effect system at a low solution flow rate of 125 mlpm is presented in Figure 7. As the double-effect testing continues over the coming month, a complete set of data at a solution flow rate of 300 mlpm will be incorporated in this figure.

![Graph showing single- and double-effect system primary moisture removal efficiency as a function of the air inlet dew point temperature.](image)

Figure 7. Single- and double-effect system primary moisture removal efficiency as a function of the air inlet dew point temperature. The inlet air, IL solution, and oil flow rates as well as the oil and inlet temperature have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, and 148 °C respectively for the single effect system. The solution flow rate for the two double-effect data points is 125 mlpm.
This preliminary MRE data compares well to the performance of current VCSHP systems (0.65-1.53 Kg/kW\textsubscript{primary}) [18–20] (Figure 8) when the data is converted from site to primary energy using a primary energy factor of 2.8. Improvements in the system’s MRE performance are expected with the optimization of the solution and air flow rates as well as system components.

![Figure 8](image.png)

**Figure 8.** A comparison of drying technologies primary energy MRE as a function of system operating temperature.

4. **Conclusions**

Laboratory-scale IL single- and double-effect absorption heat pump drying systems were experimentally tested across a range of inlet air conditions representative of those found in low temperature drying applications. The single-effect system demonstrated a MRE of 1.2 kg/kW\textsubscript{primary}. The MRE performance of the double-effect system is projected to reach 2.35 kg/kW\textsubscript{primary}. This preliminary performance compares well with the current state-of-the-art VCSHP performance based on the primary energy consumption. The use of IL demonstrated the robustness of the system without control equipment for mitigating crystallization. Further optimization of the system operating conditions and components are ongoing. This thermally-driven technology could facilitate implementation of waste heat, solar thermal, biomass, and green hydrogen powered industrial drying systems.

Abstract

Water heating and indoor latent cooling loads are great sources of primary energy consumption in many applications. Recently\textsuperscript{,} a semi-open ionic liquid absorption heat pump water heater (AHPWH) has been proposed in which the latent energy in humid air (ventilation, process air, etc.) is used to heat water. This AHPWH operates at near ambient pressure, using a novel ionic liquid, enabling stable operation across a wide range of conditions using inexpensive and passive controls eliminating the complexities and costs associated with typical absorption cycles. In this work, we experimentally compare the performance of three configurations of the semi-open heat pump water heater internal heat recovery, at several conditions, including those representative of the standard rating tests as applied to commercial storage-type water heating equipment, to determine their impact on system capacity, coefficient of performance (COP), and water delivery temperature. The results suggest that the impacts vary with the inlet air dewpoint temperature and are substantial at low dewpoints. In hot and humid inlet air conditions, the combined COP reached 2.55 with a 52 °C water delivery temperature. In these same hot and humid inlet air conditions, the combined COP decreased to 1.93 as the delivery water temperature was increased to 82 °C. These measurements demonstrated the viability of this technology in hot water-intensive applications such as commercial kitchens and food and beverage processing facilities.

1. Introduction

With rising energy demand and the dependence on fossil fuels, the world is facing the unprecedented challenges of climate change and energy security [1]. Energy efficiency improvements offer the greatest opportunities for near term decarbonization solutions [2]. Water heating and dehumidification represent two energy intensive processes that have wide-spread application across the industrial and building sector. Several applications such as commercial kitchens and food and beverage processing facilities utilize both processes simultaneously. Recent work has demonstrated the ability of a semi-open absorption heat pump water heater (AHPWH) [3] to harvest the latent energy of air moisture for water heating [4–7]. This AHPWH operates at near ambient pressure, eliminating complexities and costs associated with conventional absorption cycles. A novel ionic liquid (IL) has been successfully implemented enabling the system operation at cycle conditions not possible with conventional salts due to crystallization, and stable operation with inexpensive and passive controls. The system also benefits from compact, light, low-cost plate-and-frame membrane-based heat and mass exchangers [8,9].

Herein, three configurations of the AHPWH system involving different ways of recovering the solution heat leaving the desorber are studied to determine the impacts on system coefficient of performance (COP) and water exit temperature. In the following sections, first, the three system configurations are introduced. Then,
details of an experimental setup developed for testing these configurations is discussed. Finally, test results on performance of these systems are compared and the ability of the technology to deliver hot water in commercial applications is analyzed.

2. Experimental system

2.1. System configurations

Previous semi-open AHPWH research has been conducted using the system architecture presented in Figure 1a. In this architecture, heat is added to the process water in the absorber, solution-water heat exchanger (SWHX), and condenser. The use of the SWHX serves to increase the process water temperature, while lowering the desiccant solution temperature prior to its entry into the absorber. A heating oil loop (not shown) is used in all three configurations (Figure 1) to add heat to the desorber. The solution-oil heat exchanger (SOHX) represents the use of flue gas heat to preheat the desiccant solution prior to its entry into the desorber.

Figure 1b presents a semi-open AHPWH architecture wherein heat is added to the process water in the absorber and condenser. In this architecture a solution heat exchanger (SHX) is used to recover heat in the solution flow loop, preheating the desiccant solution prior to its entry into the desorber, while cooling the desiccant solution prior to its entry into the absorber. Figure 1c represents a hybrid version of the previous two configurations. In this configuration, heat is added to the process water in the absorber, SWHX, and condenser similar to the configuration shown in Figure 1a. Heat recovery in the desiccant solution flow loop is performed by the SHX in a similar fashion as the configuration shown in Figure 1b. The addition of the SWHX in this configuration is intended to lower solution desiccant temperature entering the absorber to increase the system’s latent capacity. In this paper, the experimental performance of these configurations is compared.

![Figure 1. The semi-open absorption heat pump water heater system configuration schematics using solution-water and solution-oil heat exchangers (A), solution heat exchanger (B), and solution-water and solution heat exchangers (C).](image)

2.2. Instrumentation Diagram

A single-effect liquid desiccant AHPWH was fabricated and integrated into a test suite (Figure 2). Two configurations of this AHPWH system (Figure 1b and 1c) were tested in this study. This experimental data was compared with legacy data for the AHPWH operating in the configuration shown in Figure 1a [4,6,7]. In each configuration, the system operates in a cycle in which water vapor is absorbed from the air flow in the absorber and is subsequently liberated in the desorber (via heating) with the heat of absorption, condensation, and recovery being used to heat the process water. Within the absorber, the concentrated desiccant solution flows down the absorber plate while interfacing with the air flow through the membrane. The water vapor is absorbed by the solution. The dilute (i.e., water-rich) solution then exits the absorber and is pumped to the desorber where it is regenerated. Depending on the system configuration, one or more heat exchangers are used to recover energy of the solution exiting the desorber to either heat the desorber inlet solution and/or the process water.

The experimental test setup consists of three primary flow loops including the solution, water, and air flow loops as well as two secondary flow loops: the heating oil loop and the air flow loop (cf. Figure 2). The IL solution exiting the absorber is pumped to the desorber by a small variable speed gear pump. The absorber is located within the closed air loop (cf. Figure 2). A chiller is used in the process water loop to control the inlet temperature and water flow rate to the system absorber, condenser, and heat exchangers (as applicable). To control the humidity level within the air loop, a steam generator in conjunction with a custom-made steam distribution manifold are utilized. To control the air temperature, a secondary water loop is connected to a
heating/cooling coil installed within the air duct. A variable speed axial fan is used to circulate air through the air loop. The heating oil loop, which powers the desorber, utilizes a heating oil bath and synthetic oil SIL 180.

The solution and water flow rates are measured using positive displacement and turbine flow meters, respectively. Due to the elevated temperature of the oil flow loop, a high-temperature positive displacement flow meter is used to measure the oil flow rate. The air flow rate is measured using a pitot tube sensing element mounted within the air loop duct. Multiple sensing ports along the length of the sensing element are used, and internally averaged to ensure accurate air flow rate measurement. All liquid temperatures were measured using T-type thermocouples. The process air temperature and relative humidity are measured using thin-film capacitive sensors. The absorber solution inlet and outlet concentrations are measured using two inline refractive index (RI) sensors. RI instead of Coriolis effect is used because the variation in density for ILs is insignificant over a wide concentration range, making accurate measurement of the concentration infeasible. Curve fits have been developed to establish RI values as a function of IL concentration and temperature. The primary system temperature, flow rate, RI, and air velocity are recorded using a data acquisition system. A second data acquisition system is used to record the air temperature and relative humidity. Time stamps are used to combine the data collected by each data acquisition system to enable a system level data analysis.

2.3. Absorber

A new generation absorber is utilized in this study. Comparison of this absorber with the configurations of absorbers used in our previous studies are presented in Table 1. The overall absorber configuration has remained the same between different generations. A schematic of an absorber panel showing the desiccant solution, cooling water, and air flows is shown in Figure 3. The absorber used in this study is fabricated from acrylonitrile butadiene styrene (ABS) sheets. Each absorber plate has an internal cooling water core containing water channels and distribution manifolds. The desiccant solution flows on the two outer surfaces of each plate. The plate surfaces are machined to include features designed to slow and spread the solution flow to “wet” the entire surface (front and back) of each panel [8,9]. A membrane is then bonded over the surface features to constrain the solution. Lastly, manifolds are bonded on the top and bottom of each side of the ABS sheet-membrane assembly (i.e., a panel) to direct the IL flow through the gap formed in between the ABS surface and membrane, and the water to the internal water cavity. Air flows across the panels (cf. Figure 3) through 3 mm gaps formed in between them within the absorber assembly.
Figure 3. A schematic of a single absorber plate showing that air flows across the membrane while exchanging moisture with the desiccant solution constrained behind the membrane.

2.4. Desorber and Condenser

In contrast to the absorber, the desorber design has remained the same in all our studies. In the desorber, the dilute solution is supplied to the desorber surface by a distribution manifold located at the top of the desorber surface (Figure 4). To ensure a uniform distribution of the solution over the desorber surface (Figure 4A) and to enhance the desorption rate, surface structures described in our earlier studies are utilized here [10]. The desorber surface is heated using silicone oil in a counter flow heat exchange configuration (Figure 4A). To utilize the heat of the desorbed vapor, a condensing surface is built adjacent to the desorber surface, separated by a porous polytetrafluoroethylene (PTFE) membrane (Figure 4B). A critical function of this membrane is to eliminate IL carryover from the desorber while permitting water vapor migration to the condensing surface. The condensing surface is used as the final heating stage of the process water within the AHPWH.
2.5. Data reduction and uncertainty analysis

The system performance presented in the results and discussion section is calculated based on the measured data described above. The system latent capacity is calculated using Eq. (1).

\[ Q_{\text{latent}} = \dot{V}_{\text{air}} \rho_{\text{air}} h_{f,g} (\omega_{\text{air, in}} - \omega_{\text{air, out}}) \]  

where \( \dot{V}_{\text{air}} \) is the absorber air flow rate; \( \omega_{\text{air, in}} \) and \( \omega_{\text{air, out}} \) are the absorber air inlet and exit absolute humidity, respectively; \( \rho_{\text{air}} \) is the air density as calculated from standard tables using the measured air inlet conditions; and \( h_{f,g} \) is the water latent heat of evaporation. The desorber heat input is calculated using Eq. (2).

\[ Q_{\text{oil}} = \dot{V}_{\text{oil}} \rho_{\text{oil}} c_{p,\text{oil}} (T_{\text{des, oil, in}} - T_{\text{des, oil, out}}) \]  

where \( \dot{V}_{\text{oil}} \) is the desorber oil flow rate; \( T_{\text{des, oil, in}} \) and \( T_{\text{des, oil, out}} \) are the desorber oil inlet and outlet temperatures, respectively; \( \rho_{\text{oil}} \) is the oil density; and \( c_{p,\text{oil}} \) is the oil thermal capacity calculated using curve fits derived from data provided by Clearco for their SIL 180 silicone oil. The system water heating capacity is calculated using Eq (3).

\[ Q_{\text{water}} = \dot{V}_{\text{water}} \rho_{\text{water}} c_{p,\text{water}} (T_{\text{water, cond, out}} - T_{\text{water, abs, in}}) \]  

where \( \dot{V}_{\text{water}} \) is the process water flow rate; \( T_{\text{water, cond, out}} \) and \( T_{\text{water, abs, in}} \) are the condenser water outlet and absorber water inlet temperatures, respectively; \( \rho_{\text{water}} \) is the water density; and \( c_{p,\text{water}} \) is the water thermal capacity. The system latent heat capacity along with the desorber heat input are used in Eq. (4) to calculate the system dehumidification COP.

\[ COP_{\text{dehumidification}} = \frac{Q_{\text{latent}}}{Q_{\text{oil}}} \]  

The system water heating capacity along with the desorber heat input are used in Eq. (5) to calculate the system heating COP.

\[ COP_{\text{heating}} = \frac{Q_{\text{water}}}{Q_{\text{oil}}} \]  

The combined system COP is the addition of the system water heating and system dehumidification COPs as shown in Eq. (6).

\[ COP_{\text{combined}} = COP_{\text{heating}} + COP_{\text{dehumidification}} \]
The uncertainty was calculated using an engineering equation solver (EES) uncertainty propagation subroutine. The subroutine is based on NIST guidelines[11] and assuming that the individual measurements are uncorrelated and random, the uncertainty in the calculated quantity can be estimated using Eq. (7).

\[ U_Y = \sum_i \left( \frac{\partial Y}{\partial X_i} \right)^2 U_{X_i}^2 \]  

(7)

2.6. Test Conditions

Each configuration was tested at the inlet air and water conditions listed in Table 3. The first test condition represents the inlet water and air temperatures outlined in the Electronic Code of Federal Regulations (e-CFR) to establish water heating Uniform Energy Factor (UEF) performance[12]. The inlet air, IL solution, and oil flow rates as well as the oil inlet temperature have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, and 148 °C, respectively.

3. Results

Legacy data is presented herein to compare the performance of system configuration A (cf. Figure 1) to configurations B and C [4–7]. The system performance data presented for configurations b and c has been collected as part of this experimental study.

3.1. Configuration B

As shown in Figure 5 for configuration B (cf. Figure 1b), the system water heating capacity depends on both the air and water inlet conditions. As expected, the system water heating capacity increases as the inlet air dewpoint increases. This is due to the increase in the air temperature and moisture content with increasing dewpoint temperature, meaning that more energy is available in the air (more humidity). Also, the water heating capacity decreases as the inlet water temperature increases, because increasing the water temperature elevates the solution temperature resulting in reduction in the heat added to the water.
Similarly, as the system water heating capacity increases as a function of the increasing inlet air dewpoint temperature and decreasing water temperature, the system heating COP (Figure 6a) and dehumidification COP (Figure 6b) also show similar trends. The very low dehumidification COP at low inlet air dewpoint temperatures is a result of the relatively high absorber solution inlet temperatures (~ 40 °C). While these temperatures served to heat the water in the absorber, they limit the amount of latent heat removed from the air, lowering the system dehumidification COP.

3.2. Configuration C

Similar to configuration A (cf. Figure 1a), configuration C (cf. Figure 1c) uses heat recovery from the solution flow loop for process water heating. However, in configuration C, the solution inlet temperature to SWHX used for heat recovery is substantially lower than that in configuration A, as the solution flow has already been used for heat recovery in the SHX. The water heating capacity, and heating and dehumidification COPs trends for configuration C (cf. Figure 1c) are consistent with those exhibited in configuration B (Figure 7). At a given inlet water temperature, the water heating capacity and heating and dehumidification COPs all increase with increase inlet air dewpoint temperature. As discussed in the section above, this is due to the increase in the energy available in the inlet air as its dewpoint temperature is increased. Although not shown in Figure 7, similar to the trend in configuration B the system capacity and performance decreases with increasing absorber water inlet temperature.
Figure 6. System heating (a) and dehumidification (b) COP as a function of air inlet dew point temperature and water inlet temperature ($T_{w,in}$) when operating in configuration B. The inlet air, IL solution, and oil flow rates as well as the oil inlet temperature have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, and 148 °C, respectively.
Figure 7. System water heating capacity as function of air inlet dew point temperature when operating in Configuration C. The inlet air, IL solution, and oil flow rates as well as the oil and water inlet temperature have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, 148 °C, and 15 °C respectively.

3.3. Comparison between Different System Configurations

As shown in Figure 8, the differences in the solution heat recovery process as defined by Configurations A, B, and C impact the system water heating capacity. As is shown in Figure 8, the addition of the SWHX in the solution loop (Configuration C) provides a fairly constant increase in system water heating capacity relative to Configuration B over a wide range of inlet air dewpoint temperature. The legacy water heating capacity data for Configuration A, does not demonstrate the same increasing capacity with increasing inlet air dewpoint temperatures [5].

Figure 8. System water heating capacity as a function of air inlet dew point temperature for all three configurations. The inlet air, IL solution, and oil flow rates as well as the oil and water inlet temperatures have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, 148 °C, and 15 °C, respectively.
As shown in Figure 9, the addition of the SWHX has increased both the heating and dehumidification COPs in at low inlet air dewpoints when compared to the COPs of configuration B (Figure 6). However, as can be seen in Figure 10 this improved COP of configuration C as compared to configuration B at low inlet air dewpoint temperatures, becomes smaller as the inlet air dewpoint increases. In comparison the combined COP of configuration A, is the best at low inlet air dewpoint temperatures, with its performance being relatively flat as the inlet air dewpoint is increased. This demonstrates the configuration C, provides the best performance across a wide range of inlet air conditions. At low inlet air dewpoint conditions, the performance of configuration A and C are comparable, but better than that of configuration B. At high inlet dewpoint conditions, the performance of configuration B and C are comparable, but better than that of configuration A.

Figure 9. System heating and dehumidification COP as a function of air inlet dew point temperature for configuration C. The inlet air, IL solution, and oil flow rates as well as the oil and water inlet temperatures have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, 148 °C, and 15 °C, respectively.

Figure 10. Combined system COP as a function of air inlet dew point temperature for all three configurations. The inlet air, IL solution, and oil flow rates as well as the oil and water inlet temperatures have been held constant at 155 cfm, 300 mlpm, 2.85 lpm, 148 °C, and 15 °C, respectively.
3.4. Delivery water temperature

For residential water heating applications, the UEF test conditions dictate a water delivery temperature of 51.7 °C. In legacy research, the water delivery rate was held constant, and the water delivery temperature was allowed to fluctuate based on the inlet air and water conditions[5]. In this study, for configurations B and C, the delivery water temperature was maintained at ~ 52 °C, and the water delivery rate was varied based on the inlet air and water conditions. As the performance of this AHPWH improves with increasing air inlet temperature and humidity, a potential application is commercial water heating for kitchens using the kitchen latent load.

The commercial water delivery temperature is 82.2 °C. As such, the ability of the system to deliver water at this temperature, at hot and humid air inlet temperatures, and the impact on system performance was investigated. At an inlet air dewpoint temperature of 32.7 °C and an inlet water temperature of 15 °C, the heating COP of the system decreases from 1.55 to 1.07 as the water delivery temperature is increased from 52 °C to 82 °C for the system operating in Configuration C. Under this same conditions and configuration, the dehumidification COP decreases slightly from 0.99 to 0.86. The decrease in heating COP is expected as the condenser operating temperature has been increased, while the desorber oil inlet temperature has been held constant. Future studies are warranted to increase the system COP by changing its regeneration temperature as well as IL properties.

4. Conclusions

A lab scale IL absorption heat pump water heater system was experimentally tested in two configurations, across a range of inlet air and water conditions, including those delineated for UEF testing. The system performance of these two configurations were compared to each other, as well as, a third configuration used in previous research efforts. These configurations demonstrated the ability to deliver 52 °C water at UEF conditions at a heating COP of 1.26 [6] (configuration A), 0.67 (configuration b), and 0.98 (configuration C). This performance increased to a heating COP of 1.52 (configuration B) and 1.55 (configuration C) at an inlet air dewpoint of ~ 32 °C. These COPs compare well to the primary COP of 1.42 [13] of the most efficient electric HPWH (UEF = 4.07) on the market today.[14] Additionally, the ability to deliver 82 °C water at hot and humid inlet air conditions demonstrated the viability of this technology in commercial water heating applications. The use of IL demonstrated the robustness of the system in providing water heating across a wide operational range, without control equipment for mitigating crystallization. Further optimization of the system flow rates offers the ability to improve.

Abstract

High-temperature heat pumps (HTHP), supply temperatures > 100°C, have received significant traction in recent years due to the high total energy usage by processing industries and the phasing down of hydrocarbons. However, despite their potential to significantly reduce greenhouse gas emissions, electrically driven HTHPs suffer considerable performance losses at temperature lifts greater than 60 °C. However, multiple industrial sectors require supply temperature > 120°C while at the same time high temperature high-capacity waste heat sources are often not readily available. Currently, the most widely used cycle for HTHPs with a large temperature lift is the cascade arrangement with different refrigerants on the high side and low side. In this work, we propose staging either the high-side or the low-side compressor, and as such, we investigated different types of economization through a thermodynamic simulation in EES. The refrigerants selected were R-32 and R-1233zd(E). It was found that by using open economization on the high side and by optimizing the cascade temperature, performance enhancements in the order of 25% are achievable over the baseline cascade cycle.

Keywords: High Temperature Heat Pumps; Cascade; GWP; Decarbonization

1. Introduction

Decarbonization policies, government initiatives (e.g., carbon taxes), and many other measures have resulted in rapid replacement of fossil fuels in applications where heating can be effectively electrified by means of heat pumps. Although the debate is mostly focused on buildings, industrial processes require vast amounts of heat, primarily supplemented by fossil fuel sources. In the work of Fox et al. (2021), it was estimated that 3416 PJ of heat are required in the U.S. for process heat, with roughly 50% used for supply temperatures between 120 to 160 °C, 30% for 160 to 200 °C and the rest for supply temperatures less than 120 °C [1,2]. Although trends from Germany and France indicate lower usage of process heat above 140 °C, it is immediately apparent that a vast potential of decarbonization potential exists in switching these processes from gas/oil burners to heat pumps. These heat pumps, labeled as High Temperature Heat Pumps (HTHPs), are usually characterized by heat sink temperatures greater than 100 °C and can be further categorized as a very high temperature heat pumps (VHTHP). However, since the specific limits are not clearly defined, this differentiation will not be used in this work. Additionally, this work will focus on closed systems, compression heat pumps, although open systems (mechanical vapor recompression, thermal vapor recompression) and closed (sorption) have been investigated elsewhere [3,4,5].

HTHPs in the recent scientific literature have received significant academic traction, with multiple review papers [2,6,7], work on refrigerant selection [8,9], advanced thermodynamic cycles [10,11], experimental pilot studies [12,13] and techno-economic analyses [14]. This interest has not only been restricted to academia, but
multiple companies have also come up with industrial models, some of which are shown in Table 1, a more comprehensive list is provided in [2].

The widespread adoption of this technology is, however, restricted by several challenges, including the following:

- **Compressor design and oil management**: The large capacities of industrial applications, the high superheat temperature and material stresses are significant challenges to compressor designs and their longevity. Additionally, synthetic lubricants that can withstand such high temperatures and operate with the selected refrigerants need to be identified.

- **Refrigerant selection**: For most of the available high temperature heat pump applications, refrigerant R245fa is used. This essentially has to do with the familiarity of the manufacturers with this refrigerant due to its extensive use in waste heat recovery Rankine cycles. However, this refrigerant has a high GWP, and due to the large refrigerant charge of these systems, its usage can be detrimental to the environment. Therefore, much research is focused on finding low GWP refrigerants, with non-flammability also being a vital attribute [15].

- **Coefficient of Performance (COP)**: The process heat industry requires massive sums of heat to be supplied. The transition to electricity would result in significant loads to the distribution grid. Additionally, the lower price of gas over kWh in most of the world gives a considerable incentive for the industry to continue using fossil fuels. Therefore, thermodynamic cycles with high COP are required to meet this challenge and incentivize HTHP adoption.

- **Cost**: Currently, HTHP presents a more costly solution over gas burners, although this difference can decrease with market maturity, economies of volume, higher gas pricing, and tax incentives.

The aim of this work is to address some of the challenges with respect to the COP decrease as the lift temperature (ΔT_{inh}), defined as the difference between the sink and the source temperature, increases. In the recent works of Kosmadakis et al. (2020) and Mateu-Royo et al. (2021), it was identified that for low temperature lifts (50 K or below), single-stage with economization and internal heat exchanger (IHX) performed best, while at higher lifts (60 K or above), two-stage cascade with different refrigerants on the high side and the low side selected appropriately performs better [10,14]. However, in many cases, a far greater ΔT_{inh} is necessary, in the order of 80 to 100 K, with some applications requiring an even greater temperature lift. An example of this could be a pulp factory in the U.S., receiving waste heat at 40 °C and needing to provide heat for its processes in the 120 to 140 °C range. Although higher source temperatures would be preferred, that is not readily available in many cases. Another example is that of air source systems, such as the HEM-HR90 (see Table 1), which are subject to atmospheric variations even at lower sink temperatures. Through a literature review, it was identified that limited research has been on this topic [16,17], and in particular, that of triple stage (treble) compression, an option widely used in the LNG and cold process industry where a large ΔT_{inh} is also necessary. A benefit of triple stage compression is that the pressure across each compressor is limited, increasing its performance while decreasing the superheat losses. As such, we propose comparing a number of possible triple stage compression architectures with some of the currently available two stage, in particular,
two-refrigerant cascade cycle, with or without internal heat exchangers, to quantify the potential expected improvements.

The novelty of the work lies in investigating multiple potential architectures as well as using a variable compressor map, unlike the previous authors [16], as well as proposing in so far as the authors are aware, a novel treble compression cycle that of cascade economization, presented in Section 2.1. This cycle can achieve three compression processes with only two compressors by staging one of these compressors. The paper is structured in the following manner:

- **Thermodynamic Modeling & Cycles**: Cycles analyzed, thermodynamic equations and assumptions.
- **Refrigerant Selection**: Selecting refrigerant the best refrigerant candidates for the cycles.
- **Parametric Analysis**: Comparative performance of different cycles and impact of operating conditions. Optimal system parameters ($T_{\text{cascade}}$). Impact of modeling assumptions and system parameters (pinch analysis, compressor map).
- **Discussion**: Outcomes from parametric analysis, identified trends, and proposed future work.

2. Thermodynamic Modeling & Cycles

2.1. Cycle Architectures

Economization cycles are able to improve thermodynamic performance of cycles by splitting one larger less efficient compression process to two smaller more efficient ones which results in performance gains. Since

![Cascade economization cycles](image)

Fig 1. Cascade economization cycles investigated: (A) Open economization HT, (B) Open economization LT, (C) Closed economization HT, (D) Closed economization LT.
this work aims to analyze the potential of staging compressors in HTHPs, closed and open economization were investigated. In particular, given the high lift temperatures sought, the cycles are proposed in a cascade format, where staging occurs either on the low or high side. These cascade sides use different refrigerants to optimize cycle performance and are henceforth referred to in this paper as LT for the low temperature loop and HT for the high temperature loops. These cycles are illustrated in Figure 1.

The cycles were compared to the industry standard for high lift temperatures, namely the cascade cycle (see Ochsner IWDSS R2R3B). Additionally, an improved cascade cycle given in [24] was investigated using two internal heat exchangers. Lastly, a triple cascade cycle with three separate compressors, rather than staged as in Figure 1(A), was also analyzed. These cycles are provided in Figure 2.

![Figure 1: Schematic of the cycles proposed.](image)

Fig 2. Variations of the simple cascade investigated: (A) Baseline cascade, (B) Triple cascade, (C) Cascade with internal HXs.

2.2. Thermodynamic Model

A thermodynamic model was developed to investigate the system performance. Calculations were performed in EES [18]. The following modeling assumptions were made to develop the models:

- Steady-state, steady-flow analysis.
- Kinetic Energy and Potential Energy are neglected.
- Negligible pressure drops and heat losses to the surrounding in heat exchangers and piping.
- Adiabatic expansion valves with isenthalpic expansion.

The compressor power can be expressed in terms of isentropic efficiency:

\[
W_c = \frac{m(h_{out, is} - h_{in, is})}{\eta_{is}}
\]  

(1)

To define isentropic efficiency, one must select a compressor technology, which is mainly subject to the refrigerant used and capacity of the system. For HTHP applications, the vast majority of research and industrial development is focused on piston, screw, twin-screw, and turbo compressors, of which the most prominent type is that of screw. As such, we will primarily focus on screw compressors, with Equations 2 and 3.
representing the compressor’s isentropic and volumetric efficiency as a function of the pressure ratio. The impact of compressor isentropic efficiency will be further investigated in Section 4.3.

\[ \eta_{is} = b + c \ln \left( \frac{v_{in}}{3600} \right) + d (r_{ec,l}) \]  \hspace{1cm} (2)

\[ \eta_{vol} = 0.95 - 0.0125 r_{pc,i} \]  \hspace{1cm} (3)

These correlations were obtained from [14,22] and the fit variables are given in [22]. The volumetric heat capacity (VHC) was used to select the best refrigerant in the cascade cycle. It was modeled accounting for the low and high sides as per [10]:

\[ VHC = \rho_{c,in} \eta_{vol} \Delta H_{cond} \]  \hspace{1cm} (4)

Heat exchangers were modeled using pinch analysis, the values shown in Table 2. For the internal heat exchanger effectiveness, Equation 5 was used.

\[ \varepsilon_{IHX} = \frac{h_{vap, out} - h_{vap, in}}{h_{vap, out} - h_{liq, in}} \]  \hspace{1cm} (5)

\[ Q_{HX} = m (h_{out} - h_{in}) \]  \hspace{1cm} (6)

For the cascade HX, the approach of [19] was used. In terms of the economization, the optimum pressure from the two-stage economization cycle was used (no cascade) [20].

\[ P_{int} = \sqrt{P_{high} P_{low}} \]  \hspace{1cm} (7)

Finally, the system COP and 2nd Law efficiency can be defined as:

\[ COP = \frac{Q_{sink}}{\sum W_{c,i}} \]  \hspace{1cm} (8)

\[ COP_{Carnot} = \frac{T_{sink}}{T_{sink} - T_{source}} \]  \hspace{1cm} (9)

\[ \eta_{II} = \frac{COP}{COP_{Carnot}} \]  \hspace{1cm} (10)

3. Refrigerant Selection

To compare the performance of the cycles in Section 2.1, it was necessary to select some appropriate refrigerants. However, choosing refrigerants in a cascade cycle for a high temperature heat pump system is not straightforward. An optimal refrigerant should address thermodynamic aspects (e.g., thermal stability at high temperatures, volumetric capacity, etc.), environmental and safety concerns (e.g., GWP, ODP, flammability and toxicity), and techno-economic considerations. The following analysis shows all relevant parameters for a proper selection. Due to the cascade nature of the cycles investigated, two refrigerants have to be selected, one to operate on the high side and one on the low side. The normal boiling point (NBP) should be low enough to allow vaporization during regular operation, while the critical temperature of the refrigerant defines the upper temperature border for a system that is not supposed to run in supercritical operation. So especially for the high temperature loop, selecting a refrigerant whose critical point is above the anticipated condensation temperature is essential. From an environmental standpoint, the refrigerant should have an ODP of 0 and a GWP that is as low as possible. Furthermore, the safety classes helped to distinguish between lower toxicity (class A) and higher toxicity (class B) as well as to estimate the flammability (increasing in the order of 1, 2L, 2, and 3) [21]. Low toxicity and flammability are generally preferred, but the thermodynamic properties sometimes require a tradeoff. Finally, the techno-economic parameters are important. Values like the volumetric heat capacity (VHC) can tell how big the components will be, so this value should be high to reduce component sizing. At the same time a high COP is preferred to allow an efficient operation. To initiate the calculations, R-290 was used as a reference fluid in the low-temperature cycle, while R-600 was the reference fluid for the low temperature loop refrigerant.

The comparison for the low-temperature cycle refrigerants (Table 3) shows that the highest COP can be achieved with R-717 (ammonia). The pros of this refrigerant are its high VHC, which is the third highest in the comparison. Also, it is a natural refrigerant with an ODP and a GWP of 0. However, it is toxic and mildly flammable. In addition, the economic factor comes into place. Ammonia systems require stainless steel components and cannot be manufactured with copper parts. Therefore, when accounting for VHC, COP, GWP, and classification, R-32 is the appropriate candidate. In this work, A3 refrigerants were eliminated due to adoption issues in practical applications, although the reader is directed to the following [9,12]. R-600 and R-601 are attractive options for the HT side, albeit flammable. As such, research has been focused on the following HFOs: R-1336mzz(Z), R-1234ze(Z), R-1233zd(E), and R-1224yd(Z) [8]. Of these, R-1233zd(E) was selected primarily due to its high performance and critical temperature. In the case of the triple cascade cycle, R-32 was used for the LT loop, while R-1233zd(E) for MT and HT. A different choice for the MT loop was not made since the analysis was limited to T\text{sink} = 150 °C. Had a higher sink temperature been required, a 3rd choice, such as R-601, would have been made.

4. Results

4.1. Impact of operating conditions and Second Law Efficiency

The cycles presented in Section 2.1 were numerically investigated in EES. The purpose of this analysis was to quantify the performance degradations resulting from compression across a range of ΔTₗIFT and the potential benefit of staging one of the compression processes. Firstly, the source temperature was fixed at 40 ℃, and the sink temperature was increased. This would indicate a process with a stable waste heat source, and the sink is required at a high temperature, similar to the pulp process industry. The results are shown in Figure 3.

Fig 3. Performance (COP) of different cycles for increasing sink temperature.

The results indicate that cycles that perform the two-stage compression on the HS outperform those that do not. Of these, open economization beats closed economization. Open economization on the high side offers an increasing COP enhancement with ΔTₗIFT over the simple cascade, starting at 10% (ΔTₗIFT = 60 ℃) and increasing up to 25% for (ΔTₗIFT = 110 ℃). Cascade with IHXs and triple cascade are the 3rd and 4th performing cycles, respectively, even when not accounting for the pressure drops in the IHXs. These trends are also shown in Figure 4 with respect to the second law efficiencies of these systems.
With the goal of HTHPs to replace typical gas furnaces, it is also vital to investigate scenarios where waste heat is not readily available and rather air source systems is used. An industrial example of such a heat pump is Ochsner IWDSS R2R3B. The sink temperature is fixed at 120 °C. This is shown in Figure 5.

The results presented so far indicate that the performance of the cascade cycle rapidly deteriorates since the lift at each compression process is significant. To understand this further, by redefining the lift temperature as \( \Delta T_{\text{lift}, LT} = T_{\text{Cas}} - T_{\text{source}} \) and \( \Delta T_{\text{lift}, HT} = T_{\text{sink}} - T_{\text{Cas}} \), and assuming that the optimal cascade temperature is approximately \( (T_{\text{sink}} + T_{\text{source}})/2 \), at \( T_{\text{sink}} = 140 \) °C and \( T_{\text{source}} = 40 \) °C we can compute \( \Delta T_{\text{lift}, LT} = \Delta T_{\text{lift}, HT} = 50 \) °C. This represents an adverse temperature lift, resulting in high-pressure ratios and that a staging process similar to the ones presented in this paper are required. The impact of \( T_{\text{Cas}} \) is further investigated in Section 4.2.

4.2. Optimizing Cycle Parameters for COP

It was identified that two system parameters could be treated as open for optimization. Those are the intermediate pressure used in the staging of the compressor and the cascade temperature. In this work, the empirical expression shown in equation 7 has been used to simplify the analysis. Instead, optimization in EES was performed by noting that \( \text{COP}(T_{\text{Cas}}) \) and using the golden-section algorithm to find the best combination of \( \text{COP}(T_{\text{Cas}}, P_{\text{inter}}) \) since the square root rule
(widely adopted empirical relation in Eq. 7) might not hold. The results presented in Section 4.1 are based on the optimized cascade temperatures.

Figure 6 indicates that based on which side the staging occurs, $T_{cas}$ is calculated so that the temperature across this side increases given that the isentropic efficiency is better for the dual-stage compressor on that side. This means that for the cascade cycle, the cascade temperature remains close to $(T_{sink} + T_{source})/2$ since staging does not occur [10]. A similar trend is seen for the triple cascade cycle, where the temperatures are attempting to split $\Delta T_{lift}$ in three equal fractions. The slight for the triple cascade in Fig 6 occurs to the refrigerant properties.

![Figure 6](image1.png)

Fig 6. Optimum cascade temperature for different arrangements and different sink and source temperatures.

4.3. Impact of System Assumptions

Finally in this section we investigate the impact of the system assumptions on the heat exchanger modeling as well as the compressor map used.

4.3.1. Heat Exchanger Modeling

Simple thermodynamic models were selected for the heat exchangers given the comparative nature of the analysis. For the refrigerant-to-refrigerant (non IHX, cascade) HXs and the air/water to refrigerant HXs, a pinch analysis approach was used since temperature on the refrigerant side remains relatively constant due to phase change. From the thermodynamic results, it was identified that while the superheat has negligible impact to the performance of the cycle, while increasing subcooling enhances capacity and therefore the COP. Figure 7 indicates the importance of using high performance heat exchangers and that an open economization cycle on the HT side can achieve a COP of almost 2.5 at a $\Delta T_{lift} = 100 \, ^\circ C$ (20 – 120 °C), at a pinch of 5 K which is achievable with current heat exchanger technology.

![Figure 7](image2.png)

Fig 7. Impact of HX modeling, pinch, superheat, subcooling and cascade pinch on cycle performance.
While the pinch analysis could be used in the case of the phase change processes, it cannot be used in the modeling of the IHX given that the refrigerant (same refrigerant on both sides) is in the subcooled and superheated regions. As such, the effectiveness approach was adopted. Figure 8 serves a two-fold purpose. Firstly, the impact of the IHX effectiveness was analyzed. By changing the value from 0.5 to 0.9, it was found that the IHX on the high side (see Figure 2C) had significantly greater impact on the performance of the cycle. As such, the impact of the effectiveness (ε) was investigated on a cycle with one IHX, two IHXs and compared to the cascade open economization cycle. It was found that using only a single higher performing IHX on the HT loop outperforms having two IHXs. However, even when using highly efficient IHXs are used on either both sides or the high side, and not accounting for pressure drops, this cycle was not able to outperform the open economization cycle.

Fig 8. COP as a function of ε for $T_{\text{sink}} = 120^\circ\text{C}$ and $T_{\text{source}} = 20^\circ\text{C}$.

4.3.2. Compressor Mapping

Using the compressor map in [14, 22] for a single screw compressor, it was identified that the compressor isentropic efficiency was approximately 0.7 for the cascade cycle. In contrast, the cycles with two-stage compressions were in the order of 0.75 ~ 0.8 due to the improved distribution of temperature lifts and compression ratios across the system. However, it should be noted that limited information and experimental studies exist on compressors for HTHPs, given that this is a nascent field.

5. Discussion

The results of the previous analysis show that a cascade cycle with economization has clear advantages compared to a simple cascade cycle. Economized cycles use a flash tank between the condenser and evaporator under a predefined intermediate pressure controlled by the expansion valve. The gaseous fraction of the refrigerant is used to cool down the compression process. Therefore, the gas at intermediate pressure gets expanded and injected into the compressor. This technology cools down the gas temperature during the compression process and therefore improves the isentropic efficiency of the compressor. Even if that cycle is more cost-intensive due to additional components and an adapted compressor design, the performance enhancements of 25% are significant. An example of a two-stage screw compressor was prosed in [23]. It should be noted that this compressor is different from a twin-screw compressor in that the two screws do not mesh, but rather, compression occurs in two different single screws driven in a single planar arrangement.

The analysis used a compressor map that changes the isentropic efficiency based on the volume ratio the compressor has to achieve (typical to volume ratio for screw compressor). For the comparison, the map of a screw compressor was used [14, 22]. The benefits of staging can be adopted by either compressor types (reciprocating, centrifugal), such as scroll for smaller capacities with the impact varying based on the impact of pressure ratio its isentropic efficiency.
Even cascades with two internal heat exchangers, as used in other publications, show lower efficiencies than the economized cycle [24]. Therefore, based on the technoeconomic results of Kosmadakis [14], it seems that the additional cost of an improved compressor with a flash tank coupled with significant performance enhancements in high lift cycles outweighs using a standard cascade cycle. Further, with respect to introducing IHXs to as an efficiency measure to the cascade cycle, limited benefit is gained by using two while using only one on the HS seems to offer some performance enhancements, albeit lower than staging. It should be noted that plate internal heat exchangers pose additional detriments, such as oil separation, pressure drops, and have a significant cost. From our preliminary analysis, the staging proposed seems to outperform this efficiency measure.

However, additional work is needed with detailed component models, particularly for the compressor, given that limited experimental data are available for HTHP compressors, to reach a conclusive outcome. This work aims to initiate this conversation, particularly in the case of high temperature lift applications, which represent a significant proportion of the process heat industry where heat pumps are or could be used.

6. Conclusions

High temperature heat pump is a technology that can offer significant greenhouse gas reduction in the area of industrial processing. However, they suffer from substantial performance losses and irreversibilities largely due to the extreme temperature lifts they need to achieve. In this work, the potential of staging one of the compression processes was investigated. A number of proposed thermodynamic cycles were investigated by varying the type of economization (open or closed) as well as the location (high or low side). These arrangements were compared against the industry standard cycle for high lift applications, the cascade cycle, with two different refrigerants, one selected for the high side and one for the low side. Additionally, a modified high performance cascade cycle was investigated with two IHXs before the compression processes. The refrigerants selected for the investigation were R-32 and R-1233zd(E) for the low-side and high-side, respectively, based on their thermodynamic properties, low GWP, and ASHRAE classifications. It was found that staging the compression process can lead to performance enhancements (COP) in the order of 25% for high temperature lift applications over the baseline cascade cycles. The highest performing cycle with a staged compression process used two-stage economization on the high side with an open economizer (flash tank). This work highlights the need for integrated cycle and compressor design to achieve widespread HTHP integration at realistic supply temperatures.

Methodologies for high-density domestic heat pump deployment in the UK

Nicola Lazenby¹, Alex Hobley²

¹Government Department for Energy Security & Net Zero (DESNZ), 1 Victoria St, London, SW1H 0ET, UK
²Government Department for Energy Security & Net Zero (DESNZ), 1 Victoria St, London, SW1H 0ET, UK

Abstract

The UK Government’s Department for Business, Energy & Industrial Strategy (BEIS) has embarked on a 3-year innovation programme, ‘Heat Pump Ready’, part of its Net Zero Innovation Portfolio. This paper considers one of the programme’s objectives to drive forward methodologies which support the high-density deployment of domestic heat pumps across urban and rural areas. Projects delivering against this objective have conducted feasibility studies which address both technical and consumer barriers to high-density heat pump deployment, bringing together key stakeholders in the journey to ensure a ‘joined up’ approach from the energy networks right through to installers and consumers. Emphasis is being placed on providing a cost-effective installation and on-going support package to consumers. The key findings from these feasibility studies, carried out by project teams across Great Britain, are presented in this paper alongside proposals for the trial of these methodologies in order to achieve high-density heat pump deployment within the project’s specific locations.

Keywords: heat pumps; high density; deployment; coordinated deployment; net zero;

1. Introduction

By 2028, the UK aims to be installing 600,000 hydronic heat pumps per year [1], this is a considerable increase from the reported rate of 55,000 heat pumps installed in 2021 [2]. To achieve this deployment aim, as set out in the ‘Heat and Buildings Strategy’ [1], many factors must be considered including elements such as: achieving significant growth in the heat pump supply chain; affordability of heat pumps; the ability of the electricity network to accommodate an increase in electricity demand; and enabling the timely connection of heat pumps to the network.

The UK government have set out a package of measures to support the increase in heat pump deployment [3] which includes:

- Reducing the cost of heat pumps to consumers through zero-rate value added tax for the next 5 years on the installation of low carbon heating technologies
- Launching £450m Boiler Upgrade Scheme to provide consumers with up to £6,000 off the cost of a heat pump
- Expanding the UK’s manufacturing capacity through a £30m Heat Pump Investment Accelerator
- Investing in heat pump innovation through a £60m Heat Pump Ready Programme, part of the Net Zero Innovation Portfolio [4], which aims to develop innovative methodologies for high density heat pump deployment, in addition to supporting the development of innovative tools and technologies to overcome barriers to heat pump deployment.

This paper sets out the development and delivery of the Heat Pump Ready Programme (HPR), considering the learnings from the programme to date.

¹ Corresponding author: Email address: Nicola.lazenby2@beis.gov.uk
2. Requirement for heat pump innovation

In the development stage of HPR, it was important to establish the benchmark of current market and industry practice for heat pumps, in order to establish the areas for innovation. To determine this benchmark, an evidence review alongside stakeholder engagement was conducted. The programme design also drew upon the learning from the department’s previous heat pump innovation programme, the Electrification of Heat Demonstration project.

2.1 Evidence review

A rapid evidence assessment (REA) of existing literature was carried out in order to establish the current benchmark for innovation [5]. This evidence review was carried out across 4 key areas:

1. Financial Innovations: What are the necessary financial innovations required to deliver a large-scale roll-out of heat pumps in the United Kingdom (UK)?
2. Low Voltage Grid Issues: What are the Low Voltage (LV) grid issues associated with a concentrated deployment of heat pumps and how can we mitigate these? What is the necessary size of a heat pump cluster to achieve appropriate grid impact learnings?
3. Roll-out Facilitation: What are the necessary innovations or learnings required to facilitate the large-scale roll-out of heat pumps? What tools or established processes of stakeholder coordination exist that could support the effective roll-out of heat pumps and are there examples of coordinated deployment?
4. Performance and Deployment: What are the technological improvements to the heat pump system and tools that could be developed to support any of the above aims - i.e. the large-scale deployment of heat pumps in the UK?

The REA found that significant benefit could be gained through innovation in the following areas:
- Design improvements - considering heat pumps as modular systems and how innovation could support the ease of design, installation, and optimization of low temperature systems. Design improvements could also support the ease of connection between heat pumps and other technologies such as heat storage.
- New ways of manufacturing - the use of computer modelling simulation tools to provide flexible, user-friendly interfaces to overcome inefficient designs, in addition to new methods of mass production such as 3D printing. These come with the opportunity to increase resilience in the UK supply chain.
- Installation – the use of ‘plug and play’ software and hardware.
- Monitoring, maintenance, and operation – the opportunity for improvements to the user interface and inclusion of internet of things data-gathering to support optimization, remote diagnostics, and predictive maintenance of heat pump systems. This presents the opportunity for an enhanced consumer experience, in addition to cost savings.

These areas were supported by recommendations for future innovation programs and research to consider:
- Trials which build on the scale of previous heat pump trials, utilizing up-to-date installation, commissioning, and operational practices.
- The performance gap between system design, installation and operational use of a heat pump and the role which different approaches to on-going monitoring and optimization can play in improving performance.
- Innovation ‘horizon scanning’ to seek out early-stage technology and tools which may be at lower technology readiness levels.
- Broader areas for innovation relating to the uptake and performance of heat pumps in areas such as noise and disruption.

2.2 Learnings from Electrification of Heat Demonstration Project

The Electrification of Heat Demonstration Project (EoH) [6] began in 2020, with the aim of demonstrating the feasibility of a large-scale roll-out of heat pumps in Great Britain. This project deployed 742 heat pumps in 3 different locations within the UK. Results from the EoH have produced the following 2 key findings:

1. All UK housing types are suitable for a heat pump [7] with no property or architecture, ranging from Victorian mid-terraces and pre-world war two semi-detached homes to 1960s blocks of flats, found to be unsuitable for a heat pump.
2. Heat pumps installed in the UK have been shown to be 3 times as efficient as gas boilers [8]. Measured real-world performance of heat pumps has shown a significant increase in performance through this
trial when compared to previous UK field trials. The study found that the heat pumps performed well even on the coldest observed days with only a relatively small reduction in performance.

EoH has demonstrated that heat pumps work in domestic properties from a technical perspective and data shows their efficiency. The Heat Pump Ready programme therefore looked to explore the tangential barriers associated with the increased uptake in heat pump deployment.

2.3 Stakeholder engagement event

To understand remaining innovation requirements for heat pumps, BEIS held a virtual stakeholder engagement session [9]. This event was attended by 342 representatives from across the sector. A total of 1,241 comments were received from participants with the key suggestions including:

- The use of smart controls to monitor heat pumps, improve consumer experience, and enable response to grid demands.
- The use of thermal storage to improve heat pump efficiency, consumer experience and enable demand reduction of electricity from heat pump users.
- Options for leasing heat pumps or heat charged as a service to a consumer.
- Green mortgage options which include heat pump and energy efficiency funding.
- The coordination of heat pumps by local authorities.
- Heating engineers and installers are the most trusted to advise consumers on heat pumps.
- The use of national media outlets, e.g. TV and radio, to raise the profile of heat pumps.
- The use of clear and simple heat pump communication.

3. Heat Pump Ready Programme

The funding opportunities available under HPR were launched in 2021 [10] with the aims of the programme being to:

- Reduce lifetime costs of domestic heat pumps.
- Improve lifetime consumer experience of heat pumps.
- Stimulate innovative research and solutions to address the impact of domestic heat pumps on the electricity system.
- Develop and strengthen partnerships between the many players involved in the domestic heat pump sector.
- Develop effective approaches and products to engage effectively on heat pump issues with homeowners and with other key players in the sector.
- Establish an evidence base to enable effective design and development of future heat pump policy and regulation.

The programme is split in line with its aims across 3 key objectives:

1. Innovative methodologies for high-density deployment: Recognizing the need for a shift from a very dispersed, consumer led approach in deployment to a coordinated, ‘street-by-street’ high-density deployment of heat pumps (Stream 1).

2. Support innovative tools and technologies to overcome barriers to high-density heat pump deployment (Stream 2) across key areas including [11]:
   a. increasing the performance whilst reducing the cost of domestic heat pumps
   b. minimizing home disruption whilst providing high quality installations
   c. providing financial solutions for heat pumps
   d. improving the consumer journey through their transition to heat pumps
   e. creating a smart home energy system

3. Providing the opportunity for knowledge transfer and the dissemination of learnings across HPR projects and the broader heat pump sector (Stream 3).

This paper provides an overview of the Heat Pump Ready Programme (HPR) with a particular focus on objective 1 – the development of innovative methodologies developed which support high-density heat pump deployment within specific locations in Great Britain.

4. Scope for Innovative methodologies for high density deployment

In the development of the scope for the funding competition for project teams to carry out feasibility studies on innovative methodologies for coordinated, high-density deployment of heat pumps it was important to ensure the projects would add to the existing evidence based within this area. One of the greatest challenges...
for heat pumps is increase their attractiveness to the able-to-pay, owner occupier and private landlord market – those who are responsible for the capital and on-going cost and maintenance of heat pumps installed within their homes. Coupled with this is understanding the impact on the electricity network of mass transition to heat pumps. This funding competition was divided into 2 Phases: Phase 1 developing feasibility studies for innovative methodologies for high-density heat pump deployment (6 months); and Phase 2 trialing these feasibility studies developed (24 months).

To ensure project developed methodologies which targets this demographic and scenario the following key elements of eligibility criteria [6] were applied to all applications:

1. Project costs must not exceed £200,000, as funding was being deployed through the mechanism of Small Business Research Initiative (SBRI) [12] with this funding being required to cover 100% of the total eligible costs of the project.
2. Projects must be up to 6 months in duration, ending 30th November 2022 to enable projects to apply their learnings to their Phase 2 application to trial the methodology they developed.
3. Projects must be looking to achieve deployment of heat pumps in at least 25% of homes either on a low voltage network feeder, supplied from a secondary substation or supplied from a primary substation, during Phase 2, in order to be considered as achieving high-density deployment.
4. Funding for the cost of the heat pump, installation and on-going maintenance of the heat pump, in Phase 2, is capped in line with the Boiler Upgrade Scheme at £5,000 per air source heat pump and £6,000 per ground source heat pump.
5. Heat pumps are to be deployed, during Phase 2, in predominately gas grid, domestic, private existing homes, with a cap of 30% of trial buildings being eligible to be social housing, new build or non-domestic properties. Applicants could opt to include up to 15% of their trial homes as off-gas homes.
6. The technology eligible for deployment as limited to hydronic air source or ground source heat pumps, with only a maximum of 20% of the trial homes being eligible for hybrid or air-to-air heat pumps or other sources of direct electric heating. Shared ambient temperature ground loops were eligible, however high temperature ground loops and heat networks were not eligible for deployment.
7. All innovative methodologies for deployment were required to be replicable in other areas of the UK.
8. All technologies, tools and finance models deployed into consumers’ homes must have already been trialed and be a commercial offering to the consumer.

5. Overview of Phase 1 projects

Following the assessment of applications, 11 projects were awarded Phase 1 funding to carry out a feasibility study into their innovative methodology for coordinated, high-density heat pump deployment [7]. The locations of project are shown below on Figure 1 with:

- Urban projects (shown in purple) based in Newcastle-upon-Tyne, Sunderland, Leeds, Oxford, Greenwich and Bristol.
- Urban with significant rural projects (shown in red) based in Perth & Kinross, Cherwell and Bridgend.
- Rural projects (shown in blue) based in Fenland and Teinbridge.
Across the project teams’ feasibility studies there was a mix of projects focusing on the deployment of either air source heat pumps or shared ground loops. The number of heat pumps which project teams were looking to deploy in their locations ranged from 30 to 1000 heat pumps, with a mixture of financial offerings being considered such as upfront capital funding from the consumer, heat pump leasing and financial loans.

6. Findings of feasibility projects

Through the delivery of Phase 1 feasibility studies [13], project teams identified a range of challenges and opportunities to support coordinated, high-density heat pump deployment. This section will consider each of these in turn.

6.1. Coordination of stakeholders

To achieve high-density deployment within a given location, there is a strong requirement for the various actors supporting deployment in that location to come together. The actors which projects have identified as having a core role in deployment include:

- Management entity: across the projects, this role was carried out by a range of organisations. For the majority of projects, this role was carried out by engineering/project management consultancies [14-19] with energy suppliers [20-21] also taking on this role. For a small proportion of projects, a technology provider/coordinator took on this role [22-23] with one local authority [14]. For the local authority, they were supported by an engineering consultancy as part of their consortium to deliver the project management elements of their feasibility study. This role was responsible for bringing together the organizations necessary to deliver a coordinated methodology, developing the project communication plan alongside their approach to data sharing and governance.

- Place based entity: where a local authority was not fulfilling the management entity, the majority of projects included within their project team a local authority to provide support within depth knowledge of the local area.

- Engagement coordinator: most of the project teams had an organization specifically responsible for coordinating the consumer engagement within their location. This role typically delivered elements such as consumer surveys, developed marketing campaigns and conducted focus groups. For some projects, this role was carried out by an organization specializing in consumer engagement whilst others utilized local community groups to support this engagement.

- Housing data modeler: Some of the projects [15, 18-19, 21] included a specific role within their feasibility study project team for an organization responsible for utilizing available data on elements
such as housing archetypes, social-economic data on occupants and energy data. How this data was utilized by the projects is discussed in Section 6.2.

- **Financing partner:*** Developing an understanding of the consumer finance offer was a key element of the project’s feasibility, which ultimately decided whether a project was confident to apply for Phase 2 of the programme to trial their methodology developed. The inclusion of a financing partner, as part of the feasibility studies was not necessarily required, however it was found to be very beneficial to have a member of the project team focused on developing the project’s consumer financing offers [17-20, 24].

- **Technology provider:** Across the projects, there was a split between whether they chose a technology provider in advance of completing their feasibility study. 4 projects [15, 17, 21, 24] opted to include a member of the Kensa Group within their project team with the aim of deploying a shared ground loop (SGL) solution, in addition to the Oxford project, which was led by Samsung, aiming to deploy specifically Samsung air source heat pumps (ASHP). Choosing a technology provider upfront enabled the projects to focus their feasibility study on delivering that specific technology. Contrast to other projects who retained the ability to adapt their specific technology offers to the needs of the consumers depending largely on their house type and financial circumstances, demonstrating high levels of replicability for their innovative, coordinated methodology developed.

- **Distribution Network Operator (DNO):** Within the phase 1 project teams, there was limited representation of DNO’s, with only a couple of projects formally including their DNO in the project team [17, 22]. It was found however through the feasibility studies that the role of the DNO was vital to deliver an innovative coordinated methodology for heat pump deployment. The key knowledge which was required from the DNO was an understanding of the network configuration and capacity within the areas the project teams were targeting, to understand whether network reinforcement would be required and to explore the opportunity for flexibility across the network to reduce peak demand. Early engagement with the local DNO provided the opportunity to develop a more in-depth feasibility study.

A key element throughout each of the feasibility studies was the understanding that a customer relationship management (CRM) platform which operated between the organizations within the project team was essential. The governance for the operation varied with approaches included a combined CRM platform across all project partners [18-19, 23], utilizing existing CRM platforms [20, 21] and the development of a cross organization ‘data hub’ architecture to support data sharing [15].

### 6.2. Technical appraisal of location and homes

Coordinating the deployment of heat pumps within a specific location unlocks the opportunity to optimize the process of technical appraisal of homes for their suitability of heat pumps. Many of the projects used a ‘data led approach’ to narrow down their location for high density deployment. Two projects which considered this in detail were Samsung’s project in Oxford [16] and Buro Happold’s project in Bristol [15]. This process included bringing together the following data (in compliance with data protection protocols):

- **Network data:** working within a specific location enables network capacity to be considered for all residents within that specific location, creating efficiencies in the network assessment process and coordinated sequencing of any grid reinforcement required. To access this data, projects established relationships with the relevant Distribution Network Operator within their location. For the Samsung project they combined this data with Oxford Brookes University’s LEMAP tool to understand the load profile on the electricity network. Buro Happold utilized the DNO substation polygon areas and distribution substation capacity data available from National Grid to support their understanding.

- **Housing stock model:** Samsung drew upon the Energy Performance Certificate (EPC) dataset to feed into the analysis of the housing stock within the location they were targeting, with Buro Happold using data provided by Parity Projects, which also included energy data. Another project, E.On [17] working in Newcastle, took this analysis further by testing the feasibility of carrying out drone surveys across the location they were targeting, to develop a thorough understanding of the archetypes and features of the homes which would impact the heat pump system design.

- **Energy data:** For Samsung’s project, work was led by the University of Oxford and Oxford Brookes University to develop analytical approaches which reveal the attributes, capabilities and priorities of the target communities. This project drew upon the Energy Demand Research Project
(EDRP) dataset and The Smart Energy Research Lab (SERL) dataset to enable demand profiling to be conducted for the homes within their focused location.

- **Occupant data:** For Samsung’s project, the ACORN classification and MOSAIC datasets were used to determine the defined socio-economic types for each of the homes within the location. This classification was used to identify common factors which explain the energy demand profile associated with the home and enable the project team to explore the demographic, socio-economic status and lifestyle of the consumer. Buro Happold utilized social housing data from Bristol City Council regarding council owned properties in addition to other social housing providers data.

This flow of data is presented in Figure 2 below, which shows how the collection of data feeds into decision making regarding the location for heat pump deployment. For most of the project teams, the decision was made to trial their methodology in a location which met the following criteria:

1. The properties have high levels of energy efficiency, requiring little to no additional fabric upgrades.
2. The majority of consumers being classified as able-to-pay, middle income residents, enabling access to a wide range of financial products such as loans or heat pump rental.
3. There is sufficient headroom on the electricity network within that location, or a Distribution Network Operator (DNO) on board with the project, supporting the required upgrades within that location.

Most projects focused on location whereby they had an existing relationship with an organization within the location; this was typically with a local authority or a community energy group.

Once this data was collected, project teams planned how it would flow through the consumer journey, to support the trial of their methodology. This data was identified to support the design and survey of the heat pump by:

- **Enabling remote survey and triaging of the properties:** Enabling an understanding of what would be required from a heat pump install to be developed prior to visiting the consumer. This data allows the project teams to make an informed choice as to where to target the high-density deployment of heat pumps.

- **Streamlining in home surveys:** Having an established data set of property details will enable the project team to reduce the number of visits to a property, but also allow for data about the property to be pre-populated into surveys so that data is checked and verified during the surveys rather than collected for the first time, leading to a reduction in errors and re-visits required.

- **Supporting occupant surveys:** Ensuring that consumers are not required to repeatedly provide their personal information, in addition to providing pre-populated information within their surveys for consumers to verify rather than specific, for example asking consumers to confirm they have cavity wall insulation, based on data drawn from their EPC, rather than having to select what type of insulation their home has.

Bringing together this data centrally was identified as being key for the project teams to support the development of their specific offer to the consumer, in Phase 2, with regards the size of heat pump they required, any energy efficiency or home upgrades required and consumer financing.

Through the understanding of the role of data throughout the consumer journey and how this data supports stakeholders throughout the journey, the project teams are able to develop a standardized process for data storage and transfer which could be replicated in other locations.

![Figure 2: Diagram showing the flow of data identified in Phase 1 feasibility studies](image-url)
**Consumer journey and engagement**

For each of the projects, a key emphasis of their feasibility study was placed on how to support the consumer throughout their heat pump journey. For each of the projects, a ‘consumer platform’ was proposed which brought together various elements of the innovative coordinated methodology. For projects with an existing consumer base, such as the energy suppliers [16, 20-21], the project teams looked to utilize their existing consumer platforms, adding to them the functionality to support their heat pump journey, including registering interest for a heat pump installation, find heat pump installers and providing post-installation guidance.

Each of the project teams conducted early consumer engagement within the location they were working. The early consumer engagement largely consisted of either focus groups, online surveys/expression of interests and/or face to face surveys either at the consumer’s home or at a community event. Where surveys were conducted, the project teams findings predominately aligned with findings from existing literature, with limited local variation regarding consumers’ perspectives or motivations. Surveys however, especially when conducted face to face, did provide the first ‘touch point’ with the consumer to open the conversation regarding the project and establish early trust in the project team and build momentum for the project.

Through location specific deployment, project teams were able to consider more bespoke engagement with their communities. Project teams identified the importance of local engagement to generate interest across the community, in addition to building momentum across residents. The findings of the consumer engagement are provided in each project’s feasibility reports [13].

**7. Projects progressing to Phase 2**

During Phase 1, projects were eligible to apply for funding under Phase 2 of the programme in order to proceed to trial the methodology developed as part of their Phase 1 feasibility study. Upon successful completion of Phase 1, 4 projects were awarded Phase 2 funding [18]:

1. Urban projects, one led by Samsung (project value £3,206,448) focusing on heat pump deployment in Rose hill, Oxford and another by Bristol City Council (project value £2,925,450.72) focusing on heat pump deployment in Westbury on Trym, Bristol.
2. Rural project being led by City Science (project value £1,815,391) focusing on heat pump deployment in Fenland, Cambridgeshire.
3. Urban with significant rural project led by City Science (project value £1,799,245) focusing on heat pump deployment in Cherwell, Oxfordshire.

Across three of the four Phase 2 applications, there was a significant decrease in ambition in comparison to their Phase 1 applications, this was primarily due to the ‘cost of living’ crisis which is ongoing in the UK. These project teams looked to minimize their delivery risk by reducing the scale of their deployment from the range of 500-700 heat pumps to 100-150 heat pumps, whilst still meeting the high-density eligibility criteria. They achieve this by reducing down from doing multiple areas of the electricity network to just limited elements. Bristol City Council were the only project to maintain their deployment ambition of approximately 200 from Phase 1 into Phase 2. From a project perspective, this reduced ambition will still provide the opportunity to trial the project innovative methodologies for coordination and gather the learnings required from the programme.

Through the trial of the projects’ innovative, coordinated methodologies for high-density heat pump deployment, some of the key overarching barriers and challenges being addressed include:

- **Capital vs lifetime cost of heat pumps:** projects are looking to demonstrate and present a detailed overview and understanding of lifetime costs of a heat pump to consumer. Through lifetime cost modelling project teams are including capital cost pay by the consumer and financing options, in addition to their projected operational cost of the heat pump and any income from electricity demand flexibility. Through trialing their methodologies, project teams will be able to establish exactly the cost associated with coordinated deployment of heat pump installations and the potential capital cost reduction available to consumers through this approach.
- **Perceived disruption of homes:** for the locations which the projects have selected, minimal home retrofits will be required, however some of the homes are likely to require radiator upgrades, for example. To demonstrate the level of distribution required, project teams are looking to set-up ‘open homes’ and ‘show homes’ to enable consumers to see and feel a heat pump installation in real-life.
- **Limited installer capacity:** project teams are taking a variety of approaches with regards to ensuring the installer capacity is in place for their deployment. The 3 approaches being trialed are: tendering for installers; including an installer provider on the project team; and including an installer training provider on the project team to develop a local installer hub and training programme.
• Requirement for network reinforcements: City Science’s Fenland project is aiming to deploy heat pumps in a constrained part of the electricity network. Here the project team are working closely with the DNO in the area to understand how to coordinate heat pump deployment alongside network reinforcements and the role of flexible demand profiles from the heat pumps. The other City Science project in Oxfordshire, and the Samsung project, whilst not working in a constrained part of the network, are using this project to demonstrate how to coordinate heat pump deployment (with DNO monitoring) in the area, to understand the network impact of deploying heat pumps at high density.

• Coherent consumer journey: All Phase 2 projects have a strong emphasis on providing a coherent consumer journey from a consumer’s initial expression of interest in a heat pump through to the operation, maintenance and getting the best performance from their heat pump once installed. All projects are establishing a ‘consumer portal’ through which consumers manage their heat pump journey, rather than having to navigate various websites and platforms of the various actors who play a role in their transition to heat pump adoption.

8. Conclusion

From the initial 6 month’s feasibility studies developed by the Heat Pump Ready, Stream 1 – Phase 1 projects, key learnings have already been provided:

• The support required for the future of heat pump deployment in terms of the actions which stakeholders can take to increase the uptake of heat pumps within their local areas.
• The role of data has been shown to be vital in unlocking the coordination of high-density heat pump deployment and supporting the consumer through their heat pump journey.
• The potential role of future policy regarding the role of DNO’s, flexibility in the energy network, developing installer capacity and engaging consumers.

The Heat Pump Ready, Stream 1 – Phase 2 projects will continue to provide vital learnings as they progress through their mobilisation stage into heat pump deployment.

Abstract

The UK Government’s Department for Energy Security & Net Zero has undertaken a 3-year innovation programme titled ‘Heat Pump Ready’ (HPR) as part of its £1bn Net Zero Innovation Portfolio. Heat Pump Ready is split into three complementary work streams. This paper focuses on stream 2 of the up to £60m programme which aims to support the development of innovative tools and technologies addressing barriers to domestic heat pump deployment across five thematic areas of: increasing the performance of domestic heat pumps whilst reducing their cost; minimising home disruption whilst providing high quality installations; providing financial solutions for heat pumps; improving the consumer journey through the transition to heat pumps; and creating a smart home energy system for heat pumps. This paper will provide an insight into the high-potential, innovative technologies and tools being developed under the programme across the thematic areas and their potential impact in supporting the deployment of heat pumps across the UK and in countries with similar climates and housing archetypes. Keywords: heat pumps; innovation; supporting deployment;

1. Introduction & background

The heating of buildings is responsible for approximately 22\% of the UK’s carbon emissions [1]. Therefore, to meet the UK’s legally binding net zero target, nearly all heat in buildings in the UK needs to be decarbonised. Without government investment in innovation and other measures to create an enabling environment for the large-scale adoption of heat pumps, gas boilers will remain the default for consumers heating their homes and there is a significant risk that net zero and interim emissions targets will not be met.

There are several potential solutions to meeting the challenge of decarbonising heat in homes and other buildings. The main potential decarbonisation pathways are: approaches involving electrification of heating, using heat pumps; those which rely on low-carbon gas, in the form of biogas or hydrogen; or a mixture of the two. In the short-term, electrification of heat is the only commercially available option for decarbonising heat. In order for the UK to meet its legally binding interim carbon budgets, it will need to rapidly scale-up deployment of heat pumps during the 2020s, both off and on the gas grid, from current levels, of about 55,000 in 2021 [2], up to the government’s aim of 600,000 installs per year by 2028 [3].

Specifically, the HPR programme supports the ambition of 600,000 UK heat pump installs per year by 2028, which was set out in the Government’s 2020 Ten Point Plan [3]. The barriers to overcome to enable a scale up of domestic heat pump deployment include: consumer acceptability, installer expertise and capacity, technology performance and cost, home suitability, electricity network suitability; installation quality and availability of financing options [4]. There are some solutions available to overcome these barriers, however, they are not at a commercial scale, or deployed most effectively, as part of a coordinated heat pump landscape. In responding to this challenge the UK Government’s Heat Pump Ready (HPR) programme seeks to accelerate the development and deployment of innovative solutions in all these areas.

* Corresponding author. E-mail address: nicola.lazenby2@beis.gov.uk
The overarching objective of the HPR Programme (which is split into 3 complementary streams [5]) is to create an enabling environment for heat pump deployment at a significantly increased density and scale than current deployment levels. This enabling environment - to stimulate and support the high-density deployment of domestic heat pumps in the UK – is to be achieved under the HPR programme stream 2 – the focus of this paper - through the development and trial of innovative tools and technology and to address barriers faced across the landscape. The parallel stream 1 of HPR programme focuses on the development and trial of innovative methodologies and solutions for local coordination of high-density heat pump deployment, consumer engagement and network upgrades.

2. Heat pump ready programme development

2.1. Evidence review

During the process of designing the HPR programme, a Rapid Evidence Assessment (REA) [6] was undertaken on behalf of the department to review available evidence on heat pump innovation in the UK and internationally including identifying any gaps in research. The REA used four questions to help focus and guide the research:

1. Financial Innovations: What are the necessary financial innovations required to deliver a large-scale roll-out of heat pumps in the United Kingdom (UK)?
2. Low Voltage Grid Issues: What are the Low Voltage (LV) grid issues associated with a concentrated deployment of heat pumps and how can we mitigate these? What is the necessary size of a heat pump cluster to achieve appropriate grid impact learnings?
3. Roll-out Facilitation: What are the necessary innovations or learnings required to facilitate the large-scale roll-out of heat pumps? What tools or established processes of stakeholder coordination exist that could support the effective roll-out of heat pumps and are there examples of coordinated deployment?
4. Performance and Deployment: What are the technological improvements to the heat pump system and tools that could be developed to support any of the above aims - i.e. the large-scale deployment of heat pumps in the UK?

Analysis of existing literature focusing on these four questions included the following four findings:

1. Considerable research has been undertaken on the business models needed to stimulate the uptake of domestic heat pumps, particularly when coupled with other energy efficiency measures. However, while there is plenty of discussion of the different models few have been trialled in-situ and at scale. Further trials and development of heat as a service (HaaS) is required to increase consumer understanding, identify what motivates consumers, and address concerns around the disruption and long-term commitment element associated with HaaS.
2. The level of impact that the electrification of heat, through the use of heat pumps, will have on the LV network will depend on a number of factors that include rate of uptake and load profile. The body of evidence suggests that LV network issues (e.g. voltage problems or overloading) can be expected from a level of heat pump penetration on the LV network. The availability of field data is limited especially at a larger scale. In order for a deployment programme to achieve the appropriate grid impact learnings, the deployment size should target achieving heat pump penetration across at least 20% of dwellings on an individual LV network.
3. A clear theme running through the body of evidence, is the benefit of effective coordination between relevant stakeholder groups. A consumer-focused framework which considers area characteristics that define the stakeholder engagement strategy may lead to increased take-up. An increased understanding of how more effective and accurate modelling of local and household energy demand approaches can assist in both scheme design and management, and operational ease-of-use and performance. It is worth noting that the evidence base for question 3 suggests using the social aspects of this kind of rollout, e.g. consumer engagement and satisfaction as a metric to compare the effectiveness of various modelling scenarios.

---

2 In the context of the Heat Pump Ready programme, high-density is defined as deployment of heat pumps to at least 25% of properties on a single low-voltage feeder, secondary substation or primary substation.
4. To bring the actual performance of heat pump systems closer to the projected performance, innovations which allow existing heat pump technology to perform in a more repeatable way could be of significant benefit. Several studies observed that there are installations where the performance gap is very small and there are installations where there is a significant gap. Potential areas where research and innovation are listed as being of significant benefit include design improvements, manufacturing, installation and monitoring, maintenance, and operation.

2.2. Heat Pump Ready Programme objectives

An assessment of the evidence as part of the rapid evidence assessment identified the following widespread key barriers to large-scale heat pump deployment:

- affordability: the high cost of heat pumps
- lack of availability: lack of a strong market presence
- lack of awareness: of systems and benefits by households and the industry
- acceptance: heat pumps are perceived to be harder to install and use than gas boilers
- consumer willingness: resistance against potential disruption during installations
- consumer behaviour: demanding and using heat as if it were being produced by a fossil fuel boiler
- long-term demand: lack of certainty required for investors and businesses

In responding to these identified barriers the key objectives of the £60 million HPR programme are:

- reduce the lifetime costs of domestic heat pumps (including capital equipment costs, installation costs and operating costs);
- improve the lifetime consumer experience of heat pumps (including the experiences of: learning about and choosing a heat pump and how to pay for it; having a heat pump installed in the home and living with a heat pump);
- stimulate innovative research and solutions to address the impact of domestic heat pumps on the electricity system;
- improve the interoperability of domestic heat pumps with other smart technology in the home;
- develop and strengthen partnerships between the many players involved in the domestic heat pump sector;
- develop effective approaches and products to engage stakeholders effectively on heat pump issues with homeowners and with the key players who can help to deliver high-density heat pump deployment across the UK;
- establish an evidence base to enable effective design and development of future heat pump policy and regulation

The HPR programme covers three streams. Stream 1 supports the design and trial of innovative, optimised solutions delivering a more cost-effective and higher-density domestic heat pump roll out. High-density deployment will be piloted in a number of areas across the UK. Stream 2 focuses on supporting the development of innovative tools and technologies addressing barriers to domestic heat pump deployment. Stream 3 is focused on capturing and sharing progress, evidence, knowledge, and lessons learned between all the different projects across the programme as well as developing tailored knowledge to disseminate amongst key stakeholders including industry.

2.3. Stream 2 objectives

Under stream 2 – which is the focus of this paper - the UK government has provided more than £15million in funding to support innovation to make heat pumps cheaper and easier to install, helping accelerate the UK’s move away from fossil fuel heating [7]. The solutions supported are at Technology Readiness Levels (TRL) 5 to 7 at the start of the projects. A total of 24 projects [8] in England and Scotland were awarded funding under stream 2. Stream 2 objectives specifically relate to supporting the development of innovative tools and technologies addressing barriers to domestic heat pump deployment under five main category objectives:

- increasing the performance whilst reducing the cost of domestic heat pumps
- minimising home disruption whilst providing high quality installations
- providing financial solutions for heat pumps
- improving the consumer journey through the transition to heat pumps
- and creating a smart home energy system
2.4. Stream 2 tools & technology outputs

Each project runs for a period of either 18 or 30 months with the programme concluding by early 2025. The tools and technologies being developed can be categorised by the expected output in the following way:

- Apps being created, for example:
  - for installers to use to ensure correct heat pump install & commission
  - for surveyors to generate heat loss calculations, radiator sizing and heat pump sizing
  - for consumers/installers going through heat pump related decisions including selection and install process
- Control systems:
  - for utilising smart meter data to embed heat pumps in a Home Energy Management System to optimise behaviour of house/renewable technology
  - for remote adjustment of heat pumps
- Data utilization, for example:
  - smart meter data enabling thermal modeling of the home considering heat pump suitability and sizing
  - data-driven solutions for installer decision-making/upskilling. Data and learning from every installation undertaken captured in structured Case Studies (including post-installation assessment)
- Financial products:
  - low interest loan products for consumers spreading the cost over the life of a heat pump
- Heat pump design:
  - design solutions for non-traditional housing archetypes
  - remote survey tool for surveyors
- Manufacturing:
  - to include; redesign of heat pump assembly processes, reducing heat pump part-count, modular heat pump design
  - heat pump and energy storage system combining energy recovery from the wastewater streams leaving a house
- Software:
  - to predict & monitor fuel usage savings from heat pump & fabric savings
  - installer selection tool allowing consumers to request installation quotes from Microgeneration Certificate Scheme (MCS)³ certified installers, filtering by name, type and location
  - to ensure improved assurance of heat pump design and installation to manage financial risk

This paper will explore these innovative outputs and their potential impact in more detail.

3. Overview of stream 2 projects by category objective

The stream 2 projects are categorized from an innovation activity perspective as either Industrial Research or Experimental Development.

Industrial Research can involve planned research or critical investigation aimed at the acquisition of new knowledge and skills for developing new products, processes or services or for bringing about a significant improvement in existing products, processes or services. It comprises the creation of components parts of complex systems and may include the construction of prototypes in a laboratory environment or in an environment with simulated interfaces to existing systems as well as of pilot lines, when necessary for the industrial research and notably for generic technology validation.

Experimental Development can involve acquiring, combining, shaping and using existing scientific, technological, business and other relevant knowledge and skills with the aim of developing new or improved products, processes or services. This may include, for example, activities aiming at the conceptual definition, planning and documentation of new products, processes or services. Experimental development may comprise prototyping, demonstrating, piloting, testing and validation of new or improved products, processes or services in environments representative of real-life operating conditions where the primary objective is to make further technical improvements on products, processes or services that are not substantially set. This may include the

³ MCS works with industry to define, maintain and improve quality by certifying low-carbon energy technology contractors including heat pumps.
development of a commercially usable prototype or pilot which is necessarily the final commercial product, and which is too expensive to produce for it to be used only for demonstration and validation purposes.

3.1. Category objective 1: to increase the performance whilst reducing the cost of domestic heat pumps;

The five projects within this category objective are outlined below.

3.1.1.

In the UK, housing associations and local authorities often find themselves as large landlords managing sites of multiple homes. In working to understand the context of the existing heating system prior to the installation of a heat pump and through continuous monitoring and analysing of ongoing heat pump performance, this Guru Systems Ltd project’s objective is to provide operators the ability to remotely adjust the heating system settings as required. The intended outcomes for this project are to enable reduced initial capital expenditure spend, improved heat pump performance in operation, resulting in fewer maintenance callouts, lower carbon emissions, and, more comfortable residents with reduced heating costs. Tools and monitoring equipment are being developed to allow landlords to actively manage their heating systems as part of the project.

3.1.2.

To improve heat pump manufacturing processes this ICAX Ltd project aims to tackle the cost barriers of heat pump deployment by designing and building a trial manufacturing assembly line for residential heat pumps, using analytical and physical tools. This is in order to offer a systemic approach to optimised manufacturing based on current intelligent manufacturing design and operation capabilities. By re-designing the heat pump assembly process, the objective is to reduce unit costs and increase product quality.

3.1.3.

By combining electrically-driven heat pumps with heat storing batteries the aim of this project is to shift heat production from times of peak electrical demand on the National Grid, enabling consumers to charge heating systems to store lower cost and lower carbon heat in anticipation of their peak heating demand. This Kensa Heat Pump Ltd project aims to achieve this by decoupling the times of heating demand in the property from the time of electrical heat production. By shifting energy demands, the project also aims to negate some of the challenges faced by the grid from electrifying and decarbonising heat.

3.1.4.

This Mixergy Ltd project aims to reduce the lifetime costs of domestic heat pump installation whilst delivering higher system efficiency throughout the year. In turn it is expected this will reduce capital and operational costs, ensuring a more seamless installation process and holistic approach to design. The project team are focusing on ground-breaking technologies which reduce installation complexity and elevate the seasonally adjusted Coefficient of Performance of real-world heat pump installations.

3.1.5.

Modular heat pump design may be able to provide significant cost and CO2 savings across the installation, operation and production phases. Ventive’s heat pumps are demand responsive, fully integrated with indoor environment control systems providing integrated ventilation, heating, and hot water with free summer cooling. The Heat Pump will arrive pre-plumbed and pre-configured with monitoring and renewable energy storage to enable quick and simple installation. Since each home is different (size, heat loss, thermal mass, occupancy, user behaviour), the project will use an array of integrated sensors to assess the indoor environment and adapt the performance of each system, learning and optimising its operation to drive improvements in energy efficiency, energy storage and load shifting capacity.

3.2. Category objective 2: to minimise home disruption whilst providing high quality installations;

The six projects within this category objective are outlined below.
3.2.1.
This project aims to create a new method to optimise heat pump specification, design and management by using on-site measurement of building performance parameters as design inputs. Through using smart meters, low-cost sensors and newly established techniques to directly measure key performance parameters on a property basis, this Build Test Solution project aims to determine:
- how calculations and measurements can co-exist, the latter providing improved confidence as well as optimisation and calibration of heat pump system specification and design
- a publicly available protocol that defines the measurement options, the standards that must be followed, what the outputs must comprise and how these should be presented
- optimal delivery models with respect to the use of quick tests, low disruption short term monitoring and/or use of existing smart infrastructure and Internet of Things (IoT) devices already installed.
- the role of ongoing measurement and condition monitoring services to validate system performance in-use

3.2.2.
This project focuses on creating a mobile app and web platform which supports the correct installation, commissioning and maintenance of heat pumps. The Guru Systems Ltd platform verifies outcomes and stores heat pump settings in order to benchmark for future maintenance and efficiency improvements, and acts as a training resource for new heat pump engineers. The modular nature of the product will allow for a dynamic service to provide apps and platforms for surveys, commissioning and subsequent maintenance which can be easily adjusted for different heat pumps and adapt to changing verification regimes depending on how the market evolves.

3.2.3.
Hoare Lea’s ‘Right Sizing Heat Pumps’ project aims to reduce capital costs, operational costs, and grid infrastructure upgrade costs through developing a tool to properly size, efficiently monitor and optimise heat pump performance. This will be achieved by improving cost and viability through standardising the approach to sizing heat pumps.

3.2.4.
A free heat pump home survey and design tool to help consumers make informed decisions regarding heat pump installation providing a knowledge base to facilitate the national rollout of heat pumps. As there are different types of Heat Pumps available with vastly different applicability, thermal output, installation complexity and cost, Q-BOT Ltd’s tool will help consumers confidently match the heat pump to the thermal demand of the house and other specific needs on a case-by-case basis.

3.2.5.
1 million non-traditional homes in the UK have poor energy performance, putting their occupiers at increased risk of fuel poverty, and presenting a key challenge to standardised energy efficiency measures that typically precede a heat pump installation. RJ Barwick’s project will utilise the Energiesprong approach to develop optimum standardised whole house retrofit solutions for four of the most challenging and/or common non-traditional home archetypes. The housing stock of West Kent Housing Association & Gravesham Borough Council will be used for these pilots, with selected archetypes that have inherent design complexities, assisting the development of optimum solutions in the future. Each house has its own complexities and sharing of practical archetypal retrofit knowledge on ‘hard to treat’ non-traditional homes underpins this project.

3.2.6.
An all-encompassing integrated software package and app for installers to streamline the survey, installation and commissioning processes required when installing a heat pump. Thormer Solutions Ltd’s project will provide a digital survey platform and a fully automated design facility. It aims to allow the system to be optimised from the beginning and uses augmented reality to provide the consumer with an upfront feel for how the system and components will look and sound when installed. The platform will also ensure that all documentation is stored and logged against the installation. There will be full traceability for consumers and installers to access in the future when it comes to heat pump maintenance and service. Overall the project will aim to streamline the installation process, significantly reducing the time and effort it takes to complete any installation.
3.3. Category objective 3: to provide financial solutions for heat pumps;

The four projects within this category objective are outlined below.

3.3.1. This project aims to transform current understanding of heat in the domestic setting and provide a scalable approach to heat pump financing and deployment throughout the UK. This will be achieved via the prototyping, deployment, and testing of a Heat as a Service (HaaS) modeling solution, which will provide decarbonisation pathways and financing models. The City Science Corporation solution features a modular design, interacting to provide a full HaaS offering. Sub-sets of these modules will also provide highly valuable use-cases, for example by enabling key insights into which buildings heat pumps can provide a viable and attractive heating solution. Through the facilitation of a complete and accurate financing package, this project hopes to enable increased financing for combined heat pump and retrofit solutions, thus accelerating heat pump deployment at the lowest cost to the consumer.

3.3.2. Heat pumps can deliver energy cost savings of over 50% when deployed as part of a high performance and high-quality retrofit. This creates an opportunity for a ‘Comfort Plan’ to be offered, which provides guaranteed heating outcomes for occupants in return for a fee (which is no more than the total savings). This could help to fund the heat pump retrofit enabling greater deployment and support access to heat pumps through reducing the requirement for upfront capital investment. This Energiesprong project will finalise the process and technology requirements to offer a seamless end to end Comfort Plan management service, and then develop and test the technical solutions required to enable delivery of this. Developments in this scheme will be shared in an initial contracted pipeline of 1,550 homes, aiming for solutions to be demonstrated within live projects.

3.3.3. The aim of this Home Infrastructure Technology project is to develop a Green Homeowner Loan to pave the way for mass adoption of green home improvements, by developing a fintech platform specifically designed to fund heat pumps and other green measures. Aiming to be financially attainable, this has the aim to help gain consumer buy-in and increase the sale of heat pumps.

3.3.4. This project from Parity Projects Ltd aims to directly address the cost and quality assurance barriers of decarbonising heat in homes, by creating a low-cost cost-effective options analysis and verification protocol to enable the offer of a financially insurable performance guarantee to homeowners and landlords. The project outcome will be software that integrates existing retrofit supply chain components to ensure improved assurance of design and installation of a suitable package of measures, with a particular focus on managing financial risk.

3.4. Category objective 4: to improve the consumer journey through the transition to heat pumps;

The six projects within this category objective are outlined below.

3.4.1. The project aims to simplify and improve the efficiency of the heat pump installation process by creating a consumer-centric digital platform to support customers through the whole heat pump installation journey. This EDF digital solution aims to improve the customer journey by streamlining the required pre-installation steps into one remote survey, adopting a self-serve approach and reducing the amount of information required upfront. The outcome will be an end-to-end digital solution which will support customers in identifying innovative heat pump solutions, tailored to their profile. The solution will split into three main digital modules:

- pre-survey assessment using basic customer-provided data and housing stock data, determining heat pump eligibility or providing advice on other steps required (e.g. insulation) to become eligible
- remote survey and analysis, carrying out detailed design, quotation and installation plan
- post-installation monitoring and customer ‘after care’ package to build long term relationships with customers
3.4.2.

The project is proposing an artificial intelligence (AI) Smart Heat Pathway to enable rapid, high-quality and scalable heat pump deployment. This will be achieved through leveraging AI on Smart Meter and Smart Thermostat data to determine a personal net-zero pathway for each home, and size the subsequent appropriate heat pump, from actual measured data. Green Energy Option’s project aims to help reduce the upfront costs of property survey and design and provide a viable customer success pathway towards net-zero heat for hard-to-treat homes. The project will be piloted across 150 homes, with the aim of scaling the AI Smart Heat Pathway nationwide subsequently.

3.4.3.

Hildebrand Technology Ltd’s project is focused on improving the heat pump adoption customer journey, installer expertise, and outcomes by leveraging data from installations and enabling peer-to-peer learning and transparency. The project will provide a data-driven solution to reduce complexity and uncertainty for consumers and provide data, tools and resources for installer decision-making and upskilling. Data and learning from every installation will be captured in structured Case Studies (including post-installation assessment) to share insights in a structured, useful and engaging way. The goal is to create a feedback loop of peer-to-peer learning, among consumers and installers, that continuously improves advice and stakeholder confidence, based on practical real-world experience.

3.4.4.

This Switchee Ltd project aims to provide tools and research to overcome the current scaling barriers relating to heat pump acceptance, lack of awareness and consumer behaviour. The project is producing smart heat pump tools specifically aimed at improving the consumer journey for residents in Social Housing. This will be delivered by:

- allowing remote reading of error warning messages from the heat pump to alert the housing association
- using heat pump specific metrics including live and historic data. Heat pump specific algorithms will be developed to alert detected heat pump performance issues i.e. excessive energy consumption
- offering tailored heat pump advice focused on resident experience
- empowering the housing association to trigger when a new resident has moved into the property so that heat pump advice and educational material can be made available to them

3.4.5.

Developing a new consumer journey for heat pumps, guiding consumers from their first engagement through to receiving quotes for installation. The journey will build a technology selection tool based on the existing, tried and tested solution provided through Home Energy Scotland to assess a property’s suitability for a heat pump. This will be linked to an enhanced version of the Microgeneration Certification Scheme’s (MCS) ‘find a contractor’ tool to allow consumers to request installation quotes from installers. The project will seek an assessment partner, to increase the accuracy and dependability of the home information data. The intention being to provide multiple installers with sufficient information to quote to 90% accuracy, without the need for several pre-quote site surveys, whilst still complying with MCS standards.

3.4.6.

This is a software project aimed at improving the customer journey. Significant barriers need to be overcome at a household level to accelerate adoption of Heat Pumps technology and to meet the target of 600,000 system installations per year by 2028. These include costs, understanding of the technology, and appreciation of the long-term benefits (financial and environmental). VIA Analytics’ project aims to help meet the 600,000 per year target by developing an online property level analytics platform enabling end to end management of the customer journey, particularly through:

- identification of suitable opportunities for domestic heat pump installations (and benefits) through digital customer engagement
- providing a platform that brings the customers and supply chain together in an efficient, optimised, digitally driven way
• developing a framework to provide accurate data management of engagement, installation, and post completion – with the objective of increasing investor confidence, to promote accelerated investment into heat pumps technology

3.5. Category objective 5: to create a smart home energy system.

The three projects within this category objective are outlined below.

3.5.1. Creating a heat pump specialist Home Energy Management System (HEMS) supported by a full-package solution to help customers understand and maximise the benefits to their home. The Gen Game project aims to reduce costs and carbon by:

- using smart meter data to identify customers who would benefit from heat pumps and inform them of savings
- sizing heat pumps based on a variety of data sources
- optimising home energy management systems across heat pumps, PV, electric vehicle charging, battery storage and other energy assets to reduce costs and carbon
- providing access to flexibility markets to enhance the benefits and business case
- remaining energy supplier and product manufacturer agnostic, giving customers choice

3.5.2. This Thermoelectric Conversion Systems Ltd project aims to overcome several major infrastructural challenges of heat pump adoption, by harnessing demand-side management to cope with peak loads and time-shifting energy use. By utilising otherwise wasted energy, this solution aims to give economic and reliable products for retrofit in existing homes and new-build properties to dramatically improve energy efficiency of buildings and cut running costs. The aim is to achieve this by:

- drawing energy from the household wastewater stream by re-using energy lost, e.g. from the shower or bath, by fitting the heat pump in the drainage system to recover energy stored in a hot water cylinder
- using a small air source heat pump to ‘top up’ the hot water tank temperature to provide the domestic hot water supply
- operating both heat pumps from a mains plug
- using a smart controller to manage both heat pumps and integrate with demand-side management systems to ensure sufficient hot water and heat are available

3.5.3. The final project is working to overcome the key technical barriers to integration and energy performance optimisation, reducing running costs of heat pumps, and more broadly support improved end-user experiences and acceptance of these systems. The Wondrwall project aims to achieve this by optimising energy management to provide a platform that underpins advanced time-shifting strategies alongside proprietary artificial software intelligence software, using machine learning for dynamic predictive modelling of energy requirements based on their patented sensing technologies.

4. Potential impact of developing the innovative tools & technology

This next section of the paper considers what impact collectively the development of the tools and technologies under HPR Stream 2 may have on supporting meeting the category objectives listed in section 2.3 of the paper.

In order to increase the performance whilst reducing the cost of domestic heat pumps there is a real focus on the manufacturing of heat pumps and how innovation can positively impact current practices. This encompasses tackling the high number of parts utilized in heat pump manufacturing and reducing this where possible to bring about cost savings. In a similar vein modular heat pump manufacturing is being closely looked at as this may also have cost saving benefits. Taking a detailed look and reassessment of how heat pumps are assembled may also enable cost savings which could be passed on to consumers in time. Efforts focused on reducing installation complexity may also support the objective of reducing costs. Finally, it will be worthwhile to quantify potential cost savings that can be made in the remote controlling of a portfolio of operating heat.
pumps through, for example, a housing association. Allowing heat pump operators to adjust settings based on continuous monitoring should allow identified savings to be realized across capital expenditure, lower maintenance costs and improved performance.

In minimising home disruption whilst ensuring high quality installations there is a real focus from the funded projects on producing mobile phone apps for a range of people involved in the process of getting a heat pump.

Taking the consumer (e.g. home owner), as an example, a whole range of information needs to be considered by them in order to make decisions relating to changing their heating system. With many different heat pump types and manufacturers available on the market with vastly different applicability, thermal output, installation complexity and cost, this app will help consumers confidently match the heat pump to thermal demand of the house and other specific needs on a case-by-case basis. The market at present often means that a consumer might be advised to get a heat pump from the manufacturer that the installer is more familiar with rather than what makes most sense for the home in question.

The surveyor app being proposed aims to properly size, efficiently monitor and optimise heat pump performance. At the moment there are a range of tools open to surveyors to undertake heat loss calculations for a home and this app is an attempt to move closer towards an easier, more standardized approach to calculating this. Finally, regarding apps they are also being produced for heat pump installers. The app would allow the installer to complete a digital survey and a fully automated design allowing for system optimisation from the beginning of the process. The platform would also ensure that all documentation is stored and logged against the installation, there will be full traceability for consumers and installers to access in the future when it comes to heat pump maintenance and service. Documents received by a consumer at handover of a heat pump can be extensive so having this in one place through an app could be very beneficial. The impact of this could facilitate a more streamlined installation process, significantly reducing the time and effort it takes to complete any installation. As well additional benefits could be derived from an installer app as it could store heat pump settings in order to benchmark for future maintenance and efficiency improvements whilst also acting as a training resource for new heat pump engineers. Better heat pump system design is being investigated through utilizing properties’ smart meter data and low-cost sensors to directly measure key performance parameters on a property basis. The output from this is a publicly available protocol that defines the measurement options, standards that must be followed, what the outputs must comprise and how these should be presented. Finally standardised heat pump system design as part of a wider retrofit for non-traditional hard to treat homes is being considered.

In providing financial solutions to support wider heat pump deployment three key initiatives are underway. The purchase of a car through finance is a widely utilized financial product. Creating a financial product for the purposes of making the purchase of a heat pump more feasible by spreading out the upfront cost is being done as part of HPR stream 2. The Green Homeowner Loan aims to be financially attainable to help increase the sale of heat pumps and allow them to be a mainstream home purchase. Heat as a service is seen as another means to provide a financial solution to accelerating heat pump deployment at the lowest cost to the consumer. Consumers that buy heat as a service choose how much to spend on the experience they want – feeling warm and comfortable when and where they want in their homes – instead of paying for kilowatt-hours of energy [9]. Finally, the offer of a financially insurable performance guarantee to homeowners and landlords aims to use software integrated with existing retrofit supply chain components to quality assure quality design and installation of a heat pump system. This may be able to assist with ensuring installations are of good quality.

To address improving the consumer journey through the transition to heat pumps a number of data utilization initiatives amongst others are being delivered. The power of data clearly has a role within this area across surveying homes, heat pump installation, optimization and maintenance. Across these points of the consumer’s heat pump journey projects are looking into smart meter data enabling better thermal modeling of the home to support accurate heat pump sizing and type suitability for a home. Installers can then obtain data of a heat pump system they’ve installed post-install to support their own learning. Housing associations responsible for heat pumps across a portfolio of homes might be interested in the ability to undertake remote reading of error warning messages from a heat pump to alert and enable a response to a heat pump performance issues. Heat pump system design is being considered through a digital solution to improve the customer journey by streamlining the required pre-installation steps into one remote survey reducing the amount of information required upfront ahead of an installation. The end-to-end digital solution could support customers in identifying innovative heat pump solutions, tailored to their profile. Other project offerings under this category objective include the ability to select MCS certified installers, filtering by name, type and location to obtain quotes. This would save the consumer considerable time in identifying an installer in what has been a difficult task due to a lack of installers in certain geographical locations.
In supporting the creation of a smart home energy system an output from the projects is to utilise smart meter data to embed heat pumps within a Home Energy Management System to optimize energy-related behavior within the home including renewable energy technology usage. This might involve for example accessing flexibility markets. Optimised energy management is also being considered through a platform that underpins advanced time-shifting strategies alongside proprietary artificial software intelligence software. This would take place through the use of machine learning for dynamic predictive modelling of energy requirements based on their patented sensing technologies. Finally, the potential for demand side management is being looked at through a heat pump and energy storage system combining energy recovery from the wastewater streams leaving a house. This will be done by drawing energy from the household wastewater stream by re-using energy lost, e.g. from the shower or bath, by fitting the heat pump in the drainage system to recover energy stored in a hot water cylinder.

5. Conclusions

This paper has showcased the high-potential innovative tools and technologies being developed under stream 2 of the HPR programme addressing barriers to domestic heat pump deployment across the five thematic areas. The paper has also considered the potential impact in supporting the deployment of heat pumps across the UK and in countries with similar climates and housing archetypes. The rapid evidence assessment undertaken during programme design highlighted the need for further trials and development of heat as a service to increase consumer understanding. HPR is directly addressing this through a heat as a service project and will obtain learnings on this. Similarly understanding the impact on the electricity grid of high-density heat pump deployment will be facilitated through stream 1 deployment as well as potentially better understood on how to mitigate this through the Kensa project. Effective coordination between heat pump stakeholder groups is being well tackled through the various apps being produced under stream 2 of which all are outlined in this paper. Finally the potential areas where research and innovation are listed under the rapid evidence assessment as being of significant benefit includes design improvements of heat pumps, manufacturing, installation, monitoring, maintenance and operational. The rationale for interventions in these areas are to address the performance gap between theoretical and actual heat pump performance. The ICAX, Ventive and Thermoelectric Conversion Systems projects should all provide interesting insights into improving heat pump manufacturing.

Experimental testing of solar photovoltaic/thermal collector as a heat pump source under outdoor laboratory conditions

Francisco Beltrán*, Nelson Sommerfeldt, Hatef Madani

KTH Royal Institute of Technology, Stockholm 100 44, Sweden

Abstract

The integration of photovoltaic-thermal (PVT) and heat pumps appears as a promising technology for the decarbonization of European buildings. Some of the benefits include the simultaneous production of renewable electricity and heat, as well as an improved system efficiency. However, there has been little research dedicated to collectors designed specifically for heat pump integration. This study aims at characterizing the performance of an unglazed and uninsulated PVT collector with fins, acting as a source for heat pump systems. Tests are performed at an outdoor testing facility in Stockholm Sweden, over two weeks in October 2022. Specific thermal output in W/m$^2$ is presented against temperature difference between ambient and mean fluid temperature for a wide range of boundary conditions. The results show that the PVT collector field can generate a peak thermal power of 9 kW during sunny days, and 5 kW during nighttime operation. In order to meet the peak heating capacity in a Swedish villa, however, the collector field should be at least 40 m$^2$.

1. Introduction

Solar photovoltaic-thermal (PVT) modules can produce electricity and heat simultaneously, thus reducing the amount of required roof area if compared to stand-alone solar PV and thermal systems. At the same time, heat pumps are the most efficient technology to produce space heating and domestic hot water in a highly electrified scenario. There are currently 190 million heat pumps installed worldwide and, according to the Net Zero by 2050 scenario developed by IEA, this number should increase to 600 million by 2030 if climate targets are to be met (IEA, 2022). Therefore, the integration of PVT with heat pumps appears as a promising technology for the decarbonization of European buildings.

When combined with heat pumps, solar thermal systems can provide a higher seasonal performance factor due to the reduction in heat pump electricity use, whereas solar PV allows for the use of less electricity from the grid (Popp et al., 2018). There are many ways of combining these two technologies, but one that has gained attention in recent years are PVT sourced heat pumps (Sommerfeldt and Madani, 2017). In this configuration, uncovered PVT collectors are connected in series with a heat pump system to act as an additional or sole heat source, in order to lift the evaporator temperature and improve system efficiency (Giovannetti et al., 2019; Hadorn, 2015). The low temperatures in the PVT circuit allow heat to be captured not only from the sun but also from ambient air, thus increasing thermal efficiency to a level on par with a high performance solar thermal system (Sommerfeldt and Madani, 2018; Weiss and Spörk-Dür, 2019). The low operating temperatures also enable the use of cheaper and lighter materials such as plastic, and an improved electrical efficiency due to the cooling effect on the PV cells. The increased electrical power generation can be enough to cover the additional pumping power, making the captured heat from the PVT a free resource (Sommerfeldt and Madani, 2018).

Schmidt et al. (2018) investigated the performance of rear insulated and unglazed PVT collectors acting as the sole source of a heat pump. The results showed that this system configuration was able to cover the space
heating and domestic hot water demand for winter days down to -10°C, and suggested that better results could be achieved if using uninsulated PVT collectors.

Although solar PVT and heat pump systems have been studied extensively in the past, there has been little research dedicated to collectors designed or optimized specifically for heat pump integration. For example, the heat capture could be enhanced by adding fins on the rear side of the absorber/exchanger, improving heat production even at low solar irradiance levels. A few studies have looked at the performance of PVT+HP systems with unglazed and uninsulated PVT collectors with fins. Chhugani et al. (2020) looked at the performance of an unglazed and uninsulated PVT collector with fins serving as a sole source of a heat pump in a single-family house in Germany. The system was tested under a Hardware in the Loop test environment, and the results showed that the seasonal performance factor (SPF) during the winter months reached daily averages of 3.3. It was suggested that the PVT collectors could replace the noisy heat exchanger in an air source heat pump, while keeping a good system efficiency. Giovannetti et al. (2020) calculated the U-values of a 20m² PVT collector array with fins under no solar irradiance conditions according to ISO 9806:2017, and found that they were in the range of 22.9 and 27.0 Wm⁻²K⁻¹ at specific heat flows between 75 and 175 W/m².

2. Objective and Methodology

This study aims at empirically characterizing the performance of an unglazed and uninsulated PVT collector with fins designed specifically for heat pump integration. The tests are performed at an outdoor testing facility between the 4th and 20th of October 2022, for different inlet temperatures and flow rates, which provides a wide range of solar irradiance levels (G) and ambient temperatures (T_{amb}). Three different volumetric flow rate ranges are considered: 30 to 35 lh⁻¹m⁻², 40 to 45 lh⁻¹m⁻² and 50 to 55 lh⁻¹m⁻². Thermal power output is monitored for the collector array and plotted against the temperature difference between ambient and mean fluid temperature of the collector field (T_{f,m}). Linear regression is used to determine the thermal performance curves, and the key parameters such as the slope of the curve, the performance at ∆T=0 and the coefficient of determination (R²) are presented and discussed. The U-value obtained from the collector field is then compared against the results for the same stand-alone collector and other finned collector designs. Finally, time series data for the days between 15th and 18th of October is presented, looking at daily heat and electricity generation.

2.1. Testing facility

The testing facility is located on the rooftop of the Energy Technology Laboratory at KTH Royal Institute of Technology in Stockholm, Sweden, and consists of a 14 PVT collector array with an area of 20 m², connected in series to a 12 kW variable speed heat pump. The array is oriented to the south and has a tilt angle of 45°. It is made up of two subarrays connected in series, where each subarray has seven collectors connected in parallel. The testing facility also includes a hot water tank and air to water heat exchanger for heat dissipation. Figure 1 shows the PVT collector array and mechanical room of the testing facility at KTH.

The facility allows for two operation modes:
- brine circulates directly into the solar PVT loop
- brine and solar loops operate independently, with a cold storage tank connecting both circuits
For the purpose of this study, only the operation mode in which the tank is bypassed is utilized.

### 2.2. PVT module

The PVT collector is manufactured by the company Solhybrid i Småland and consists of an extruded aluminum manifold mechanically pressed to the rear side of a glass-glass PV module. The manifold has a trough that fits a 12 mm copper pipe, also mechanically pressed. To increase heat transfer between the different absorber materials, thermal grease is added between manifold and rear glass, as well as between the aluminum trough and the copper pipe. A picture of the PVT absorber can be seen in Figure 2.

![Figure 2. Unglazed and uninsulated sheet and tube PVT collector from Solhybrid i Småland](image)

The PV module is an off-the-shelf 60 monocrystalline-cell panel manufactured by Perlight Solar. The electrical ratings and specifications are presented in Table 1. Each PV module is connected to a micro inverter for DC/AC conversion.

The monitoring system consists of a weather station for ambient temperature measurement, dew point and wind speed; a solar irradiance meter for measurement of the incident solar irradiation on the collector plane; a heat power meter for the measurement of flow rate, inlet temperature, outlet temperature and thermal power; the already mentioned micro inverters for electrical power measurement. All the measured data is obtained in 1-minute time steps, except for the electricity generation that is measured every five minutes. A schematic diagram of the testing facility with the monitoring equipment is presented in Figure 3.

![Figure 3. Test rig diagram](image)
3. Results and discussion

Firstly, the weather data for the period of study is presented in Figure 4. The range of ambient and dew point temperatures is 2 to 16°C and 0 to 13°C, respectively, throughout the experiments. Regarding in-plane solar irradiance levels, there is a wide range of conditions, from zero to around 1000 W/m². Looking at the daily solar irradiation on the collector plane, the sunniest day is October 9th with 5.1 kWh/m², and the lowest is October 5th with 0.4 kWh/m².

![Figure 4. Weather data between 4th and 20th of October](image)

The results for specific thermal production of the PVT collector in W/m² are presented against the temperature difference between ambient and mean fluid temperature of the collector field, separated by solar irradiance levels and volumetric flow rates.

3.1. Volumetric flow rate of 30 to 35 lh⁻¹m⁻²

Figure 5 shows the results when the volumetric flow rate is set in the range of 30 to 35 lh⁻¹m⁻². In this case, the thermal output can reach a value of 425 W/m² for solar irradiances in the range of 700 to 900 W/m² and a ΔT of around 13 K. It can also be seen that, even at low solar irradiance levels (200 - 400 W/m²), the thermal output of the collector field can be over 300 W/m² for ΔT=14K, which shows the importance of the heat exchange with ambient air. However, such high ΔTs can be a limitation for the heat pump as ambient air temperatures approach the evaporator’s limit. Looking at lower temperature differences of 6K or 7K, we can see that the thermal output goes from just over 100 W/m² for low solar irradiances, up to 300 W/m² for the upper range. For the 14 PVT collector array, this equals a total thermal power production between 2 and 6 kW fed directly into the heat pump evaporator.

Linear regression is used to represent the thermal performance curve of the collectors as a function of temperature difference between ambient and mean fluid temperature of the collector field for different solar irradiance levels. The key parameters of such curves, such as the slope of the curve in W/K, the thermal output at a ΔT=0 and the coefficient of determination (R²), are shown in Table 2.
As the solar irradiance increases, the U-value of the collector field decreases (i.e. slope of the curve) and the thermal output at ∆T=0 increases (y-intercept). Another aspect to highlight is the fact that the coefficient of determination decreases as the solar irradiance increases. This can be explained by the fact that the PVT collector has a limit on how much heat it can capture based on the flow rate and absorber geometry, so the curve tends to start flattening as we increase the difference between T_{amb} and T_{f,m}. The coefficient of determination is between 65% and 82% for all cases, which shows that the presented linear relationships are relatively weak. This is primarily due to missing aspects of wind velocity, sky temperature or thermal capacity in the regression model, as described by (Fischer et al., 2004; Perers, 1997) for quasi-dynamic conditions.

3.2. Volumetric flow rate of 40 to 45 lh⁻¹m⁻²

Figure 6 shows the results when the flow rate is increased by 10 lh⁻¹m⁻². The specific thermal output can reach a value of approximately 450 W/m² for solar irradiances over 500 W/m² and a ∆T of around 13-14 K, representing a 5% increase in thermal output if compared to the previous case. For the 14 PVT collector array, this equals an increase in thermal power of 0.5 kW. Looking at a ∆T of 6-7 K we can see that thermal output
is in the range of 150 to 325 W/m². For the 14 PVT collector array, this equals a total thermal power production of between 3 and 6.5 kW that could be fed directly into the heat pump evaporator.

The main parameters of the thermal performance curve are presented in Table 3. As solar irradiance increases, the U-value of the collector field decreases and the y-intercept increases, as was observed for the 30 to 35 lh⁻¹m⁻² case. Another aspect to highlight is that even when there is no temperature difference between ambient and mean fluid temperature, the PVT collector can still generate heat regardless of the solar irradiance level. The coefficient of determination is between 61% and 85% for all cases, which shows that the presented linear relationships are relatively weak, as explained in the previous section. When comparing the values in the Table to the previous case, the U-values of the collector field are lower at higher flow rates, but the specific heat production at ∆T=0 becomes higher as the flow rate increases.

3.3. Volumetric flow rate of 50 to 55 lh⁻¹m⁻²

Figure 7 shows the thermal performance of the PVT collector when the flow rate is further increased to the range between 50 and 55 lh⁻¹m⁻². In this case, the thermal output can reach values of around 450 W/m² for ∆Ts as low as 8 K and high solar irradiance levels. Once again, if we look at a more likely 6 to 7 K temperature
difference, we can see that the thermal power production is in the 150 – 350 W/m² range, or 3 to 7 kW for the full collector field.

An interesting observation when looking at the thermal performance curves is that they start to spread out for lower irradiance levels, but tend to converge as ΔT increases. This can be explained by the fact that the PVT collector has a limit on how much heat it can capture based on the flow rate and absorber geometry, so the curve tends to start flattening as we increase the temperature difference between ambient and mean fluid temperature. Another aspect to consider is that as the temperature difference increases, the relative importance of solar irradiance decreases within the overall heat transfer, meaning that convection will play a larger role. An important takeaway of this is that it seems to be convenient to work at higher flow rates at lower ΔTs, and lower flow rates at higher ΔTs.

The main parameters of the linear regression curves are presented in Table 4. As happened with the previous two cases, it can be seen that as the solar irradiance increases, the U-value decreases and the thermal output value for ΔT=0 increases. If compared with the 40 to 45 lh⁻¹m⁻² case, the slope of the curves are higher for lower solar irradiance levels and lower for higher solar irradiance levels. The same occurs with the specific thermal output at ΔT=0. Opposite to what happened with lower flow rates, the value of R² increase as solar irradiance increases and is higher than 70% for all cases.

3.4. No solar irradiance

Figure 8 shows the performance of the PVT collector for a solar irradiance level of 0 W/m², for different ∆Ts and volumetric flow rates. It can be seen in the chart that when working exclusively as an air to water heat exchanger, the PVT collector can generate up to 250 W/m² for a ∆T of 10 K, and as high as 150 W/m² when ∆T is in the 6-7 K range. The latter means a total thermal energy production for the collector field of more than 3 kW.

![Figure 8. Specific thermal output of collector array as a function of T_{amb} – T_{f,m} for solar irradiance levels of 0, 400 and 800 W/m² and varying flow rates](image)

The main parameters of the thermal performance curves are presented in Table 5. It can be observed that the slope of the curve increases together with the flow rate. When looking at the thermal output at ∆T=0, it decreases with increasing flow rate. Finally, the coefficient of determination is higher than 60% for all cases, meaning that the linear regression curves are a good fit for the empirical data.

3.5. Time-series performance between 15th and 18th of October

Figure 9 shows the time-series specific thermal and electrical output of the 14 PVT collector array for 4 days between the 15th and 18th of October. The temperature difference between ambient and mean fluid temperature is also plotted. It can be seen that the thermal and electrical output are the highest for the 17th of October, which coincides with day with highest solar irradiation and temperature difference between T_{amb} and T_{f,m}.
Table 6 shows a summary with the total heat and electricity production for each day per m² of collector, together with the daily solar irradiation, average ambient temperature and average temperature difference between ambient and fluid. One of the main observations here is that the performance of an unglazed-uninsulated PVT collector with fins is more dependent on temperature difference with ambient than solar irradiation. For example, the total solar irradiation for the 16th of October is three times more than that of the 15th of October; however, the total heat production from the PVT collectors only experiences a 3.7% increase. This is because the average ΔT is practically the same, with a value close to 9°C. On the other hand, electrical power production is highly dependent on solar irradiance levels and very little on ambient and/or fluid temperature. For the day with the highest solar irradiation levels, the electricity production of the full array is 12.9 kWh, with a peak power of 3.2 kW. For the considered study period, the 20-m² PVT collector array generated a daily average of 64 kWh of heat and 5.2 kWh of electricity. This translates into a daily average solar efficiency of 370% for heat and 17.1% for electricity, which is near the rated efficiency for the PV module.

4. Discussion

For this study, the U-value calculated as the slope of the thermal performance curve, is in the range of 13 to 19 W m⁻² K⁻¹ for high solar irradiance levels, which is on the upper range of what a typical unglazed and uninsulated PVT collector would have (Brötje et al., 2018). However, it is 40 to 60% lower than other PVT collectors specifically designed for heat pump integration that were found in the literature.

Most residential heat pumps in villas are in the range of 10-15 kW, and likely to have a COP of 2 when operating at peak capacity. Assuming those operating conditions, the PVT field should be able to supply between 5 and 7.5 kW at the evaporator, meaning a minimum of 250 W/m² with the 20-m² array presented. The results in this study show that during sunny days, this could be achieved by the 20-m² collector array when temperature difference between ambient and mean fluid temperature is higher than 3 or 4 K. However, when looking at nighttime performance, it would be required to have a ΔT higher than 10 K, which is unlikely to happen during low ambient temperatures when the heat pump needs to operate at maximum capacity due to temperature limits at the evaporator. Under those circumstances, a PVT array of at least double the size would be required to meet the heating needs.

With regards to the seasonal performance factor (SPF) of a solar PVT sourced heat pump system, previous simulation research by the authors showed that an SPF of 1.6 can be achieved for a typical multi-family house in Stockholm with a PVT collector area of 4.5 m² per kW of nominal heat pump power (Sommerfeldt et al., 2020). Although this is on the lower end of what would be expected for an air source heat pump system, several design improvements to enhance heat capture with the air were also demonstrated that could bring the SPF up to 2.6, making it competitive with an air source heat pump in Stockholm. This performance is corroborated by studies carried out in Germany, where Chhugani et al. (2020) found that an SPF of 3.3 can be achieved during the winter period in Hamelin, using a sheet and tube collector with fins with an area of 2.5 m²/kW. Lämmlle and Munz. (2022) showed that an SPF of up to 3.6 can be achieved when using double-finned micro-channel PVT collector, with a collector area as little as 3 m²/kW.

Although the effect of wind velocity or direction was not considered in this study, it has been proven significantly lower for a collector array than for a stand-alone collector. Chhugani et al. (2021) found that the overall heat transfer coefficient of a 20-m² PVT array is around 20% lower than that of a single PVT collector, and the wind dependence of the heat loss coefficient is reduced by half.

The effects of condensation and frost formation were not considered either, which could enhance the thermal performance of the collectors. However, once an ice layer is formed, it decreases the thermal output of the collector. Chhugani et al. (2021), found a 15% reduction in measured against simulated thermal output when frost formation occurs, showing that ice formation hinders the heat exchange with ambient air considerably.

Even though the coefficient of determination for the different thermal performance curves was within an acceptable range for certain data sets, there was a large variance of the data around the linear regression curve. This can be explained by the previous two limitations in the study: the effect of wind velocity (even if not as high as for a stand-alone collector) and the effect of condensation and frost. Usually tests on PVT collectors are performed at indoor testing facilities with fixed solar irradiance, wind velocity, ambient temperature and humidity. In this case it was tested outdoors, so there was no control on the weather conditions. Another limitation is that instead of using fixed values of solar irradiance or flow rates, ranges are used, which can bring differences in the measured values. Besides, as can be seen from the weather data, most of the days were partially cloudy which adds another layer of uncertainty.

The coefficient of determination for all curves was between 60 and 90%, which is relatively weak for a regression model. However, it was not the aim of this study to present a regression model for PVT collectors, rather use it to help in the description of the data that was gathered. A widely accepted empirical model of unglazed and uninsulated PVT collectors already exists, where factors such as wind speed, radiation to sky and thermal capacity of the collector are considered and will be part of future work.

5. Conclusion

The performance of a 20-m² PVT collector array specifically designed for heat pump integration was tested under outdoor weather conditions for 16 days in October 2022, in Stockholm, Sweden. The results show that the specific thermal output of such collectors varies primarily with the difference between ambient temperature and mean fluid temperature. With a specific thermal output in the range of 100 and 250 W/m² when there is no solar irradiance, a standard villa-sized PVT array can act as an air to water heat exchanger producing...
between 2 kW and 5 kW of heat to use as a source for a heat pump. Looking at peak heat capture capacity, the 20 m² PVT field is expected to provide 9 kW peak on a sunny day, and 5 kW peak during nighttime.

The U-values found for this collector at high solar irradiances are in the range of 13 to 19 Wm⁻²K⁻¹, which compared to other collectors found in the literature, shows that there is room for improvement in the design. The addition of more and thinner fins can improve these values to a level with state-of-the-art heat pump PVT collectors. However, this could lead to an increase in collector weight and manufacturing costs, which need to be considered in a detailed techno-economic analysis.

The presented 20 m² PVT field is likely to meet the demand at the evaporator of the heat pump working at full capacity during cold and sunny winter days, but at least double the size would be required to meet the demand at night. Alternatively, more fins would increase the U-value, but even still it is likely that a larger area would be necessary. This study does not analyze how PVT and HP work together to meet building loads, but it gives some perspective on the required area and temperature difference that is needed.

The period of study produced a wide range of boundary conditions, which capture a wide range of possible operating conditions. It is observed that as solar irradiance, flow rate and temperature difference increase, so does the specific thermal output of the collector. A maximum value of 450 W/m² is registered throughout the experiments, suggesting that the thermal output may be limited at around that number for this particular design.

Finally, the time-series performance of the PVT collector array was studied, where it was found that the daily electricity production for four days in October was 7.5% of the daily heat production. However, the percentage of electricity production during the summer and spring should increase thanks to more hours of available sunshine. Looking at the solar efficiency of the collector, the daily average for heat is around 370%, meaning that around 75% of the energy captured by the PVT collector throughout a day in October comes from the ambient air. The daily average for electrical efficiency is 17.1%, which is around the rated electrical efficiency of the PV module.

6. Future work

This study looks exclusively at the thermal and electrical performance of an uninsulated/unglazed PVT collector with extruded fins. Future work should expand the system boundaries by examining the empirical performance of the heat pump when using PVT as the source, as a way to understand how PVT collectors can improve COP and SPF of the heat pump for real operating conditions under Nordic climate conditions. Moreover, different collector designs should be evaluated for benchmarking and better understanding of the characteristics that make a collector suitable for heat pump integration. Condensation and frost formation were not considered in this study, but these phenomena are going to be the focus of future work, particularly strategies for defrosting. Finally, it would be interesting to look at the benefits of having a cold water storage tank between heat pump and PVT array. The heat production fluctuations that are experienced by the PVT with changes in solar irradiance levels, can put a lot of stress on the compressor, which can affect its lifetime. The addition of a cold storage tank would act as a buffer tank with a certain thermal inertia, which would keep the heat flux to the evaporator at a constant rate.

Abstract

R448A, a zeotropic blend with GWP of 1390, is being proposed as an alternative refrigerant working in air-conditioning and heat pump systems. Despite being suitable as drop-in refrigerants, some redesigning of R448A systems was recommended for achieving maximum efficiency. In the work, the heat transfer coefficient of R448A inside multiple multiport mini-channel tube with different geometries were experimentally investigated. The experimental range of mass flux is from 100 to 500 kg/m$^2$s, heat flux from 3 to 15 kW/m$^2$ at a fixed saturated temperature of 6$^\circ$C, in 3 multiport tubes with varying hydraulic diameter, number of ports and aspect ratio. The influence of mass flux, heat flux, and vapor quality are examined, as well as the effect of channel geometry on the heat transfer performance. Finally, a correlation including the channel geometrical effect is proposed for the prediction of R448A heat transfer coefficient.

1. Introduction

The HVAC industry have been rushing in research and development toward the 4\textsuperscript{th} generation of refrigerant. Ultra-low GWP HFOs blend are currently considered best candidate as they can reduce GWP while retaining a good system performance. R448A is among those candidates, which is a zeotropic blend of 5 different components, consisting of R32, R125, R134a and the HFO’s R1234ze and R1234yf. With non-flammability, non-toxicity (safety class A1), and a GWP of 1387, which is over 60\% lower in GWP than R404A, it intended replacement, R448A has met many requirements of a high priority candidate.

Theoretical evaluation by Mota-Babiloni et al. [1] of alternative refrigerant with R404A as a baseline considered R448A (N-40) to be the best option in term of energy efficiency among 6 candidates in application which non-flammability is required. Past retrofit testing of R448A in different systems has also been available with the experimental work by Mota-Babiloni et al. [2], which tested R448A and compared against R404A in vapor compression systems. They found R448A charged systems to have lower mass flow rate, cooling capacity, power consumption and higher COP than R404A. The authors considered R448A to be a good alternative for R404A for medium temperature (food conservation) application, and warm climate countries would benefit from R448A due to it higher discharge temperature.

Investigation of R448A flow boiling heat transfer has been available within literatures. Lilio et al [3] experimentally measured R448A heat transfer coefficient and pressure drop in a 6mm steel tube. Heat transfer degradation observed at the mass flux of 150 kg/m$^2$s, which was attributed due to flow stratification. The higher mass flux shows convective behavior, with the heat transfer coefficient increases with quality. Heat flux does
not only increase the heat transfer coefficient but also change the data trend with quality and dry-out characteristic. Kim & Kim [4] investigated the heat transfer coefficient and pressure drop of 4 different alternative refrigerants of R404A inside a smooth tube, the interims (R448A, R449A) and long-terms (R455A and R454C) in a smooth tube. At lower mass flux (100 kg/m²s) and low vapor quality at the high mass flux of 300 kg/m²s, R404A heat transfer coefficient is larger than the alternative refrigerant, due to the heat transfer penalization from the alternatives larger temperature glide. However, at the high mass flux of 300 kg/m²s and high vapor quality, R404A heat transfer coefficient is exceeded by the alternative refrigerants, due to their more favorable thermos-physical properties. By the same author, Kim & Kim [5] studied those same blends heat transfer coefficient and pressure drop but in multiport mini-channel tube. Here the heat transfer coefficient of R404A is higher than all of the alternatives. At lower mass flux of 200 kg/m²s, heat transfer coefficient of the alternatives is higher than the interim, while the reverse is true at 400 kg/m²s. Like in Kim & Kim [6], the finding was attributed to the relationship between temperature glide and thermos-physical properties.

A literature survey shows that although R448A is a relatively well researched blend recently, their database for multiport mini-channel tube should be supplemented with further data, for better consideration when applying to refrigeration or heat pump systems. Up to date, only Kim & Kim [4] had investigated heat transfer coefficient and pressure drop of R448A inside multiport mini-channel, albeit with only one channel. The current work extends the data for various different channels with varying geometry. The experimental range of mass flux is from 100 to 500 kg/m²s, heat flux from 3 to 15 kW/m² at a fixed saturated temperature of 6°C, in 3 multiport tubes with varying geometry. The effect of mass flux, heat flux as well as channel geometry are discussed. Finally, correlations are examined and new one proposed for practical prediction.

2. Experimental Apparatus and Methodology

2.1. Experimental Apparatus

The investigation is carried out through a testing apparatus shown in the following schematic diagram 1.

Fig. 1. Experimental systems.

Fig. 2. Test section in detail and layout of thermocouple attachment
The refrigerant micro-gear pump is the driving force of flow circulation. The mass flow rate can be varied using an inverter controlled, while measurement is done by a flow meter installed after the pump. Heating was provided via preheater section, which is a 4m length tube wired to a DC power source. The DC power source power output can be controlled up to 1500W, so as to heat refrigerant up to desired quality before entering the test section, where the measurement of heat transfer coefficient and pressure drop took place. Outlet of the test section is the condenser, where the refrigerant return to liquid phase for next circulation. All sensor from the systems is connected to a data-logger then onto a PC for monitoring and recording of data.

Heating for the test section is provided from a warm brine bath. The test section is a counter current heat exchanger, with two acrylic slab sealed a multiport mini-channel tube in the middle. The brine pump was also connected to an inverter controlled to varying the mass flow rate, and a flow meter of same type is used for the measurement of it. Inlet and outlet temperature of the test section are both measured by RTDs, and is used along with mass flow meter for the calculation of applied heat flux. The pressure drop is monitored with a differential pressure sensor, connected from 2 ports from the inlet and outlet of the test section. In order to calculate the heat transfer coefficient, the wall temperature was measured using thin thermos-couples wire. In total 12 was embedded at the surface, in 3 different positions from the inlet, 2 on top and 2 down the bottom in each position, as it is shown in figure 3.

2.2. Data reduction

With inlet temperature and inlet pressure, it is possible to deduce the vapor quality and enthalpy at the inlet.

\[
x_{\text{in}} = f(T_{\text{in}}, P_{\text{in}}), \quad i_{\text{in}} = f(T_{\text{in}}, P_{\text{in}}) \tag{1}
\]

The heat flux can be calculated using the brine inlet, outlet temperature and the brine mass flow rate

\[
q = \frac{m_{\text{water}} c_{p,\text{water}} (T_{\text{water,in}} - T_{\text{water,out}})}{A_{\text{ext}}} \tag{2}
\]

Assuming an even distribution of heat flux across the tube, the enthalpy of \(i^{\text{th}}\) measurement point can be calculated as follow:

\[
i_i = i_{\text{in}} + \frac{q P_{\text{tube}}}{m_{\text{ref}}} z_i \tag{3}
\]

Likewise, assuming linear pressure drop, the pressure at the \(i^{\text{th}}\) measurement point can be calculated as

\[
P_i = P_{\text{in}} - \frac{\Delta P}{L} z_i \tag{4}
\]

With both pressure and enthalpy, it is possible to infer the saturated temperature at that location:

\[
T_{\text{sat},i} = f(P_i, i_i) \tag{5}
\]

The internal wall temperature can be readily calculated with one dimensional thermal conduction equation through wall. Generally, the difference between internal and external wall temperature is insignificantly small due to the thin wall. The wall temperature is the average temperature of the 4 thermocouples
Finally, the heat transfer coefficient can be calculated with the internal wall temperature and the corresponding saturated temperature.

\[ h_i = \frac{A_{\text{ext}}}{A_{\text{int}}} \frac{q}{T_{\text{w, in}} - T_{\text{sat}, i}} \] (7)

The average uncertainty for heat transfer coefficient is roughly 15.4%, while for vapor quality it is kept small at about 0.02.

3. Result and Discussion

3.1. Heat transfer coefficient result

Figure 3 displays the effect of mass flux on the heat transfer coefficient.

![Fig. 3. The effect of mass flux on heat transfer coefficient.](image)

As shown increase the mass flux increases the heat transfer coefficient. The current trend is universal within literature. The contribution of convective boiling in flow boiling heat transfer coefficient is mainly driven by mass flux. With increase mass flux, the annular regime is expanded due to strong inertia of vapor phase. Under annular flow, thin film evaporation occurring at the interface is driven significantly by the effect of interfacial shear stress, which increases along with mass flux. Additionally, an increase in mass flux will decrease the thermal resistance between the liquid film and the vapor core by enhancing the effective turbulent thermal conductivity. Improved turbulent effect at high velocity also help to offset the effect of mass transfer resistance on heat transfer of mixture by improving compositional mixing, as mentioned in Li [6] or Berto [7].

Figure 4 displays the effect of heat flux on the heat transfer coefficient.

![Fig. 4. The effect of heat flux on heat transfer coefficient.](image)

Heat flux affects heat transfer coefficient differently, as it is more dependable on the specific mass flux condition. As explained in conventional nucleate boiling theory as well as being well reported in literature,
increasing heat flux activate more nucleate site and hasten the bubble nucleation and growth cycle, overall enhancing convective boiling. However, with an increasing of mass flux, convective boiling become a dominate flow boiling mechanism, owning to strong effect of interfacial shear and turbulent. Consequently, the effect of heat flux become less noticeable at high mass flux.

![Fig. 5](image)

Evidently, at lower mass flux condition, where nucleate boiling have more noticeable effect on heat transfer, the heat transfer coefficient follows the descending order of B, D and E. From table 2, the heat transfer was found to generally increase with the decreasing of hydraulic diameter, although tube D is higher than tube E heat transfer coefficient, despite having larger hydraulic diameter, suggesting hydraulic diameter alone is not the only geometrical feature that is important toward heat transfer. Literature survey of heat transfer investigation using multiport mini-channel evaporator types was performed to compare against the current trend with past trend. Yun et al. [8] commented that decreasing the hydraulic diameter was found to increase the overall heat transfer coefficient. However, Yun [10], claimed the enhancement of heat transfer was found with the increasing of internal perimeter. Additionally, Al-Zaidi et al. [11] comments that for rectangular mini-channel, increase the aspect ratio also increase heat transfer coefficient. This explain why despite having larger hydraulic diameter, tube D heat transfer coefficient than tube E.

3.2. Evaluation of existing correlation

The current experimental database was compared against various correlations in literature. In 2015, Shah [12] presented a simple method of correcting the heat transfer coefficient of zeotropic mixture when applying correlation of pure fluid. The database is compared against the heat transfer coefficient correlation in its original form and its modified form.

<table>
<thead>
<tr>
<th>Correlation</th>
<th>MAD (%)</th>
<th>MSE (%)</th>

<tr>
<td>Saitoh et al. [16]</td>
<td>25.5</td>
<td>18.3</td>
</tr>
</tbody>
</table>

As it is shown, the heat transfer coefficient database is relatively well predicted by the current database, and improvement upon original was observed, with the most spectacular improvement from the model of the Bertsch [13]. Although they are well predicted, it is preferable to introduce an optimized correlation for the best prediction of the present database for the more precision design of heat exchanger. In addition, since the Shah [12] method was found to made improvement to original prediction, this method is also employed during the development of correlation.
3.3. Correlation proposal

Enhancement and suppression factor can be proposed by optimizing the coefficient from the experimental data as follow:

\[
E = 1 + 12000B_0^{1.5} + 0.9X_{tt}^{-0.85}
\]

\[
S = \frac{1}{1+1.1Re_l^{0.5}Pr^{1.15}10^{-6}}
\]

With the nucleate boiling and single phase liquid heat transfer coefficient both used the common equations of Cooper and Dittius-Boelter respectively

\[
h_{nb} = 55M^{-0.5}q^{-0.67}Pr_e^{0.12}(-\log_{10}Pr_{red})^{-0.55}
\]

\[
h = 0.023Re_l^{0.8}Pr_l^{0.4}k_l/d_h
\]

The evaluation was done with MAD and MAE as previously and shown the new correlation performed the best against the current experimental database.

4. Conclusion

The current work investigates the heat transfer coefficient of R448A inside 3 different multiport mini-channel tube. The key findings can be summarized as follow:

1. The heat transfer coefficient is a strong function of mass flux. Heat transfer coefficient increase with increase heat flux under low mass flux conditions but display insignificant effect at higher mass flux conditions.
2. Channel geometry have important effect at lower mass flux conditions. It is found that decreasing hydraulic diameter, increasing aspect ratio (W/H), and increasing number of multiport to have favourable effect on heat transfer coefficient.
3. Past correlation can provide a reasonable prediction against the current database, with modification to account for temperature glide effect can reduce the error further. A new correlation is proposed which achieved a good accuracy with present data.

Abstract

River water-source heat pumps show higher energy efficiency than conventional air-source heat pumps because water has better thermal characteristics than air. However, as the river water temperature decreases in winter, there is a risk of freezing in heat exchangers during the heating season. In this study, the performance of a hybrid heat pump system using a hot gas bypass valve (HBHPS) was compared analytically to that of a conventional hybrid heat pump system (CHHPS). In the HBHPS, the refrigerant flow rate can be controlled by the hot gas bypass valve to decrease the heating capacity, hence reducing the temperature difference of the secondary fluid on the evaporator side. Accordingly, it can increase the heat pump operation time in winter. Mechanical components of the HBHPS were modeled analytically. The performances of the two energy conversion systems were compared through transient simulations based on a water temperature measurement in Han River, South Korea. As a result, the HBHPS showed higher life cycle climate performance than the CHHPS owing to the increase in the heat pump operation time.

1. Introduction

Many efforts are being carried out to reduce greenhouse gas emissions around the world. Among these efforts, research related to renewable energy conversion systems is actively being conducted. A heat pump system that uses surface water as a heat source is one of them. The water source heat pump system obtains energy required for heating and cooling loads by using the energy of water sources including river water, lake water, and seawater. The temperature of the water source is higher in winter and lower in summer than that of the air source, which has the advantage of a lower seasonal temperature difference. Therefore, water source heat pumps have the advantage of being able to operate at high efficiency year-round compared to conventional air source heat pumps [1]. However, there is a disadvantage that the use is limited due to the problem of freezing in the heat pump evaporator or source-side heat exchanger when the water temperature is low in winter. For this reason it is difficult for water source heat pumps to be operated alone even though they show high efficiency in summer. To overcome this problem, the conventional water source heat pump system mainly adopted a hybrid configuration in which a gas boiler is installed to satisfy the heating load when the heat pump is not operable. The use of boilers reduces the efficiency of the entire system but allows the system to operate reliably annually. However, the gas boiler is less energy efficient and emits a larger amount of carbon dioxide than the heat pump. Therefore, to reduce the operation time of the gas boiler and increase the operation time of the heat pump, it is essential to control the capacity of the heat pump to broaden the operable water temperature range.

There are several ways to control the capacity of heat pumps. The first way is to use a variable-speed compressor. It uses energy efficiently by changing the compressor frequency in response to the load and heat source. Nasution and Wan Hassan [2] showed that controlling the compressor through the inverter can save energy consumption more than the compressor on-off control. Jeong et al. [3] compared the hot gas bypass method and the variable-speed compressor method and showed that the COP was higher in the variable-speed compressor control using the inverter during a partial load operation. Generally, most of heat pumps use variable-speed compressors to control the capacity. To continuously operate the heat pump using the low water temperature in winter, it is necessary to reduce the temperature difference of the primary fluid by controlling the capacity of the heat pump. However, in the case of a large heat pump system, limitation exists to control capacity through the compressor owing to the surging problem or degradation of the volumetric efficiency. Therefore, the operation of heat pumps is not available during the winter season when the water temperature is low.

The second way to control the capacity of heat pumps is to apply a hot gas bypass valve. It controls the evaporator inlet enthalpy by bypassing a part of the high-temperature and high-pressure refrigerant gas at the compressor discharge to the evaporator inlet or controlling the mass flow rate of refrigerant by bypassing a part of the high-temperature and high-pressure refrigerant gas at the compressor discharge to the compressor inlet. Yaqub et al. [4] suggested three methods of capacity control in refrigeration and air conditioning systems through the hot gas bypass method and analyzed the performance characteristics of each method through experiments and analysis. Baek et al. [5–6] analyzed the performance characteristics of the three methods proposed by Yaqub et al. according to changes in load and operating conditions. Ahn et al. [7] experimentally compared the hot gas bypass method in which a part of the refrigerant gas at the compressor outlet bypassing to the evaporator inlet and the method in which a part of the liquid refrigerant at the discharge of the condenser bypassing to the suction of the compressor. It was shown that the hot gas bypass method was advantageous during the heating period, the pressure of the condenser was lowered, and the COP was also lowered as the bypass ratio increased.

In this study, the heating performance of a hybrid heat pump system using hot gas bypass (HBHPS) was analyzed analytically. The river water was used as a heat source. The heat pump system using hot gas bypass was simulated by using Python. In the simulation, the characteristics of controlling the capacity of the heat pump by the hot gas bypass valve in the low water temperature condition were simulated. Through the heat pump simulation, performance map data were obtained according to the conditions of the heat source and the load side. The transient simulation program, TRNSYS, was used for the simulation, and the performance change was analyzed compared to the conventional boiler hybrid heat pump system (CHHPS).

2. Simulation method

2.1. Heat pump simulation method

The heat pump simulation was performed with the algorithm shown in Figure 1, based on the ORNL method [8] proposed by Fischer and Rice. The algorithm started by assuming an initial condensing pressure and an evaporation pressure. Then, the state of each component was calculated. The calculation proceeded until the energy balance converged, and when the convergence was reached. The efficiency model was used for the compressor modeling. The heat transfer occurring in the evaporator and the condenser was calculated using the e-NTU method. To simplify the simulation, the effectiveness (ε) was fixed at 0.7. In addition, the heat transfer was calculated by dividing the section according to the phase of the refrigerant. Accordingly, energy balance convergence conditions in the evaporator and condenser were set considering the degree of subcooling and superheating. The hot gas bypass method was applied in which some refrigerant was bypassed from the compressor outlet to the inlet. The opening ratio of the hot gas bypass valve (x) was set as an input value. However, the mass flow rate that can be bypassed is limited because the high bypassed mass flow rate can cause the compressor to overheat severely. The maximum ratio of bypassed flow rate can be expressed as y, which is the point where heating capacity can be controlled down to 73% of design capacity [7]. The bypass opening ratio (x) became 1 when the ratio of actual bypassed mass flow rate (y') is that of the maximum bypassed mass flow rate (y). R-134a was used as the refrigerant, and the physical properties at each point were obtained through CoolProp [9], which is a Python module. The schematic of the hot gas bypass heat pump is shown in Figure 2. The process of from points 2 to 6 is assumed to be the isenthalpic process because the hot gas bypass valve is an expansion valve for reducing the pressure. The operating characteristics of the hot gas bypass method were obtained by Equations (1)–(4).
Fig. 1. Flow chart of heat pump simulation.

\[ x = \frac{y'}{y} \quad (0 \leq y' \leq y) \]  \hspace{1cm} (1)

\[ y' = \frac{\dot{m}_6}{\dot{m}_1} \]  \hspace{1cm} (2)

\[ y' = \frac{(h_1 - h_5)}{(h_2 - h_5)} \]  \hspace{1cm} (3)

\[ COP = \frac{[(1 - y')(h_5 - h_4)]}{(h_2 - h_1)} \]  \hspace{1cm} (4)

Fig. 2. Schematic of hot gas bypass water source heat pump.
2.2. TRNSYS simulation method

Based on the heat pump simulation, the performance map data was obtained according to the temperature and flow rate of the heat source and load, and the ratio of bypass valve opening. The schematic of the TRNSYS model is shown in Figure 3, and the simulation conditions are shown in Table 1. The load for simulation was based on the actual measured data of a commercial building in Gwacheon in 2020. The actual measured temperature of the Paldang Dam basin in 2018 was used for the river water temperature. The average water temperature in winter was 5.3 °C and the range of temperature was 1.3–13.5 °C. Simulations were performed during the heating period in Korea, January–March, and November–December. A 500 RT heat pump system was used based on the maximum heating and cooling load, and water was used for both the heat and load side secondary fluid. When water is used as the secondary fluid, freezing can occur at the outlet of the heat pump evaporator when the river water temperature is low in winter, which makes the entire heat pump system inoperable. Therefore, when the heat pump is not operable, a gas boiler was mainly used for heating. To prevent freezing in the evaporator, the flow rate of source-side water can be increased or the capacity of the heat pump decreased to reduce the water-side temperature change in the evaporator.

As shown in Figure 4, the performance comparison was analyzed by TRNSYS modeling of two cases according to the control method of the heat pump system. The first case was a conventional hybrid heat pump system (CHHPS) which conventional water source heat pump applied. When the low water temperature condition was reached, the temperature change between the inlet and outlet of the primary and secondary fluids can be reduced by increasing the pump flow rate of the heat source. It is possible to increase the flow rate up to 2.0 times for P0 and 1.2 times for P1. Accordingly, the operation time of the heat pump can be extended. However, the power consumption can increase.

In the second case, the hot gas bypass heat pump was used in the hybrid heat pump system (HBHPS). The temperature change between the inlet and outlet of the evaporator of the heat pump can be further reduced by lowering the heat pump capacity through the hot gas bypass method in the low water temperature condition that even CHHPS cannot operate. However, the capacity in the condenser is also reduced, so to maintain the temperature difference on the load side, the flow rate of P2 must be reduced by 0.7 times. The coefficient of performance decreases as the opening of the hot gas bypass valve increases.

2.3. Performance indices

For the above two cases, the performance change was analyzed with various evaluation indices. Performance change was compared with seasonal performance factor (SPF), operation time, greenhouse gas emissions (GHGE), and operation costs. The formulas of each evaluation index are as follows. The SPF is the factor of efficiency for the whole heat pump operation period. The SPF is expressed as the heat supplied by the heat pump system ($E_{th,HP}$) divided by whole energy consumption ($E_{p,tot,P} + E_{p,tot,HP}$) for the operation period. The greenhouse gas emission factors for electric power and gas were 0.4594 ($EF_e$) and 0.2016 ($EF_g$), respectively, which are based on the Korean standard. Each emission factor was multiplied by the annual energy consumption of electricity and gas (AEC). In addition, for the annular operation costs of electricity and gas (AOC), rate tables based on Korean standards [10–12] were used. The exchange rate of the dollar was as of November 1, 2022. Greenhouse gas emissions and operating costs were compared under the assumption that the heat pump was operated for 16 years, which is the life cycle of the heat pump ($L$), under the same water temperature and load conditions. Inflation rate ($i$) and discount rate ($d$) were both set as 0.1.

$$SPF = \frac{E_{th,HP}}{E_{p,tot,P} + E_{p,tot,HP}}$$  \hspace{1cm} (5)

$$GHGE = L \times (AEC_e \times EF_e + AEC_g \times EF_g)$$  \hspace{1cm} (6)

$$Operation cost = \sum_{n=1}^{L}(\frac{1+i}{1+d})^{n-1} (AOC_e + AOC_g)$$  \hspace{1cm} (7)

3. Simulation results

3.1. Heat pump simulation results

Figure 5 shows the change in the P-h diagram when the condenser water inlet temperature was 40 °C, the evaporator water inlet temperature was 12 °C, and the $x$ was 0.5. As a part of the refrigerant gas at the compressor outlet passed through the hot gas bypass valve and flowed into the compressor inlet, the condensing pressure was lowered. However, the evaporating pressure was slightly increased because a part of the high-temperature and high-pressure refrigerant gas flows into the outlet of the evaporator. Additionally, the compression ratio and compressor work were reduced, but the heat pump capacity reduction was larger. Accordingly, the COP was lowered.
3.2. TRNSYS simulation result

Figure 6 shows the load supply period by the heat pump of CHHPS and HBHPS. The operating time of the HBHPS was 97 hours longer than that of the CHHPS. This corresponded to 2.68% of the total heating period. This was because the capacity of the heat pump was lowered by the hot gas bypass valve and can operate until the water source temperature was 2.38 °C compared to CHHPS which can operate until 3.03 °C. Both cases cannot cover the heat load by heat pump operation alone during the coldest season in winter because the river water temperature was below than 2.38 °C.
the energy consumption was 28.30% higher and heat supply was 16.43% higher. The increase in energy consumption was larger than the amount of heat supplied, resulting in a lower SPF of 9.26%.

Figure 7 shows the energy consumption, heat supply and SPF for CHHPS and HBHPS. Figure 8 shows the greenhouse gas emissions of CHHPS and HBHPS, and Figure 9 shows the operating costs of CHHPS and HBHPS. As the heat pump operation time in HBHPS increased, the boiler operation time decreased. The decrease in gas usage was larger than the increase in electric energy usage. Accordingly, GHGE was reduced by 2.23%, and winter season operating cost was reduced by 5.88% in HBHPS compared to CHHPS.

Fig. 7. Energy consumption, heat supply and SPF for CHHPS and HBHPS.

Fig. 8. GHGE of CHHPS and HBHPS for life cycle.
4. Conclusion

In this study, the performance change according to the hot gas bypass heat pump application of the hybrid heat pump system for heating load in winter was analyzed. As a result, when the hot gas bypass heat pump was used, the SPF of the heat pump system was reduced by 9.26%. However, the operating time increased by 2.68%, GHGE was reduced by 2.23%, and operating cost by 5.88%. This study was based on the water temperature in the Paldang Dam basin in 2018, where the average water temperature condition in winter was very low. The hot gas bypass heat pump system is expected to show better performances in areas where the water temperature is relatively higher.

Abstract

In heat-pump-driven liquid-desiccant (HPLD) air-conditioning systems, the release of condensing heat from the heat pump to the regenerator solution and exhaust air (i.e., capacity matching) is very important to maintain the dehumidification performance as well as the operational feasibility and stability of the system. Therefore, in this study, the capacity matching especially focusing on the release of extra condensing heat of the HPLD air-conditioning system is optimized in conjunction with the energy performance. With four design variables under the various outdoor air conditions, a multi-objective optimization is conducted to simultaneously maximize a system coefficient of performance and minimize a newly defined capacity matching index of extra condenser. Pareto front which is a set of optimum points is obtained using multi-objective genetic algorithm, and final optimum solutions are then determined and discussed based on a decision-making scenario. In conclusion, the system coefficient of performance is maximally increased by 24 % and the capacity matching index of extra condenser is maximally decreased by 55 %, compared with each initial value.

Keywords: Liquid desiccant; Heat pump; Capacity-matching performance; Energy performance; Multi-objective optimization

1. Introduction

Recently, as the significance of indoor humidity control has increased [1], a liquid-desiccant (LD) system which has an energy saving potential due to its decoupled control of the indoor temperature and humidity has emerged as a promising alternative to the traditional dehumidification systems [2]. Both the dehumidification and regeneration performances in the LD system improve via increase of the vapor pressure difference between the desiccant-solution and air. Thus, the desiccant-solution should be cooled before the absorber and heated before the regenerator [3]. Therefore, the integration of a heat pump to the LD system, referred to as a heat-pump-driven liquid-desiccant (HPLD) system, would be a practical approach because the heat pump can provide the solution cooling and heating simultaneously [4].

Many previous studies have mainly focused on improving the energy performance of the HPLD air-conditioning system and demonstrating its energy saving potential [5,6]. By contrast, some previous studies have been performed to match the solution heating load and the actual heat released from the solution-side condenser, and to control the extra condensing load which generates as the heat released from the solution-side condenser is higher than the solution heating load, referred to as capacity matching. Niu et al. [7] defined a novel performance index to evaluate the capacity matching and concluded that the HPLD system should possess double-condenser to handle the extra condensing load. Abdel-Salam and Simonson performed the parametric study on both the capacity matching and energy performance with varying the operating parameters and finally revealed the most influential parameter based on a sensitivity analysis [8]. In addition, they established an operating logic under the various capacity matching situations [9].

E-mail address: jjwarc@hanyang.ac.kr
The abovementioned previous studies focused only on the capacity matching of the solution-side condenser; however, to ensure the operational feasibility and stability of the system, the release of the extra condensing heat in the extra condenser based on thermodynamics should also be concretely handled in the capacity matching research. Furthermore, although the capacity matching, including releasing the extra condensing heat, must finally be optimized considering the energy performance together, no related optimization study has been previously conducted. Therefore, in this study, a multi-objective optimization of the HPLD air-conditioning system which can provide both the latent and sensible cooling is presented. With four design variables under the various outdoor air conditions, the two objectives are optimized as follows: extra condenser’s capacity matching index (CMI) which is much focused on releasing the extra condensing heat and coefficient of performance (COP) of the entire system for the energy performance index. A parametric study is first conducted to help to select the design variables and also understand the results of multi-objective optimization. Subsequently, a set of optimum points (i.e., Pareto front) is obtained using multi-objective genetic algorithm (MOGA). This would significantly contribute to providing engineers with a guideline for optimally designing and operating the HPLD air-conditioning system in various situations.

2. System Overview

2.1. System description

Figure 1 shows the proposed HPLD air-conditioning system. The process air as the room-return air mixed with outdoor air is initially dehumidified in the absorber via contact with the desiccant-solution which is cooled to the target temperature by the solution-side evaporator of heat pump. The dried process air is then sensible cooled to the target supply air temperature (i.e., $T_{sa} = 15\, ^\circ C$) in the air-side evaporator of heat pump. In the regenerator, the desiccant-solution which is heated to the target temperature by the solution-side condenser of heat pump discharges moisture to the outdoor air (i.e., scavenging air) to increase its concentration (i.e., regeneration process). When the amount of heat released from the solution-side condenser is greater than the solution heating load, the extra condenser which is a kind of the air-cooled condenser is activated to release the extra condensing heat into the regenerator outlet air.

![Fig. 1. Proposed HPLD air-conditioning system.](image-url)
2.2. Performance indices

Before defining the CMI, the amount of heat absorbed by both the solution-side evaporator and air-side evaporator is assumed to be equal to the amount of heat required to cool the absorber solution and process air, respectively. In other words, the actual cooling capacity of evaporator is always the same as the cooling load of evaporator by adjusting the refrigerant flow rate in accordance with the inverter control. Therefore, two evaporators’ CMIs (i.e., the ratio of the actual cooling capacity of evaporator to the cooling load of evaporator) are 1.0 all the time, which is not the focus and will not be more discussed in this study. The CMIs of both the solution-side condenser and particularly the extra condenser are the major performance indices to assess the condensing heat release and quantify the capacity matching. The solution-side condenser’s CMI ($CM_{sol,cond}$) is defined as the ratio of the total condensing heat to be released, referred to as total condensing load ($Q_{tot,cond,load}$), to the heat required to heating the regenerator solution to the target solution temperature ($Q_{reg,load}$) (Eq. (1)).

$$CM_{sol,cond} = \frac{Q_{tot,cond,load}}{Q_{reg,load}} = \frac{m_{ref}(h_{cond,i} - h_{cond,o})}{(m_c p)_{reg,i}(T_{reg,i} - T_{reg,o})} \tag{1}$$

Therefore, the increase in $CM_{sol,cond}$ indicates the increase in the total condensing load, and when $CM_{sol,cond}$ is greater than 1.0, the extra condensing load ($Q_{extra,cond,load}$) then occurs. The extra condenser is a kind of the air-cooled heat exchanger; therefore, the maximum thermodynamically possible heat transfer rate of the extra condenser ($Q_{extra,cond,max}$) should be estimated via multiplication of the minimum capacitance rate by the maximum possible temperature difference [10]. Accordingly, the extra condenser’s CMI ($CM_{extra,cond}$) is defined as the ratio of $Q_{extra,cond,load}$ to $Q_{extra,cond,max}$ (Eq. (2)) to assess the operating stability and feasibility of the extra condenser based on thermodynamics. The decrease in $CM_{extra,cond}$ indicates the decrease in the extra condensing load, which is ideal in terms of reducing the waste heat and extra condenser size. In addition, when $CM_{extra,cond}$ is lower than 1.0, the extra condensing heat is well released at the extra condenser. On the other hand, when $CM_{extra,cond}$ is higher than 1.0, the extra condensing heat is not completely released and remains inside the heat pump, which results in a fatal entire system failure.

$$CM_{extra,cond} = \frac{Q_{extra,cond,load}}{Q_{extra,cond,max}} = \frac{Q_{tot,cond,load} - Q_{reg,load}}{(m_c p)_{reg,o}(T_{cond,i} - T_{cond,o})} \tag{2}$$

The system COP ($COP_{sys}$) is selected as the energy performance index and defined as the ratio of total cooling capacity ($Q_{cooling}$) to total input power ($W_{tot}$), as shown in Eq. (3).

$$COP_{sys} = \frac{Q_{cooling}}{W_{tot}} = \frac{m_{abs,i}(h_{abs,i} - h_{sol})}{W_{comp} + W_{fan} + W_{pump}} \tag{3}$$

3. Optimization Overview

3.1. Design problem formulation

In the design and operation of the proposed HPLD air-conditioning system, the design problem of multi-objective optimization is formulated to derive the optimum combination of design variables both to achieve the capacity matching including the release of extra condensing heat and to improve the energy performance. The overall design problem formulation is outlined in Table 1.

3.1.1. Design variables

The influential design variables commonly used in the previous studies on the LD systems are as follows: inlet air temperature, inlet air humidity, packing geometry, air flow rate of absorber and regenerator, solution flow rate of absorber and regenerator, solution temperatures of absorber and regenerator, solution concentrations of absorber and regenerator. However, in this study, some of the conventional influential design variables which meet the following criteria are fixed, excluded, or neglected:

- First, the relatively less influential variables
- Second, the uncontrollable or nonmanipulable variables
- Third, the variables related to the latent cooling for a target conditioned zone
Based on the criterion assessment, the multi-objective optimization is conducted for three cases of summer outdoor air temperatures (i.e., low temperature, standard temperature and high temperature), and finally four design variables are selected as follows: the ratio of the air flow rate of regenerator to absorber \(R_{\text{air}}\), the ratio of the solution flow rate of regenerator to absorber \(R_{\text{sol}}\), the solution temperature of absorber \(T_{\text{abs.i,s}}\) and the solution temperature of regenerator \(T_{\text{reg.i,s}}\). The range of design variables is set in consideration of the range commonly used in the previous studies of the HPLD systems [11] and also the system practicality. Then, the medium of each variable’s min-max range was considered as the representative value for each variable and put as its initial value.

### 3.1.2. Objective function and constraint

Among the performance indices, \(\text{COP}_{\text{sys}}\) and \(\text{CMI}_{\text{extra,cond}}\) are selected as the objective functions to be maximized and minimized, respectively. They also correspond to the constraints because they should be improved compared with their initial values. Particularly, \(\text{CMI}_{\text{extra,cond}}\) must be lower than 1.0 to completely release the extra condensing heat within \(\dot{Q}_{\text{extra,cond,max}}\) as specified in Section 2.2. In addition, \(\text{CMI}_{\text{sol,cond}}\) corresponds to the constraint too and should be greater than 1.0 because \(\dot{Q}_{\text{reg.load}}\) should be satisfied to heat the regenerator solution to the target temperature. The humidity ratio of the absorber outlet air \(\omega_{\text{abs.o,a}}\) is the final constraint which should be lower than 0.010 kg/kg to handle the room latent load of the target zone [12].

### 3.2. Optimization algorithm

The optimization algorithm should be appropriately selected according to the type of optimization problems. All four design variables are the continuous variables, and because one of the objective functions and constraints has nonlinearity based on the parametric study which will be described later in Section 4.1, nonlinear programming should be handled. In addition, the multi-objective optimization problem with two conflicting objective functions should be solved, and global optimization results, not local optimization results, should be derived. Therefore, MOGA which is based on the genetic algorithm for the multi-objective optimization problem is selected as the optimization algorithm. MOGA is noted as one of the most popular multi-objective optimization algorithms and can generate a better spread of Pareto front for the multi-objective functions. Particularly, two specialized multi-objective operators, corresponding to crowding distance sorting and non-dominated sorting, are applied to MOGA, which is referred to as a non-dominated sorting genetic algorithm-II (NSGA-II) [13]. The population size is 100, and the crossover rate is 0.9. The mutation rate is 0.25 considering the number of design variables, and the random speed is 100. The maximum number of generations is 250, and the violated constraint limit is 0.003. The multi-objective optimization is conducted using a commercial process integration, automation and optimization (PIAnO) software.
4. Results and Discussion

4.1. Parametric study

To help to understand the selection of design variables and the optimization results, the parametric study is first conducted on the two objective functions (i.e., \(COP_{sys}\) and \(CMI_{extra,cond}\)) by varying all possible operating parameters as follows: outdoor air temperature \(T_{oa}\), outdoor air humidity ratio \(\omega_{oa}\), the ratio of the air flow rate of regenerator to absorber \(R_{air}\), the ratio of the solution flow rate of regenerator to absorber \(R_{sol}\), the solution temperature of absorber \(T_{abs,i.s}\) and the solution temperature of regenerator \(T_{reg,i.s}\).

Figure 2 shows the results of parametric study for each operating parameter. As \(T_{oa}\) increases, both \(COP_{sys}\) and \(CMI_{extra,cond}\) are increased (Fig. 2(a)). The increase in \(COP_{sys}\) at the high \(T_{oa}\) is attributed to the significant increase in the total cooling capacity \(Q_{cooling}\). The increase in the heat absorption rate of evaporators and input power of compressor result in the increase in total condensing load \(Q_{tot,cond,load}\) and then extra condensing load \(Q_{extra,cond,load}\). However, \(Q_{extra,cond,max}\) is decreased because the difference in the temperature between the regenerator outlet air and condenser is decreased, which increases \(CMI_{extra,cond}\).

On the other hand, in Fig. 2(b), \(COP_{sys}\) is slightly decreased as \(\omega_{oa}\) increases because the increase in \(Q_{cooling}\) is insignificant. In addition, \(CMI_{extra,cond}\) is almost constant regardless of the change in \(\omega_{oa}\) because \(\omega_{oa}\) is not directly involved in the parameters that make up \(CMI_{extra,cond}\).

In Fig. 2(c), \(COP_{sys}\) is slightly increased when \(R_{air}\) increases because as regenerator air flow rate increases, it could increase the regeneration performance and solution concentration, which increases the dehumidification performance and \(Q_{cooling}\). However, because the fan power is increased and also the solution cooling load is increased due to the increase in the exothermic reaction during the dehumidification process, \(COP_{sys}\) cannot be increased significantly. Meanwhile, \(CMI_{extra,cond}\) is found to be much significantly decreased as \(R_{air}\) increases due to the increase in the air flow rate of regenerator and the increase in \(Q_{extra,cond,max}\) accordingly.

In Fig. 2(d), as \(R_{sol}\) increases, \(COP_{sys}\) is shown to be decreased mainly due to the increase in the pump input power. However, \(CMI_{extra,cond}\) is slightly increased as \(R_{sol}\) increases. The higher solution flow rate of regenerator is less influenced by the decrease in solution temperature caused by the endothermic reaction during the regeneration process. Therefore, the solution temperature of regenerator sump is increased, and then the temperature of the condenser and the regenerator outlet air is decreased at the high \(R_{sol}\), which results in the \(CMI_{extra,cond}\) increase.

In Fig. 4(e), \(COP_{sys}\) is maximized between 15–20 °C of \(T_{abs,i.s}\). This is because at the higher \(T_{abs,i.s}\), the dehumidification rate is decreased due to the decrease in the vapor pressure difference, and at the lower \(T_{abs,i.s}\), the dehumidification rate is also decreased according to the previous absorber model used in this study [14]. Therefore, the dehumidification rate is maximized at the intermediate \(T_{abs,i.s}\), which results in \(COP_{sys}\) being maximized between 15–20 °C of \(T_{abs,i.s}\). Meanwhile, as the dehumidification rate is maximized, the regeneration rate is also maximized between 15–20 °C of \(T_{abs,i.s}\). Accordingly, the solution temperature of regenerator sump is minimized due to the decrease in solution temperature caused by the endothermic reaction during the regeneration process. Therefore, between 15–20 °C of \(T_{abs,i.s}\), \(Q_{reg,load}\) is maximized and \(Q_{extra,cond,load}\) is then minimized, which causes the minimization of \(CMI_{extra,cond}\).

In Fig. 4(f), as \(T_{reg,i.s}\) increases, both \(COP_{sys}\) and \(CMI_{extra,cond}\) are noted to be decreased. The decrease in \(COP_{sys}\) at the high \(T_{reg,i.s}\) is resulted from the high input power of the compressor as the condensing temperature is increased to produce the high \(T_{reg,i.s}\). On the other hand, the increase in the condensing temperature at the high \(T_{reg,i.s}\) increases the temperature difference between the condenser and the regenerator outlet air, thereby decreasing \(CMI_{extra,cond}\).
Fig. 2. Effect of operating parameters on two objective functions.

4.2. Optimization results

4.2.1. Pareto front

Pareto front which is a curve presenting a set of optimized non-dominated points obtained by MOGA should be generated to find the optimum solution. Figure 3 shows both the initial model and the generated Pareto fronts by MOGA for each case of $T_{oa}$. In all three Pareto fronts, all non-dominated optimized points are indicated to be adequately plotted in maximizing $COP_{sys}$ and minimizing $CMI_{extra,cond}$. In addition, the constraints are noted to be satisfied in that all optimized non-dominated points have greater $COP_{sys}$ and lower $CMI_{extra,cond}$ compared to the initial values, respectively, and particularly, all optimized non-dominated points have $CMI_{extra,cond}$ lower than 1.0.

According to the parametric study, when $T_{oa}$ increases, the points of the Pareto front generally have a higher $CMI_{extra,cond}$ value because at the high $T_{oa}$, releasing the condensing heat is more difficult. Moreover, the maximization of $COP_{sys}$ on the Pareto front in Case 3 is found to be insignificant compared with that in Case 1 and Case 2. This is because in Case 3, in most cases, $CMI_{extra,cond}$ is greater than 1.0 which violates the constraint. Therefore, although $COP_{sys}$ could be further maximized, the points that violate the constraints were excluded from the Pareto front. Meanwhile, in Case 1 and Case 2, a section, names as Section B, is shown on the Pareto front wherein $CMI_{extra,cond}$ is further minimized while $COP_{sys}$ is almost constant. Because $R_{air}$ is the most influential parameter in $CMI_{extra,cond}$, $R_{air}$ is primarily increased in
section B. However, \( R_{\text{air}} \) is the least influential parameter in \( \text{COP}_{\text{sys}} \), therefore \( \text{COP}_{\text{sys}} \) is almost constant in Section B. In section A, \( R_{\text{air}} \) has maximum value and does not change, and then \( T_{\text{reg},i,s} \) which corresponds to the next most influential parameter in \( \text{CMI}_{\text{extra,cond}} \) primarily minimizes \( \text{CMI}_{\text{extra,cond}} \). However, \( T_{\text{reg},i,s} \) also corresponds to the influential parameter in \( \text{COP}_{\text{sys}} \), thus the graph rapidly changes in Section A.

(a) Case 1 \( T_{\text{oa}} = 27 \degree \text{C} \).

(b) Case 2 \( T_{\text{oa}} = 31 \degree \text{C} \).
4.2.2. Final optimum solutions by decision-making scenario

All non-dominated points on the Pareto front are the acceptable optimum solutions to the multi-objective optimization problem. However, the final optimum solutions should be presented based on a decision-making process to provide the designers and engineers with a practical guideline for optimally designing and operating the HPLD air-conditioning system.

The established decision-making scenario consists of three different scenarios with respect to the different weights allotted to each objective function. First, in Scenario I, $COP_{sys}$ maximization and $CM_{extra,cond}$ minimization have weights of 0.0 and 1.0, respectively, which corresponds to point A in Fig. 3. Scenario I focuses only on improving the operational feasibility and stability of the system and reducing the extra condensing load while maintaining the energy performance just at its initial value. Second, in Scenario II, $COP_{sys}$ maximization and $CM_{extra,cond}$ minimization have weights of 0.5 and 0.5, respectively, which places the same importance on both the system energy performance and the heat release. Finally, in Scenario III, $COP_{sys}$ maximization and $CM_{extra,cond}$ minimization have weights of 1.0 and 0.0, respectively, which corresponds to point B in Fig. 3. Scenario III focuses only on improving the energy performance while maintaining the operational feasibility and stability of the system just at its initial value. Tables 2, 3 and 4 reveal the selected final optimum solutions in all scenarios for each case of $T_{oa}$.

5. Conclusion

In this study, the multi-objective optimization of the HPLD air-conditioning system was conducted to simultaneously improve the energy performance and achieve the capacity matching especially focusing on the release of extra condensing heat. The capacity matching indices were defined for solution-side condenser and extra condenser, respectively to assess the release of condensing heat and quantify the capacity matching. With four design variables (i.e., $R_{air}$, $R_{sol}$, $T_{abs,l,s}$, $T_{reg,l,s}$), a set of optimum points, referred to as Pareto front, which aims maximizing $\text{COP}_{sys}$ and minimizing $\text{CMI}_{extra,cond}$, was generated based on MOGA for each case of outdoor temperature ($T_{oa}$). Subsequently, the final optimum solutions were determined based on the decision-making scenario which is established by diversely assigning weights to the objective functions.

Finally, at the low $T_{oa}$, $\text{COP}_{sys}$ and $\text{CMI}_{extra,cond}$ maximally increased and decreased by 24 % and 55 %, respectively, compared with initial value, and at the standard $T_{oa}$, by 22 % and 55 %, respectively, and at the high $T_{oa}$, by 12 % and 47 %, respectively. The results of this study would be a practical guideline for engineers to optimally design and operate the HPLD air-conditioning system while simultaneously improving the energy performance and capacity matching in various situations. In future, an experimental investigation will be conducted to validate the optimization results in this study, and an optimal prototype will also be constructed based on the optimization results in this study.

Abstract

In a power system with a large share of intermittent sources, the need for flexibility to balance variations in electricity production will increase. Flexibility can also help to reduce problems with bottle necks in the electricity grids. An advantage of using a combination of heat pumping technology and thermal networks is the larger flexibility in heat production and storage options that it entails. This article discusses the potential of using the flexibility of heat pumps in Swedish thermal grids from the perspective of energy company and end users. In an interview study with district heating companies that have heat pumps in their thermal grids, possibilities and barriers to use heat pumps for flexibility was investigated. It was found that those who have heat pumps already use them for flexibility. Barriers for even more use was investment cost for new heat pumps. More frequent shifts are connected to organizational, behavioral, and technical barriers. The study also investigates the economic benefits for end users by utilizing the flexibility of heat pumps combined with district heating. Simulations are carried out for buildings located in different electricity price areas and climate zones in Sweden. It also considers different price scenarios for electricity, grid tariff, district heating and system services. The result shows that the energy cost for end users could be effectively reduced by using the flexibility of the hybrid heating system. The cost saving potential varies among locations, price scenarios and the type of system services provided by the heat pump.

1. Introduction

In a power system with a large share of intermittent sources, the need for flexibility to balance variations in electricity production will increase. Flexibility can also help to reduce problems with bottle necks and shortage of capacity in the electricity grids. An advantage of using a combination of heat pumping technology and thermal networks is the greater flexibility in heat production and storage options that it entails. Today, there is an ongoing work to find affordable solutions to increase the robustness and flexibility of the power system. Several international reports [1]-[3] have in recent years pointed out the combination of heat pumps and district heating as a technical solution that can help to manage an increasing share of electricity from intermittent sources. Here Sweden is an interesting country to evaluate since the country has well-developed district heating systems in almost all cities as well as a large number of heat pumps installed, giving good conditions to combine district heating and heat pumps for a more flexible energy system.

Within EU there is an ongoing trend with an increasing share of electricity from renewable sources. EUs Renewable Energy Directive towards 2030 [4] sets a binding target for the EU for 2030 that 32% of the final energy consumption should come from renewable sources, and there are ongoing discussions to increase the target to 40% as part of the European green deal [5]. Sweden has similar targets, with a political goal that 100% of the electricity should be fossil-free by 2040 [6][7]. There is also an ongoing electrification of the whole

Swedish society. “Fossilfritt Sverige”, an initiative to reduce the climate impact from different industrial sectors in Sweden, has developed several roadmaps for different industrial sectors and many of them points out an increased electrification as the way forward to reduce the climate impact of their respective industries [9]. In order to support the transition, the Swedish government has published an electrification strategy [8]. The strategy highlights a flexible use of electricity as one important part and mention especially a higher degree of flexibility related to electrical heating. All this indicates that an increased load on the electricity grid is to be expected in the future and a large part will be covered by intermittent sources.

1.1. Background

Most Swedish buildings are today heated by district heating, followed by electricity, either by a heat pump or electrical heaters, on third place comes biofuel-boilers. While heat pumps and electric heaters are most common in single-family homes, district heating dominates in apartment buildings. Today there are almost 1.5 million installed heat pumps in Sweden, mainly in the approximately 2 million single-family-houses in the country [11]. When it comes to heat pumps installed for production of district heating a survey from 2016 identified 149 units of large-scale heat pumps (>1 MWa) from 11 different countries. According to the survey Sweden is by far the country with the largest installed capacity in Europe (approximately 1200 MW). Many of these Swedish heat pumps was installed during the 80’s and have now been in operation for many years [12].

Using heat pumps located at the end users for demand response, without altering the heat source between heat pump and district heating, makes use of the thermal inertia of the building to shift the heat production in time. The thermal inertia makes it possible to start or stop the heat production for a while without any large impact on the indoor comfort, for how long depends highly on the thermal inertia of the building. A study simulating single family buildings in Denmark [14] concluded that it is possible to shift the heat production by 2-5 h in poorly insulated buildings and still maintain a good comfort. For well isolated buildings (passive house standard) the allowed shifted period could be even longer, a complete shutdown of the heating system is possible for more than 24h while still fulfilling the defined comfort criteria. Weiβ et al. [13] showed by simulations in IDA ICE that for residential buildings in Austria, built according to Austrian standards after 1980, at least 50% of domestic heating peak loads can be shifted to off-peak periods during the day, using a comfort band between 19-22°C. For heat pumps located in the district heating grids the thermal inertia is many times larger due to the possibilities to store heat in pipes and accumulator tanks. [28]

1.2. Scope

The scope of the study is to evaluate potentials and constraints to use heat pumps for increasing the flexibility of energy systems. It investigates two types of heat pump systems: 1) centrally placed heat pumps in thermal grids which are operated by district heating companies; and 2) decentralized heat pumps which are installed on customer side and combined with district heating as a hybrid heating solution.

1.2.1. Delimitations

The article focusses on Swedish conditions in terms of climate, demand for space heating and hot water consumption, prices for heating and electricity, market conditions for frequency regulation services, projection of future scenarios, etc.

1.3. Definition flexibility

Flexibility and demand response are broad terms without a clear definition. EU:s Electricity Directive [10] states that: “demand response ‘means the change of electricity load by final customers from their normal or current consumption patterns in response to market signals, including in response to time-variable electricity prices or incentive payments, or in response to the acceptance of the final customer’s bid to sell demand reduction or increase at a price in an organised market ... whether alone or through aggregation’.”

In this study, we focus on demand response of heat pumps that are owned either by district heating companies or by property owners with a hybrid heating solution. The demand response refers to the adjustment of heat pump operation for two purposes: 1. Respond to dynamic prices such as the variations in price for electricity, district heating or fuels. 2. Respond to dedicated markets for flexible resources such as local flexibility markets or TSO:s market for ancillary services.

The flexibility is achieved by varying the running order between different heat sources, or utilizing the
heat storage in the thermal grid, accumulator tanks or thermal inertia of buildings.

2. Interview study with district heating companies using heat pumps

2.1. Method in interview study

An interview study has been done with district heating companies in Sweden that have heat pumps in their production mix. Statistics about heat production in district heating system for 2020 and 2017 [15][16] have been used to find companies for interviews. About 17 companies with heat pumps in the production in 2020 was found. To find informants on these companies the contact network within the project has been used along with contact details from the energy companies. Some contacts have been found on the energy companies web pages. Contacts has been taken by email with 16 persons representing 14 different companies. The contact details did not match for 4 and 3 did not answer and 1 turned out to not have a heat pump in the grid. Finally, 8 interviews, (named 11-18 in the study), with 13 persons were booked and finalized, representing 10 district heating grids distributed across Sweden. The interviews were done with the digital meeting tool zoom and recorded. Notes were also taken during the interviews that lasted between 30-60 min. The informants had both strategical roles and works closely with the production.

Before the interviews was conducted a semi structured interview guide was developed including the following themes: background about the informants and the company, facts about their thermal grids and production, their heat pumps, their attitudes and actions for flexibility, and finally their attitudes on decentralized heat pump at end consumers. Recordings and notes from the interview have been analyzed to find how heat pumps in district heating grids are used and what possibilities and barriers there are for contribution to flexibility.

2.2. Results from the interview study

2.2.1. Heat pumps in the district heating grids

In the 1980’s many heat pumps were installed in district heating grids in Sweden. Since these decisions were taken about 40-50 years ago, knowledge about the accurate basis for decisions may only be found in old documentation.

"They wanted to replace heavy oil... I found some old document from when decisions were made, and then it was expected that there were quite high electricity prices for that time, but they were stable and then you dared to make this investment." 15

The informant 15 talks about ambitions to reduce fossil fuels in combination with a lot of available electricity from nuclear plants and with stable electricity prices as motivation of the investment back in the 1980’s. Some of those heat pumps are still in use and have high efficiency. Three different ways to handle this have been found in the study. The first way is to replace the heat pump by other heat production. One example is described by 17:

"It was old, since 1984, and expensive to renovate. More power was needed as the city grow, then they installed a new heating plant with bark and wood chips... and scrapped pellets and heat pump. They had calculated that it was much cheaper to run on bark and wood chips than the electricity price for the heat pump. I don't think the heat factor was very good. ... I know that when I ran it, it took water from about 8 m depth. It was about 2 degrees Celsius. It wasn't even 4 degrees." 17

The heat pump was scrapped because of age, high costs for renovation and a low coefficient of performance, COP, which contributed to calculated higher energy production cost than with bark and wood chips. One reason for low COP was that the inlet of seawater was not deep enough to deliver 4 degrees C which normally is the bottom temperature due to high density, during winter when the sea water is cold. For some of the old heat pumps in the study there are plans for replacing them with other kind of production further on. This is the most common way and probably the answer to why there is less heat pumps in 2020 than 2017. The second way is to maintain the heat pumps to prolong their lifetime. There is a variation from smaller reparations to replacement of vital parts. Lack of spare parts is a barrier for reparations that some companies overcome it with special manufacturing based on old drawings. The most deep-going renovation is described by 13 where the control system and vital parts are renovated to prolong the lifetime with 30 years. This was motivated by a good heat source on the cold side and that there was no other heat production that was suitable in the system near a city with limitations for combustion. The third way is to replace the old heat pump with a new. 18, describes how the old heat pumps were demolished as they were found unprofitable since they had built new production with biogas as fuel. A few years later the gas price was high, and it was considered profitable to install new heat pumps, which was done in 2017.
There are also some other heat pumps that are installed in recent years in district heating grids where there is an available heat source for the cold side of the heat pump. District cooling is an upcoming product for energy companies. Some of these plants are also used for production of heat during winter. Other more recent heat pump installations are “island installations” where the normal grid is not connected.

2.2.2. District heating production and heat pumps

The informants describe how their district heating production is planned based on a forecasted heat need in the coming day and week according to weather forecasts, historical data and fuel prices. Available production units and personal resources are also considered as input for the planning. The planning results in a dispatch order for the different production units connected to the grid.

2.2.3. Flexibility in district heating grids

One way to create more flexibility than the thermal inertia of the supply pipes is to add an accumulator tank in the grid. This has been adopted by almost every grid in the study. The companies who have heat pumps in their grid describe the accumulator tank as an asset for accessing flexibility when the electricity price varies. On the other hand, it is hard to motivate an investment in heat pump only for getting more flexibility because of the low profitability. The startup time for heat pumps is shorter than that for other heat production units e.g. boiler with wood chips. Technically it is possible to start or stop heat pumps almost immediately, but in practice the minimum running time for heat pumps lasts from at least 3–4 hours to 12 hours in most grids. Frequent start and stop increases the risk of higher maintenance costs, especially for older heat pumps. Many of the informants also talk about the easy capacity regulation as an advantage of heat pumps. But there is a limitation in delivered temperature that must be supplemented by other fuels, at least in wintertime.

Barriers for the use of existing heat pumps, even when electricity prices are low, have been found in the study. The first barrier is that other production must be up and running and then fulfills the heat demand. A typical example is the waste combustion i.e. where there is a commitment to combust a specific volume of waste and it is not possible to save it for later needs. The second barrier is the monthly electrical power fee that occurs when a heat pump is used. The size of the fee is so high that it is unprofitable to start a heat pump if it is not going to be used at least for about 7 days in the actual calendar month. The third barrier found is the lack of capacity on the cold side of the heat pump, caused by for example low water temperatures in sea water, low volumes of wastewater or lack of waste heat caused by revision or lower production. The fourth barrier is a need of both available and motivated personnel to start or stop a heat pump when the electricity price change. The larger energy production units are seldom fully automated, so active control by personnel is needed to change between production units.

2.2.4. District heating companies’ view of smaller heat pumps located at end-users in their grid

Informants from the district heating companies in the study describe existing or possible customers using heat pumps as a competitor situation and how they use pricing to overcome this.

"We price against customers who have heat pumps so that we outcompete it.” I8

The reason why combination of heat pumps and district heating is rarely seen as a referable combination from the district heating companies is because it causes more costs and is hard to plan.

"Nope... But really, we think they're free riding on us. They remove the base load when we have the best production and then they want to buy peak load production from us that is expensive, difficult to provide and has poor environmental performance.” I2

They also say that using district heating as peak load often results in the need to have and use fossil production, which causes bad environmental performance. In the company in I7 they have handled the situation with a special agreement for customers who only use district heating as peak load. The aim is to make it more profitable for the district heating company and provide fairer pricing for their other customers who use district heating for all their consumption. One argument against the smaller heat pumps is that the district heating company cannot control them. In the study there are few examples of the collaboration between energy companies and customers for and controlling the smaller heat pumps in the grid. The company in interview I8 gives one example: where the district company has bought a 0,8 MW-size heat pump installation, (which are seen as a small heat pump), from a customer and now use and control it. The informant I8 describe it as a win-win situation for both customer and district heating company. Heat pumps out in the grid compensate for heat losses and contribute with higher temperature and capacity out in the grid. Economic benefits for energy customers to use the flexibility of heat pumps.
3. Economic benefits for energy customers to use the flexibility of heat pumps

This section analyses the economic benefits of Swedish property owners for utilizing the flexibility of heat pumps. It focuses on the customers who use a hybrid heating system i.e. heat pump combined with district heating. It firstly identifies the cost and revenue streams for the common Swedish energy customers with hybrid heating solutions. Then it introduces a simulation model for analyzing the energy usage and operation cost of the heating system. The model is applied in a case study to simulate the operation of a hybrid heating system under different conditions. The simulation results are shown and discussed in the end.

3.1. Cost and revenue of property owners with both heat pump and district heating

A Swedish property owner with a hybrid heating system needs to pay both electricity cost and district heating cost. The electricity cost is related to the electricity consumed by the heat pump. It consists of two parts: one part is paid to the DSO (distribution system operator) for connection and usage of the power grid; another part is paid to the electricity retailer for buying the electricity. The district heating cost is paid to the heat supplier for extracting heat from the thermal grid. The property owner signs separate contracts with DSO, electricity retailer and district heating supplier. [18] Table 1 lists the cost components that are usually included in the three contracts. The electricity price paid to retailer is mainly affected by the price on the wholesale electricity market. The grid tariff and district heating tariff are defined by DSO and heat supplier and supervised by Swedish Energy Markets Inspectorate.

Note: the costs components in the parentheses are not always included in the contract.

With the thermal inertia of the building envelope, the property owner can also provide flexibility to the power system by adjusting the default set points of the heat pump. The flexibility can be used as different types of services. This study focuses on four frequency regulation services purchased by TSO (transmission system operator) on the corresponding reserve markets. Table 2 is an overview of the four reserve markets [19]. As a service provider, the property owner could get compensation for the reserved capacity and/or the actual delivered regulation volume.

### 3.2. Simulation model

A python-based model is developed to simulate the operation of the hybrid heating system in buildings. The model structure is illustrated in Figure 1. The input of the model includes parameters about the building, heating devices, climate, and the information from market and system. The model simulates both normal and flexible operation modes of the heating system. Both operation modes are formulated as optimization problem.

For the normal operation mode, the objective function is to minimize the indoor temperature deviation from the desired set point during the planning horizon. It subjects to the constraints for estimating the heat balance and indoor temperature at each time step, and the capacity limits of the heating devices. The solution of the optimization problem is the total heat demand at each time step. It is assumed that the heat pump is always prioritized in the normal operation mode. District heating is only used when the demand exceeds the heat pump capacity. Accordingly, the heat power provided by heat pump and district heating are estimated for each time step, respectively. Then the corresponding cost is calculated. For the flexible operation mode, the objective function is to minimize the energy cost during the planning horizon considering the potential revenue from providing frequency regulation services. It subjects to similar constraints as in the normal operation mode. Additional constraints are considered to fulfill the requirements of the specific reserve markets. The heat power...
provided by heat pump and district heating are estimated by solving the optimization problem. The corresponding cost and revenue are calculated accordingly.

3.3. Case study

The case study analyzes the economic benefits of a property owner in different situations. It is based on a residential building with 93 apartments and 7161m² heating areas. The thermal inertia of the building is estimated based on parameters specified in Error! Reference source not found. The building is installed with a ground source heat pump system and district heating. The COP of the heat pumps are affected by the outdoor temperature as shown in Table 3 and has a maximum heating capacity of approximately 350 kW (at +2°C), giving the building in the case study a bivalent temperature of -12°C. A validation of the model has been carried out by comparing the modelling results in the normal operation mode with a previous study [29]. The yearly energy consumption and cost estimated from the model are on the similar level as in the previous study.

Four locations are investigated for the building: Kiruna, Östersund, Stockholm and Malmö. The four cities represent different climate zones in Sweden from north to south. In addition, they belong to the four electricity price areas which are divided because of the transmission bottlenecks. For the building at each location, six operation modes are simulated for the heating system:

- ref: normal operation, prioritize HP, no frequency regulation service is provided.
- DR_None: flexible operation, cost minimization, no frequency regulation service is provided.
- DR_FCRN: flexible operation, cost minimization, provide FCR-N service.
- DR_FCRD: flexible operation, cost minimization, provide FCR-D service.
- DR_aFRR: flexible operation, cost minimization, provide aFRR service.
- DR_mFRR: flexible operation, cost minimization, provide mFRR service.
For each operation mode, 16 scenarios are analyzed to represent the possible price for energy and frequency regulation services in the future. The spot price scenarios are based on the long-term market analysis by Svenska Kraftnät [20]. The scenarios are defined for the Nordic power system in 2035 and 2045, considering the growing electricity demand, higher penetration of renewable energy, coupling with hydrogen production and grid expansion. The grid tariff and district heating tariff in 2035 and 2045 are estimated according to the base tariffs in 2021 [22][23] and the historical price development trend [24][25]. The price on different reserve markets and system frequency are based on the historical data in 2018-2021, which are extracted from ENTSO Transparency Platform [26] and FinGrid Open Data [27].

Figure 2 shows the simulation results of the yearly heating cost of the building. Each box indicates the cost distribution among the 16 scenarios. In general, the cost increases from Malmö in the south of Sweden to Kiruna in the north. It is mainly due to the climate conditions i.e. more heating energy is needed in colder regions. For each location, the costs in the five DR cases are apparently lower than the cost in the reference case. It implies that the flexible operations with cost minimization can effectively reduce the overall cost for heating. The cost reduction is achieved by utilizing the thermal inertial of the building and actively selecting the heating source with a favorable price. Figure 3 shows the annual bought energy for the heating system in an example case, in which the building is assumed to be in Stockholm and the spot price scenario for 2035 is adopted. It indicates that the heating system consumes more district heating energy and less electricity in DR modes compared with the reference operation mode. Further analysis shows that the increased heat extraction from the thermal grid mainly happens in summer when the heating price is low.

The cost could be further reduced when the heat pumps provide frequency regulation services. However, the economic potential may vary among locations and scenarios. In most scenarios, the lowest cost can be found when the heat pumps provide FCR-N or aFRR service. Taking the building in Östersund as an example, the lowest cost is found when the heat pumps provide FCR-N service. The reason is that the property owner gets both capacity and energy compensation from TSO when participating in FCR-N and aFRR markets.
In the interview study with district heating companies, it was found that it is an asset to have heat pumps in the district heating grid for flexibility. They also are perceived as easy to regulate and have shorter start and stop time than many other production units. The largest barrier to an increased use of heat pumps in the thermal grids is the investment. The investment cost is high, and it is mostly hard to motivate new installations and it compete with investments in combustion units that could cover all temperatures and heat need and may also produce electricity. Only in one of the interviews they had found it more profitable with a heat pump, but then their other production was based on gas, which have rising prices. To plan and produce heat to the lowest cost and to use inertia in grid and accumulator tank to cut peak loads is an everyday activity in district heating companies and how things have been done for long time. Heat pumps could be used more in the thermal grid if some barriers could be removed as for example, monthly calendar basis for power fee. There is also a potential for more flexibility with motivated and available resources in personnel, so the fast variation in electricity price could be met. Traditional planning goes out from the nearest 24 hours and the coming week.

The case study of decentralized heat pumps shows that large economic potentials could be expected for the property owners when utilizing the flexibility of heat pumps. However, the potentials vary among scenarios, and it is based on the assumption of perfect market forecasts. Further studies are needed to investigate how the uncertainties in the market price and required regulation directions would affect the benefits for the property owners. Economic potential of delivering ancillary services to the TSO is a focus of the analysis. But in practice, before this is up and running there are still technical issues to solve on how to communicate with the heat pumps and how the heat pumps should react on signals to deliver the demand response to the grid. One barrier to solve is to make sure that the heat pumps can react and adjust the power consumption fast enough on signals for demand response, although the ramping rate of heat pump is not considered in the model. Among the frequency regulation services analyzed in this study, FCR-D up is the fastest reserve with an activation time of 50% within 5s and 100% within 30s. Discussions with the Swedish heat pump manufacturers indicate that it should be possible from a technical point of view to fulfill the demands for FCR-D, but updates of today’s heat pumps might be needed. Another issue to solve is how to fulfill the requirements on the verification of delivered flexibility since today’s heat pumps have no electric meters installed.

The interview study shows that energy companies consider customers with the hybrid heating solution, i.e. heat pumps combined with district heating, as lost customers or free riders. The customers are blamed for only using district heating during peak load period and causing more combustion with expensive fossil fuels. Some district heating companies choose to use a special pricing scheme to overcome it. On the other hand, the case study of decentralized heat pump shows that the property owners may consume more district heating energy annually in DR modes compared with the reference level. If more customers in the thermal grid adopt the hybrid heating solution and apply similar flexible operation modes, the heat demand could be significantly changed from today and consequently affect the planning and operation of district heating production. However, this does not necessarily lead to an increase of peak load in the thermal grid. The analysis shows that in DR modes district heating would be mainly used during summer when the heat demand is conventionally low.

4. Discussion

![Annual bought energy (district heating and electricity to the heat pump system) for the example heating system: Stockholm, spot price scenario 2035](image)
Therefore, more studies are needed to further clarify the effects of decentralized heat pumps on the thermal grid, especially when demand response is taken into account. Better data exchange between energy companies and end customers would be needed to enable energy companies to have a better overview of the grid. More active actions should be taken by the energy companies by e.g. improving the forecast of heat demand and flexibility potential of customers, and enhancing the efficient planning and operation of the heat plants with different energy mix. A holistic strategy is needed to coordinate the flexibility from both centralized and decentralized heat pumps and utilize them in a more efficient manner.

5. Conclusions

This article discusses the potential and constraints of using the flexibility of heat pumps in Swedish thermal grids from the perspective of energy company and end users, respectively. An interview study with district heating companies has been carried out to identify the possibilities and barriers to use heat pumps for flexibility services. The study shows that the companies with heat pumps in their grids today think it is an advantage to use them for flexibility when electricity prices variates. But to invest in a new heat pump to get additional flexibility is described as hard to motivate and to get profitable. Technically it is possible to start or stop heat pumps almost immediately, but in practice the minimum running time for the heat pump is from at least 3-4 hours or 12 hours in most grids. Other identified barriers for additional use of existing heat pumps are: 1) other heat production must be up and running, e.g. waste combustion; 2) a high monthly electrical power fee makes it unprofitable to start a heat pump if it is not going to be used at least for about 7 days in the calendar month; 3) lack of capacity on the cold side of the heat pump, caused by for example low temperatures in sea water, low volumes of wastewater or lack of waste heat; 4) need of both available and motivated personnel to start or stop a heat pump.

In addition, a quantitative analysis has been performed to investigate the economic benefits for end users by utilizing the flexibility of heat pumps combined with district heating. It is based on the simulations for buildings located in different electricity price areas and climate zones in Sweden, and considers the future price scenarios for electricity, grid tariff, district heating and system services. The analysis shows that the energy cost for end users could be effectively reduced by using flexibility of the hybrid heating system, whereas the cost saving potential may vary among locations, price scenarios and the type of system services provided by the heat pump. More studies are needed in the future to further clarify how demand response of customers may affect the operation of the district heating production, and how the flexibility from centralized and decentralized heat pumps can be coordinated and utilized in a more efficient manner.

Abstract

Air conditioning systems using liquid desiccant have been gaining attention due to their great energy-saving potential, but cooling and heating load for dehumidification and regeneration process remained a vital role in energy consumption. In this research, we proposed a membrane-based liquid desiccant air conditioning system, which is a vapor transportation driven system with gas separation membrane technology, and evaluated its thermodynamic performance by equation-based simulation. The proposed system has five components: an absorber, a regenerator, a membrane for dehydration, a membrane for hydration, and a vacuum compressor. The membranes were used to control solution concentration without heating and cooling; the water vapor separated by the membrane is transported from the dehydration solution to the hydration solution. The vacuum compressor operated to separate the water vapor from the solution and then transport the separated vapor to the membranes. The results showed that the ideal COP (coefficient of performance) of the proposed system in the thermodynamic analysis is 1.55, which is 5.17 higher than that of the conventional liquid desiccant (heat driven dehumidification and regeneration system), which is 0.3 COP at the design air.

1. Introduction

The importance of humidity control in air-conditioning systems has increased as the ratio of sensible load to total air-conditioning load of a building has decreased dramatically due to improved building envelope thermal performance [1]. Decoupling the sensible and latent cooling functions of air conditioning has been suggested as a possible alternative to the typical condensation dehumidification technique. Several unique energy-efficient systems that can individually accommodate sensible and latent loads have been disclosed in the open literature [2].

One of these systems is the liquid-desiccant-assisted air-conditioning system [3, 4], in which the process air is dehumidified by a liquid-desiccant solution and then sensible cooling to the supply air’s setpoint temperature. To improve the dehumidification performance, the concentrated desiccant solution should be cooled, and the diluted desiccant solution should be regenerated in the regenerator by heating. The heating and cooling of the desiccant solution are the most energy-intensive processes [5].

Numerous research have investigated the performance of various types of liquid desiccant systems to enhance the dehumidification performance. In the previous studies, air to liquid flow direction (i.e., cross flow, counter flow), has been investigated. Recently, internally-cooling [6] and heating [7] system was introduced to increase the system performance. Nevertheless, heating and cooling of the desiccant solution, which has high regeneration temperatures between 50 and 80 °C results in considerable energy consumption if free heat sources are unavailable [8, 9].

In previous research, heat (heating and cooling) based liquid desiccant air conditioning system have been mainly conducted for evaluating energy performance; however, it is rare to evaluate the thermodynamic and energy performance using vacuum pressure driven liquid desiccant system. In this study, we proposed a novel system that uses dehydration and hydration in the liquid desiccant with separation membrane. The sensitivity of the operating conditions to the dehumidification performance of the proposed system was analyzed by numerical simulation. The energy performance of the proposed system was also evaluated by comparing the existing liquid dehumidification system (heating and cooling-based system) with design conditions.

2. System overview

2.1. System overview

Figure 1 depicts the five components of the proposed system: an absorber, a regenerator, a membrane for dehydration, a membrane for hydration, and a vacuum compressor. The membranes were utilized to regulate solution concentration without the use of heating and cooling; the water vapor separated by the membrane is delivered from the dehydration solution to the hydration solution. The vacuum compressor was used to separate the water vapor from the solution and transfer it to the membranes.

The diluted liquid desiccant solution leaving the absorber is preheated by the sensible heat exchanger and then hydrated by the hydration membrane, which make increase of the partial vapor pressure as decreasing solution concentration. The desiccant solution is regenerated in the regenerator, and the strong solution is precooled by the heat exchanger (HX). Finally, the supply air is dehumidified by the strong solution that is made by the dehydration membrane.

![Fig. 1. Proposed system: Hydration/dehydration integrated liquid desiccant air conditioning system](image)

Figure 2 showed the detailed configuration of the dehydration and hydration membrane (DHM) system used in the proposed system as a device for concentration control of the solution. The DHM consists of a dehydration membrane, a hydration membrane and a vacuum compressor. The dehydration and hydration membrane is separation membrane, which permeate the water vapor from solution because of the partial vapor difference between the feed-side (solution) and the permeate-side (vacuum) channels. When the week solution is introduced into the dehydration membrane, the water vapor in the dehydration membrane permeate to the vacuum compressor inlet. Then, the water vapor compressed by vacuum compressor permeate into strong solution in the hydration membrane.
2.2. Reference system

As a reference system, a typical liquid desiccant-based air conditioning system consisting of an absorber, a regenerator, a cooling coil, a heating coil, and a liquid-to-liquid type sensible heat exchanger was chosen (Figure 3). In case of the reference system, the partial water vapor pressure of the diluted solution leaving the absorber and regenerated solution leaving the regenerator were controlled by varying the solution temperature. In an absorber, before hot, humid air and desiccant solution coincidently cross the packing media, the desiccant solution is cooled by the cooling coil until the water vapor pressure of the desiccant solution is lower than that of the target supply air. The diluted desiccant solution leaving the absorber is then heated by the heating coil so that the water vapor pressure of desiccant solution is higher than the air introduced to the regenerator. The sensible heat exchanger precools and preheats the regenerated and diluted solutions, which leads to reduction in solution heating and cooling loads.
3. Simulation model

3.1. Numerical model of separation membrane: Dehydration and hydration

The process of dehydration and hydration in the membranes transfers the water vapor by the partial vapor pressure gradient between the feed and permeate sides as shown in Figure X. To estimate the mass transfer of the dehydration and hydration, the gas separation model with infinity selectivity for Water vapor was used as shown in Equation 1. The governing equation of the mass transfer driven by partial vapor gradient between membrane layers for each node. The change of the solution concentration along the membrane was estimated by mass balance equation (Equation 2), which address that the concentration change is driven by ratio of the permeated water vapor to the solution mass flow rate. As shown in Equation 3, the solution temperature change in the dehydration membrane is calculated by the evaporative cooling from desorption process of the membrane, whereas the solution temperature change in the hydration membrane is calculated by the condensation heating and air compressed heat from the vacuum compressor. To evaluate the partial vapor pressure of the solution, the desiccant solution model (Equation 4), which is driven by solution temperature and concentration was used.

\[
\Delta M_{\text{dehy}} = \text{Permeance}(p_{\text{v,sol}}^i - p_{\text{vac}})M_{\text{mass}}\Delta A
\]

\[
p_{\text{v,sol}}^i = f(T_s^i, X_s^i)
\]

\[
X_{s,i}^{i+1} = X_{s,i}^i/(1 + (\Delta X_{s,i})) \times (\Delta M_{\text{dehy}}/\dot{m}_{\text{sol}})
\]

\[
T_{s,i}^{i+1} = T_{s,i}^i - (h_{fg} \Delta M_{\text{dehy}})/(c_{p,sol}\dot{m}_{\text{sol}})
\]

3.2. Liquid desiccant

The temperature and concentration of the liquid desiccant at each point (i.e., inlet and outlet conditions at the absorber and regenerator) were calculated by using the empirical models predicting the dehumidification/regeneration effectivenesses the absorber and regenerator.

The first model for the dehumidification effectiveness of the absorber \(\varepsilon_{\text{abs,lm}}\) was derived by Chung and Luo \[10\]. As shown in Equation 5, this model was derived for the packed-bed type liquid desiccant dehumidifier using the seven variables – the inlet temperature of air \(T_{\text{abs,la}}\), inlet partial water vapor pressure of air \(p_{\text{v,abs,la}}\), inlet temperature of desiccant solution \(T_{\text{abs,ls}}\), inlet partial water vapor pressure of solution \(p_{\text{v,abs,ls}}\), outlet temperature of air \(T_{\text{abs,la}}\), outlet partial water vapor pressure of air \(p_{\text{v,abs,la}}\), and outlet temperature of desiccant solution \(T_{\text{abs,ls}}\).
The solution temperature and concentration have the greatest effect. As the temperature of the solution increases and the concentration of the solution changes, the partial pressure of water vapor decreases from 5.12 kPa to 0.41 kPa. The effect of solution of hydration was lower than that of the steam solution rises from 0.84 kPa to 3.89 kPa, and as the concentration changes, the partial pressure of water vapor in the steam solution rises from 0.84 kPa to 3.89 kPa, and as the concentration changes, the partial pressure of water vapor decreases from 5.12 kPa to 0.41 kPa. The effect of solution of hydration was lower than that of

\[(\gamma) = \frac{1}{0.185 \left( \frac{T_{abs,a}}{P_{abs,a}} \right)^{0.638}} \]  

\[\frac{1 - 0.192 \exp(0.615 \frac{T_{abs,a}}{P_{abs,a}} - 21.498)}{1 - 0.024 \left( \frac{m_{sol}}{m_{abs,a}} \right)^{0.6} \exp(1.057 \frac{T_{abs,a}}{P_{abs,a}})} = \frac{\omega_{abs,a} - \omega_{abs,s}}{\omega_{abs,a} - \omega_{abs,eq,s}} \]  

(5)

\[\varepsilon_{abs,T} = \frac{T_{abs,a} - T_{abs,s}}{T_{abs,a} - T_{abs,s}} \]  

(6)

As for the empirical model of the regenerator, the model established by the Martin and Goswami [12] was used in this study (Equation 7). As shown in Equation 8, the regeneration effectiveness \((\varepsilon_{reg,m})\) is predicted by using five parameters – enthalpy of inlet air \((h_{reg,i,a})\), enthalpy of inlet desiccant solution, mass flow rate of air \((m_{reg,i,a})\), and mass flow rate of solution \((m_{reg,i,s})\), and packing specific surface area \((aZ)\). Identical to the absorber, the thermal effectiveness of regenerator was assumed to be similar to the regeneration effectiveness.

\[\varepsilon_{reg,m} = 1 - 48.3 \left( \frac{m_{reg,a}}{m_{reg,s}} \right)^{0.396 (y_L/y_c)^{-1.57}} \left( \frac{h_{reg,i,a}}{h_{reg,i,s}} \right)^{-0.751} \left( aZ \right)^{0.0331 (y_L/y_c)^{-0.906}} = \frac{\omega_{reg,a} - \omega_{reg,s}}{\omega_{reg,i,a} - \omega_{reg,i,s}} \]  

(7)

\[\varepsilon_{reg,T} = \frac{T_{reg,a} - T_{reg,i,a}}{T_{reg,eq,a} - T_{reg,i,a}} \]  

(8)

The equilibrium humidity ratio of desiccant solution, which determines the ideal maximum humidity ratio variance between the process air and the desiccant solution, was obtained by Equation (9).

\[\omega_{eq,s} = 0.622 \cdot \frac{P_{v,s}}{101.325 - P_{v,s}} \]  

(9)

4. Results

4.1. Parametric analysis of the separation membrane: mass transfer of the water vapor

In order to estimate the dehumidification performance of dehydration and hydration of the membrane, the effect of mass transfer was evaluated by varying the desiccant solution conditions. Parametric analysis was performed by solution temperature, solution concentration, and liquid to gas ratio in the dehydration and the hydration side. The base case of the solution in the dehydration and the hydration side set to 20 °C, 20%, and 0.01 of liquid to gas ratio. The compression ratio of the vacuum compressor was set to 10. Range of each parameter was set 10 °C to 40 °C (temperature), 10% to 40% (concentration), and 0.0025 to 0.16 (liquid to gas ratio).

In the Figure 5 (a) to (c), as the dehydration solution changes, the solution temperature and concentration have the greatest effect. As the temperature of the solution increases and the concentration of the solution decreases, the partial pressure of water vapor in the solution increases. As the temperature changes, the partial pressure of water vapor in the steam solution rises from 0.84 kPa to 5.12 kPa, and as the concentration changes, the partial pressure of water vapor decreases from 2.08 kPa to 0.41 kPa. Therefore, it can be confirmed that the mass transfer increases as the driving force between the membranes increases.

In the Figure 5 (d) to (f), the solution temperature and concentration have the greatest effect as solution changes in the hydration membrane. When the water vapor partial pressure of the solution increases, the water vapor partial pressure difference (driving force) between the membranes decreases, and thus the overall mass transfer of the proposed system decreases. As the temperature changes, the partial pressure of water vapor in the steam solution rises from 0.84 kPa to 3.89 kPa, and as the concentration changes, the partial pressure of water vapor decreases from 5.12 kPa to 0.41 kPa. The effect of solution of hydration was lower than that of
solution of dehydration, which shows that the effect of water permeation in hydration is greater than the effect of water permeation of dehydration.

4.2. Performance evaluation: COP

For the performance evaluation of the proposed system, the thermodynamic changes of the existing system, heat demand and solution were confirmed. (Figure 6) The design air condition of the absorber and regeneration was set to 32 °C and 60%, and LG was assumed to be 1. The solutions of the reference system were 25 °C and 35% (Absorber) and 58 °C and 34.5% (Regeneration) respectively, and the proposed system reference system solutions were 25 °C and 35% (Absorber) and 63 °C and 33.5% (Regeneration) respectively.

As shown in Equation 10, in the reference system, the enthalpy change of the absorber was 27.96 kJ/kg (120.2 kJ/kg to 92.24 kJ/kg), and the enthalpy change of heating and cooling was 54.7 kJ/kg and 36.66 kJ/kg, respectively. The COP of the reference system is 0.3.

On the other hand, in the proposed system, the absorber's enthalpy change was 27.96 kJ/kg (120.2 kJ/kg to 92.24 kJ/kg) as in the reference system. As shown in Equation 11. The power of the vacuum pump can be expressed as the enthalpy change of hydration and the enthalpy change of dehydration, and was 54.7 kJ/kg (hydration) and 36.66 kJ/kg, respectively. Therefore, the power of the vacuum pump at unit mass flow rate (1 kg/s) is 18.04 kW/(kg/s). The COP of the proposed system is 1.55. The results showed that the ideal COP (coefficient of performance) of the proposed system in the thermodynamic analysis is 5.17 higher than that of the conventional system.

\[
COP_{Ref} = \frac{Q_{a,c}}{Q_{h,s} + Q_{c,s}} \quad (10)
\]

\[
COP_{Ref} = \frac{Q_{a,c}}{P_{vac}} = \frac{Q_{a,c}}{Q_{Hyd} - Q_{dehyd}} \quad (11)
\]
5. Conclusion

In this research, a membrane-based liquid desiccant air conditioning system, which is a vapor transportation driven system with gas separation membrane technology, was proposed and its thermodynamic performance (dehumidification and energy performance) evaluated by equation-based simulation.

The parametric study of the proposed system for dehumidification performance (mass transfer) showed that the solution temperature and concentration is mainly affected as driving force. Especially, the mass transfer of the dehydration membrane side is more affected than that of the hydration membrane side on dehumidification performance. The vacuum compressor operated to separate the water vapor from the solution and then transport the separated vapor to the membranes. The results showed that the ideal COP (coefficient of performance) of the proposed system in the thermodynamic analysis is 1.55, which is 5.17 higher than that of the conventional liquid desiccant (heat driven dehumidification and regeneration system), which is 0.3 COP at the design air condition. This study demonstrates the thermodynamic analysis of the proposed system in simple principles. In further studies, we will construct a prototype unit of proposed system, and experimentally analyze the effect of thermodynamic and energy performance of the proposed system.

Abstract

In a previous work we recorded a significant contribution to urban air pollution attributable to heating systems powered by fuel. Thus, we propose the replacement of existing boilers for heating and domestic hot water (DHW) production systems with high temperature air-to-water heat pumps as an intervention to improve urban air quality and energy use. We analyze replacement scenarios within the entire residential building stock of two Italian cities, Milan and Salerno, belonging to different climate zones and with their own thermophysical characteristics. For each of them, the consequences of the replacement intervention in terms of primary energy savings and lower CO₂ production are evaluated. The results show a reduction of primary energy consumption by 34% in Milan and 43% in Salerno, and of CO₂ production by 30% in Milan and 39% in Salerno.

Keywords: Urban air quality; Heat pumps; Primary energy; CO₂ emissions.

1. Introduction

In a previous work [1], a significant contribution to urban air pollution, related to fuel-fired heating systems, was recorded. Based on an analysis of the heating and domestic hot water (DHW) requirements of the residential building stock of two different Italian cities and the installed thermal systems, we propose to replace these systems with high temperature air-to-water heat pump systems of a suitable size that can supply the existing radiator systems.

The proposed measure is studied for two different Italian cities, Milan and Salerno, characterised by different outdoor air temperatures and with different thermophysical characteristics of the building stock.

In particular, replacement scenarios are analysed in the case of an outdoor temperature equal to the design temperature and for heat pump power generation equal to the current mix.

The evaluation of the intervention, while considering some approximations and working hypotheses, confirms to varying degrees for both cities a substantial reduction in both primary energy and CO₂ production needs, thanks to the highest generation efficiencies obtainable in the large thermoelectric power plants and the abatement systems present there.

Finally, it can be minimally invasive for citizens (since the existing radiator systems are not modified) to reduce air pollution in the long term, since it implies a significant decrease of emissions of pollutants in urban areas, with reduced energy (and, therefore, environmental) costs, towards environmentally sustainable cities.

2. Materials and methods

2.1. Climatic characterization

Two Italian cities were considered, belonging to two different climate zones according to national legislation. Milan, in Lombardy, located in the north-west of the Italian peninsula and characterised by an external design temperature \([\text{EDT}]\) of \(-5\,^\circ\text{C}\), and Salerno, a city in central-southern Italy facing the Tyrrhenian Sea and having an external design temperature of \(2\,^\circ\text{C}\).

2.2. Characterization of building stocks

According to ISTAT \([3]\), Milan is outlined as a city made up of approximately 70% of buildings constructed between 1919 and 1970. Only 5% of the buildings were built after 1990. Most (66%) are four and more storeys above ground, while only 7% are one storey. This is confirmed by the fact that more than half of them (55%) have more than eight interiors.

Although less evident also in Salerno, the majority (55%) of residential buildings were built between 1919 and 1970. Only 7.5% of the buildings were built after 1990. Most (46%) are 2 or 3 storeys above ground with 37% consisting of 1 or 2 interiors.

In order to characterise the building stock of the city of Milan from an energy point of view, the CENED +1.2 database \([4]\) of the Lombardy Region was taken into consideration, which contains information useful for drawing up energy certificates.

From the database it was possible to obtain the average values of the thermal transmittances of the dwellings in the Municipality of Milan for each period of construction. Figure 1 shows the trend of the thermal transmittances of the windows and vertical opaque envelope, the basement and the roof.

![Fig. 1. Trend of the average thermal transmittances of the walls, floors, roofs and windows of the average flat in Milan by age of construction](image)

It can be seen that up to 1976 the average thermal transmittance of all components remained fairly constant and then decreased, probably due to the approval of Law 373 of 1976 on energy efficiency and Law 10 of 1991.

The energy analysis for private buildings carried out in the Municipal Energy Plan of the Municipality of Salerno \([5]\) shows the trend of average thermal transmittances of opaque components and windows shown in Figure 2.
It can be seen that up to the 1970s, the average thermal transmittance of all components remained fairly constant, but then decreased, again due to the passing of Law 373 of 1976 on energy efficiency and Law 10 of 1991. In the case of roofs, on the other hand, an anomalous increase was noted for the data available in [5].

2.3. Thermal energy needs associated with building stocks

In order to evaluate the average thermal requirements for heating associated with the flats in the Municipality of Milan, from the entire CENED +1.2 database the certificates of dwellings with destination of use E.1(1) [D.P.R. 412/93] were taken into consideration, dwellings used as residences with a continuous character, relative to a single sub-terrain, so as to exclude those referring to entire blocks of flats.

For simplicity’s sake, it was decided to consider only the inter-floor building units, identifiable in the database as those without a numerical transmittance value of the basement and roof, indicating the absence of these dispersing elements.

From the values of the transmittances and the dispersing surfaces, the heat requirement for heating was thus calculated, assumed as a first approximation to be equal to the heat dispersion by transmission through the vertical opaque envelope and windows.

The simplified calculation of the heating heat requirement was carried out in line with what was adopted by UNI TS 11300-1-2:2014 [6], by summing the monthly heating needs, relative to the period of the winter season, for twenty-four hours per day.

An internal temperature $t_i$ of 20°C was assumed and an external temperature equal to the monthly average value of the daily average external temperature, obtained from UNI 10349:1994 [7].

The calculation was applied to all the certificates present in the Cened +1.2 database, from which the average characteristic values of relative to each period of construction shown in the Table 1 were then obtained.

The thermal energy requirements for domestic hot water $Q_w$ were obtained according to UNI TS 11300-1-2:2014 [6], considering a 24-hour daily use period extended to the entire year (1).

$$Q_w = \rho_w \times c_w \times V_w \times (\theta_{er} - \theta_0) \times G$$

Where:
\( \rho_w \) is the density of the water, which is approximately 1000 \([\text{kg/m}^3]\);  
\( c_w \) is the specific heat of water equal to 1,162 \([\text{Wh/kg K}]\);  
\( V_w \) is the volume of water required during the calculation period \([\text{m}^3]\);  
\( \theta_{er} \) is the hot water supply temperature \([\circ C]\);  
\( \theta_0 \) is the cold water inlet temperature \([\circ C]\);  
\( G \) the number of days in the calculation period considered \([\text{d}]\).

The domestic hot water supply temperature \( \theta_{er} \) is assumed to be 40\(^\circ\)C and the cold water inlet temperature \( \theta_0 \) is assumed to be equal to the annual average of the monthly average outside air temperatures taken from UNI 10349. The required volumes of water \( V_w \) are obtained according to table 30, reported in [6] as a function of the useful surface area of the dwelling, which is present as data in the Cened +1.2 certificates.

The formula was applied to all the certificates present in the Cened +1.2 database, from which the average characteristic values for each period of construction were then derived. The results are shown in the Table 1.

In order to represent and compare the data of the two different cities, coming from two different databases with different periodization, it was decided to use the subdivision of construction periods adopted by ISTAT. The average values of thermal needs related to the time periods of the ISTAT database were obtained by taking into account the degrees of temporal overlapping between the two periodization systems and using them as weights for the computation of the weighted average.

The results show higher thermal needs associated with the average intermediate flats after the 1960s, probably associated with higher average transmittance by windows and walls together with higher dispersing surfaces.

In order to evaluate the average heating requirements associated with the flats in the Municipality of Salerno, the dispersing surfaces were first obtained.

In particular, reference was made to Annexes A and B of the Salerno Municipal Energy Plan, where the recurring architectural types in the building stock are represented.

These are shown in succession, according to the number of floors above ground and the number of interiors present. From the diagrams shown it was possible to deduce the net floor area and the lateral area of the buildings.

From Annex D, on the other hand, the values of the net heights, the surfaces of the walls and the windows, and the surfaces dispersing towards the stairwell were obtained. The latter ones were subtracted from the lateral surfaces to obtain the side opaque surfaces.

From each building typology reported, characterised by a certain number of floors and interiors, the individual flats of which each building typology is composed were approximated, focusing attention, as in Milan, on the inter-floor building units. Their characteristic dimensions correspond to a weighted average of the various inter-floor flat sizes available in the building stock.

Once the heating requirements for each of them had been calculated, a weighted average was made on the basis of ISTAT data on the number of buildings by number of interiors and above ground floors, in order to obtain a representative average value for each period of construction. Table 2 shows the results obtained in summary.
Similarly for Milan, thermal energy requirements for domestic hot water were then calculated according to UNI TS 11300-1-2:2014 [6] and reported in Table 2.

For Salerno, the division of construction epochs adopted by ISTAT was also used.

From the data obtained, a progressive decrease in thermal requirements could be observed as the years progressed.

2.4. Heating systems fleet

According to the ISTAT census of 2011 on the type of fuel or energy source that fuels the heating system of homes in the Municipality of Milan [8], methane gas is the most widely used source (81.92%), followed by diesel (12.12%) and electricity (3.10%).

The percentage of homes using solid fuel such as wood or coal (0.47%), LPG (0.57%), fuel oil (0.15%) or other types of fuel or energy is lower.

According to the “Catasto Unico Regionale degli Impianti Termici”, the regional register of the thermal plants, (CURIT) [9], the number of heating systems in the Municipality of Milan is composed of approximately 153,000 autonomous systems with a capacity of less than 35 kW and 27,000 centralised systems with a capacity of more than 35 kW and typically serving more than one property unit.

According to the 2011 ISTAT census on the type of fuel or energy source that fuels the heating system of homes in the Province of Salerno [8], the most used source (53.88%) is methane, followed by solid fuel such as wood or coal (24.92%) and LPG (10.29%).

The percentage of dwellings using electricity (6.64%), diesel (2.14%), fuel oil (0.07%) or other types of fuel or energy is lower.

The census on the number of dwellings equipped with a heating system [10] shows that there are approximately 38,000 autonomous and 3,000 centralised heating systems in the municipality of Salerno.

With regard to the combustion efficiency for winter air conditioning of the systems present in the Municipality of Milan, CURIT deduces an average value of 0.9.

In order to calculate the average global efficiency, the tables contained in UNI TS 11300-2 of 2014 [6] are used to estimate the distribution, regulation and emission efficiency values, assumed to be 0.98, 0.95 and 0.94 respectively. The average global efficiency value obtained from the product of the four efficiencies is 0.8.

From the 2014 UNI TS 11300-2 prospectuses [6], the average global efficiency of the generator for the production of domestic hot water is also estimated at 0.7, obtained from the product of the efficiencies of generation equal to 0.8, supply equal to 1, and distribution equal to 0.9.

Since we do not have data on the efficiency of the thermal plants in the Municipality of Salerno, we assume the same efficiency value for winter air conditioning equal to 0.8 and for the production of domestic hot water equal to 0.7. As in the case of the Municipality of Milan, Salerno's thermal plants are mainly made up of autonomous plants (over 90%) that use methane gas as their main fuel.
2.5. Heat pumps identified in the proposal

Considering the scenario of replacing the entire thermal systems of the two cities with high-temperature air-water heat pumps, the nominal capacities are evaluated.

Considering a configuration based on the logic of prioritizing DHW production overheating, and since the two thermal needs are never satisfied simultaneously, the sizing is carried out on the basis of the thermal load for winter heating.

In particular, for both cities, from the values of the transmittances and the dispersing surfaces, the winter heat load NP at the external design temperature was calculated, assumed as a first approximation equal to the heat dispersion by transmission through the vertical opaque envelope and the windows, as follows:

\[ NP = (H_o \times S_o + H_w \times S_w) \times (t_i - t_p) \]  \hspace{1cm} (2)

Where \( H_o \) and \( S_o \) are respectively the transmittance and the dispersing surface of opaque walls, \( H_w \) and \( S_w \) the transmittance and the dispersing surface of windows, \( t_i \) the desired internal temperature equal to 20°C, \( t_p \) the design external temperature, equal to -5°C for Milan and +2 for Salerno. Tables 3 and 4 show the nominal powers NP of the heat pumps (HPs) at the design external temperature by year of construction.

In particular, air-water heat pumps are considered to be those that can work with radiators, the most common terminals in the existing building stock, and are therefore capable of producing flow water at a temperature of 70°C or higher.

The compressor of the HPs selected is a scroll type with inverter capacity control and economizers to increase the efficiency of the system. The refrigerant they use is R32, which offers a low global warming potential (GWP) compared to standard refrigerants and ensures higher energy efficiency and lower CO\(_2\) emissions.

The size of the machine was chosen in line with the commercial state of the art from a manufacturer's catalogue considering an outside temperature not higher than the design outside temperature and closer to this.

In order to ensure operation at high temperature, an oversizing choice is made with respect to the required heat output. The analysis carried out was related to full load performance at design conditions. The real working conditions imply different values of outdoor temperature during the heating season, with favorable consequences for HP performance, as a result of a direct thermodynamic effect and reduced heat losses from machines (with inverter) operating under partial load conditions. The present study concerned, thus, the worst-case scenario.

The plate power (PP) values of the selected heat pumps, obtained from the manufacturers’ catalogues as the heating capacity at the design outdoor temperature and outlet water temperature of 70°C, are shown in Tables 3 and 4 for each requirement.

The COP of the selected HP is provided by the manufacturer as the ratio between the heating capacity and the electrical power input; the heating capacity is defined as the integrated power between the power for heating and the power used between the start of one defrosting cycle and the start of the next, also provided by the manufacturer for a value of outside air temperature and a value of water supply temperature.

To derive the COP at design conditions, if not present in the values declared by the manufacturer (as in the case of Milan with an external design temperature of -5), proceed according to UNI EN 14825 [11].

Specifically, with the same outlet water flow temperature, if the design outdoor air temperature is within the range of values provided by the manufacturer, the COP is calculated by linear interpolation of the second principle efficiency values \( \eta_{II} \), calculated on the basis of the known data. If the outdoor air temperature is outside the range of values provided by the manufacturer, but within a maximum deviation of 5 K, the efficiencies \( \eta_{II} \) calculated on the basis of the nearest possible known data can be extrapolated (i.e. \( \eta_{II} \) is considered to remain constant up to a temperature difference of 5 K). The second-principle efficiency \( \eta_{II} \) is defined for electric heat pumps as the ratio of equation (3) between the actual efficiency of the heat pump declared by the manufacturer (COP) and the theoretically achievable maximum efficiency (theoretical maximum COP\(_{\text{max}}\)).

\[ \eta_{II} = \frac{\text{COP}}{\text{COP}_{\text{max}}} = \text{COP} \times \frac{t_h - t_c}{t_h + 273.15} \]  \hspace{1cm} (3)
where \( t_h \) is the outlet water temperature (at the condenser) and \( t_c \) is the cold source temperature (at the evaporator). The COP value at conditions \( x \) is therefore obtained by the efficiency \( \eta_{II} \) interpolated to conditions \( x \) as in equation (4).

\[
COP_x = \frac{\eta_{II,x} t_h + 273.15}{t_h - t_c, x}
\]  

(4)

Since the COP values for the desired value of the design external temperature of Milan (\( -5 \, ^\circ C \)) were not available from the manufacturer, we proceeded by analogy with the interpolation of the second principle efficiencies of the known data. Table 3 for Milan and 4 for Salerno show, for each selected HP and by year of construction of the buildings, the calculated COP values referring to the desired delivery water temperature (70°C), as it is reiterated that the current radiators are to be left as terminals, and to the external temperature of \( -5 \, ^\circ C \) (Milan) and \( +2 \, ^\circ C \) (Salerno).

Table 3. Nominal (NP) and plate powers (PP) and COP of the HP required for the design value of the external temperature of Milan (\(-5 \, ^\circ C\)), per year of construction CY (outlet water temperature 70°C); portion of the buildings stock %BS.

2.6. Impact of replacement interventions

In order to assess the overall impact, in terms of primary energy consumed, tonnes of CO\(_2\) produced and pollutants emitted, that replacing the boilers currently most used in homes in Milan and Salerno with HPs would entail, the 153.000 autonomous systems with a power output of less than 35 kW and the approximately 27.000 centralised systems are considered for the Municipality of Milan.

The latter, considering a condominium composed of an average of 12 flats, are considered equivalent to 324.000 autonomous systems. Therefore, 480.000 HPs are considered installed, with the characteristics described above, distributed in number as summarised in Table 7.

For the Municipality of Salerno, given the 38.000 autonomous systems and 3.000 centralised systems, considered as 36.000 autonomous systems, we have a total of 74.000 HPs installed, distributed as in Table 8.

In the following evaluations, the methane gas/primary energy conversion factor and the renewable electricity conversion ratio are considered unitary; the efficiency of the existing boilers is 0.8 for heating and 0.7 for DHW production, the distribution losses in the electricity grid are 10% \([12][13]\). Concerning electricity
generation, a 35% renewable fraction and a fuel fraction of 65% are considered, the latter mainly composed of natural gas (Terna source [12][13]). The fossil-to-electric conversion efficiency for 2021 is assumed equal to 48%. The COP considered is that relative to the external air temperature conditions of the project, -5 °C for Milan and +2 °C for Salerno.

The useful coefficient for the calculation of CO₂ emissions related to the consumption of methane used to fuel the boilers is found in the table of the UNFCCC national inventory of CO₂ emission coefficients [14] for which the result is 202.36 g CO₂/kWh thermal. The coefficient useful for the calculation of CO₂ emissions related to the production of electricity used to fuel the boilers is found in the ISPRA report on emissions in the electricity sector [14] for which the result is 449.1 g CO₂/kWh electricity for the current mix of fuels relative to the non-renewable fraction.

Tables 5 and 6 show, by building construction period, the thermal needs for heating and DHW production and the relative primary energy needs for the current boilers and for the selected HP for the current energy mix for the cities of Milan and Salerno.

### Table 5. Total heat requirement and primary energy requirement for boilers ($\eta_h=0.8$; $\eta_w=0.7$) and for selected HPs, per year of construction CY of buildings of the city of Milan (generation fraction from renewable energies 35%, grid losses 10%, COP at design temperature of -5°C)

As expected, the heat requirements, and corresponding the primary energy requirements were significantly higher for the older buildings in Salerno.

In Milan, on the other hand, the thermal needs, and consequently in the primary energy needs, were higher if associated with the average intermediate flats built after the 1960s, probably due to the higher average transmittance values of windows and walls, together with higher dispersing surfaces.

Primary energy requirements when using HPs are always lower than those of boilers, both for Milan and Salerno and for all years of construction.

The overall primary energy consumption from fossil fuels, in the case of the current boilers and the proposed replacement HPs, are shown in Tables 7 and 8. Results are presented in terms of percentage ratio, between heat pumps and boilers, of global primary energy from fossil fuel and CO₂ production.

One can see that the percentage ratios, representative of the reduction in consumption and CO\textsubscript{2} production, were irrespective of the year of construction; this was due to the fact that the same machine, with a certain COP under design conditions, was selected to ensure operation at high temperatures (70 \, ^\circ\text{C}) with radiators.

The replacement of the entire boiler fleet, considering the external design conditions, implies a reduction in primary energy consumption of 34\% for Milan and 43\% for Salerno and a reduction in emissions of 30\% for Milan and 39\% for Salerno.

The greater reductions obtained in the case of the city of Salerno are probably associated with the more favourable external design temperature conditions for the use of HP, which assume higher COP values in those conditions.

3. Conclusions

Starting from the results obtained in a previous work [1] on the analysis of pollutant concentrations and from the identification of the weight of heating systems as an emissive source, the replacement of boilers in current heating and domestic hot water production systems with high temperature air/water heat pumps was proposed as an intervention to improve urban air quality.

The study was mainly dedicated to assessing whether the proposed replacement of the approximately 480,000 autonomous methane gas boilers for the city of Milan and 74,000 for the city of Salerno, all with the same efficiency of 80\% for heating and 70\% for the production of DHW, of which, to a first approximation, the entire thermal systems of the municipalities of Milan and Salerno can be considered to be made up,
implying a significant reduction in polluting emissions in the urban area, would on the other hand entail additional energy (and therefore environmental) costs. Replacing the current boilers would eliminate individual local emission sources, concentrating emissions at a thermal power plant, located in suburban areas, characterised by the highest generation efficiencies, equipped with pollutant abatement systems (sulphur oxides, nitrogen oxides, particulate matter, CO₂), with a discharge into the atmosphere at significant heights compared to those in urban areas.

The study demonstrated the validity of the proposal in terms of reducing primary energy needs and CO₂ emissions for the two different cities considered, in particular for an external temperature at design conditions and for electricity generation mixes that in the future will be modified in favour of increasing shares of renewable sources. The proposal analysed is also in line with the electrification targets set in recent years, essential to achieve the energy transition and aimed at a sustainable development model.

The results obtained are a useful indication for overall incentive measures, given the low invasiveness of the interventions for individual citizens, and cannot be considered a feasibility study of the individual intervention.

It should be remembered that the assumptions made (average efficiency of boilers) and selections performed (the machines) were a first approximation and, therefore, cannot be used for the evaluation of the individual intervention, which will also have to take into account the real overall dimensions (with on average little space available for old buildings, for which the use of centralised heat pump systems could be considered).

It is worth noted that full load operating condition at design temperature are not the most frequent. The real working conditions characterise by different external temperature and partial load performance imply greater advantage in terms of COP.

A more in-depth analysis will be carried out in a future work, to evaluate the behavior of the systems in real operating conditions. Future works will also investigate more favorable/unfavorable climatic conditions related to different Italian and European cities.

High temperature test results and application cases of a Rotation Heat Pump

Andreas Längauer\textsuperscript{a}, Bernhard Adler\textsuperscript{a}
\textsuperscript{a}ecop Technologies GmbH, Perfektastraße 73/Top A1, 1230 Vienna, Austria

Abstract

The environmentally friendly working fluid, based on noble gases like Helium, Argon and Krypton, is used in the counterclockwise Joule-cycle in a Rotation Heat Pump (RHP). Combined with centrifugal compression this leads to a very high Coefficient of Performance (COP) at high sink outlet temperatures compared to conventional compression heat pumps. Since the realized Joule-Cycle is based on an always gaseous working fluid, the heat transfer in the heat exchangers is sensible. Therefore, neither the issue of lubrication of the compressor nor the critical point of the working fluid limit the maximum sink output temperature. The data shown provides information about the electricity consumption, the flow temperatures and the heat output provided by the system. The results show that the prototype of the RHP K7 can achieve a COP >3.5 for sink outlet temperatures higher than 100 °C. The correlations between the main rotor speed, temperature spread and thermal power are analyzed for the test run as well. Based on this, application cases in the industry and the field of energy services are presented and the advantages of the Rotation Heat Pump are described. Those are, for example, the high spread of sink and source when providing cooling and heating as well as the flexibility using one machine at different temperature levels. Further, an outlook for adaptions to realize sink outlet temperatures >150°C will be given.

Keywords: Rotation Heat Pump, Test Results, High Temperature, Application Cases

Introduction

An enormous amount of energy is required in industry in the form of heat, De Boer et al [1]. In many cases, the temperature level is between 100 °C and 200 °C, Fleiter et al. [2], whereby the availability of heat pumps is limited, especially above 100 °C utilisation temperature. For this reason, many research projects and developments are being carried out with the aim of tapping this potential. Heat pumps are one of the key technologies in industrial applications and make a very large contribution to the reduction of CO2 emissions. By integrating them into different processes such as brick, food and feed drying, pasteurisation, distillation as well as chemical processes, the consumption of fossil fuels can be greatly reduced. The variety of applications, Schlosser et al [3], requires maximum flexibility of heat pumps as well as different technologies that can be used. The great potential of high temperature heat pumps in general and different implementation possibilities were described in Arpagaus et al [4], [5] and [6] as well as the currently still existing market barriers. Furthermore, the use of heat pumps in Austrian district heating networks is presented with examples in Arnitz [7] and the status quo and potentials of industrial heat pumps in Wilk et al [7]. Applications and potentials for industrial heat pumps in Switzerland are presented in Arpagaus et al [8]. Results of a propane-butane heat...
pump for high temperature applications are shown in Bantle [9]. Further synthetic refrigerants with low global warming potential and heat pump cycles are analysed in [10].

Due to the design of conventional compression heat pumps (CHP) with the main components - compressor, condenser, evaporator and expansion valve - heat is in most cases transferred latently (i.e. by evaporation or condensation of a refrigerant). This means that comparatively high mass flows of the process media are necessary to scale up the performance if small temperature spreads between source inlet and outlet are to be achieved. Smaller spreads in conventional CHP are therefore to be aimed for, as this also keeps the temperature lift between condensation and evaporation low. The electrical power consumption of the compressor is reduced. The required compressor power has a direct effect on the COP (Coefficient of Performance).

The special characteristics and the design of the Rotation Heat Pump (RHP) make it possible to use heat pumps in new areas of application (hot air, steam, water) that have not been exploited so far.

Providing heat pumps for higher temperatures is very important and there has a lot of research been done in this area by different manufactures. Most of standard compressors in CHP are limited in terms of temperature by the working fluids and the lubrication. The RHP, using the Joule-cycle, is not limited by those factors for a temperature range \(>100^\circ\text{C}\). Based on previous publications, where the basic function, design, calculation methods and first test results of a Rotation Heat Pump have been published (Längauer et al., [11]), further tests are finished. Those are focused on higher temperatures at sink and source as well as showing how different parameters effect the Joule-Cycle in the RHP. Therefore, beside steady state conditions for sink and source also the start-up period and the shutdown process are explained. The test setup in terms of a scheme is described as well, which is essential to allow a comprehensible analyse of the test results. The aim is not to give a detailed calculation about COP including error estimations and tolerances but more to give an overview of the test procedure and how a certain measuring period looks like. Of course, detailed analyses are essential for accurate results when the COP is focused on. In this case tolerances of sensors are given but further calculations will not be implemented in this paper to keep the focus on temperature curves. The first part of the paper will give a short overview of the technology and references and further deal with this high temperature test of a RHP. After the results and discussion an outlook will be given for further tests. Also, the possibility to reach higher temperatures will be addressed and necessary changes will be given.

The Joule process implemented in the RHP realises a wide spread of both heat source and heat sink due to the sensitive heat transfer and is especially optimally suited for this purpose. In contrast to CHP, the temperature lift and the compressor capacity are decoupled from the spread. They can be controlled almost independently of each other. The COP therefore remains at a high level compared to the CHP, with a similar temperature range and a spread of up to 30 K. The strong cooling of the source offers the advantage of transferring very large heat outputs from the process water to the working fluid at lower mass flows. This means that not only the pipelines, but also other peripherals such as pumps, filters, etc. can be dimensioned much smaller. The high efficiency of RHP with large spreads brings great advantages in terms of costs and application in industrial processes with specified cooling or target temperatures (provision of cooling water).

The efficiency of heat pumps is usually compared using the COP at certain operating points. Together with other criteria, this is ultimately decisive for the final selection. As boundary conditions, often only the temperature at the inlet of the source and the temperature to be aimed for at the outlet of the sink are mentioned here. In combination with the thermal power and the mass flow, the other temperature levels are finally determined based on thermodynamics. If a fluid with a very high heat capacity flow is available as the source, it is of little or no relevance if the thermal power is primarily achieved via the mass flow. This could be the case, for example, when using river water, geothermal energy or similar heat sources. In many industrial processes, however, these mass flows are limited and thus thermal power must be seen as a product in which the temperature difference factor is much more important. This plays a major role in the dimensioning of heat pumps. It is therefore essential to consider the temperature spread of source and sink when designing and considering implementation options. Examples of this are various heating processes such as the provision of hot air, hot water or steam or air preheating for drying processes (e.g.: Wilk et al. [12]). A second part of this paper will discuss and show how the thermodynamic process is affected by having high spreads for sink and source in a CHP and RHP. For this purpose, a conventional HFO (Hydrofluoroolefine) refrigerant - R1336mzz(Z) with low GWP (Global Warming Potential) and the Joule process as implemented in the RHP with a noble gas mixture as working fluid are compared in an industrial process for distillation. Also, some more application cases will be shown and discussed where the temperature spread is essential and an advantage.
1. Main Principle

In the RHP, the counterclockwise Joule cycle is realised whereby the working medium used is always gaseous. The compression is realised by centrifugal forces, the pressure and the temperature increase outwards due to the rotation (approximately adiabatic compression). This principle was first presented in Adler [13] and further in Adler [14], [15]. Further descriptions, explanations and test results can be found in Adler and Mauthner [16], Längauer [11], [17]. Since the technology is worldwide patented and there is no other manufacturer providing it, only references by ecop can be given. Essential for the function is the centrifugal acceleration occurring due to the rotation, which causes the compression of the working gas. Thus, a very efficient compression can be realised, since the relative velocity of the working gas in the pipes is very small compared to the absolute velocities. Figure 1 schematically shows the Joule process in an RHP.

![Figure 1: Schematic representation of the cycle process in an RHP [17]](image)

2. High temperature test

2.1. Test setup

To test the performance of a RHP a test rig is used which is connected to the sink and source of the RHP. The two different circuits are each closed and mass flow is ensured by pumps. Temperatures are measured at the RHP as well as at the test rig where also the mass flow is captured. The electrical power consumption is measured via frequency converters which are used for controlling the rotational speed of the components as well. All sensors and components necessary are connected by a Bus-system with the programmable logic controller where the signals are postprocessed and the final value is stored in a file. Beside several sensors and pumps the test rig also includes heat exchangers which are used to recover heat during the test process. Much less energy than the thermal output at the sink has to be dissipated to the environment because of this arrangement. For steady state conditions the electrical power consumption of the fan and rotor, which are finally transformed to heat, have to be dissipated. Therefore, a separate circuit including two water-air heat exchangers with fans (Fan1, Fan2), is used. The following Figure 2 shows the RHP-K7 and the test rig during the test process.
Essential components and sensors as well as details about the measurement system and configuration are given in [11]. They will not be summed up here again. Also, the COP calculation is based on this publication, it should only be mentioned here, that for the COP the thermal power at the sink side and the electrical power consumption of the main rotor plus the fan engine are used.

2.2. Results and discussion

In the following section test results based on the test setup described above will be shown and discussed. Therefore, one day of testing is split in three sections which will each be illustrated in a quartet of diagrams. They will include measured values of temperatures (sink and source), electrical power consumption, mass flows, thermal power (sink and source) and COP. This is useful to explain the behaviour of the RHP for different conditions and the corresponding results. The first section will describe the ramp up of the Rotation Heat Pump, the second section will discuss the curves for almost steady state and the third section will be about the shutdown of the System. To give an overview, the following diagram (Figure 3) of the temperature curves shows the related sections. The shown test was started at 07:00h and lasted till 17:30h. After the results are presented, a short discussion will follow where different effects of changed boundary conditions are analysed.

Figure 2: RHP-K7 and Test rig at production site

![Figure 2: RHP-K7 and Test rig at production site](image)

Figure 3: Temperature curves of sink and source of testing day including different time periods

![Figure 3: Temperature curves of sink and source of testing day including different time periods](image)
The ramp up time represents the time where the system is started and heated up from initial conditions. Figure 4 shows the mentioned curves for these conditions. Initial conditions means that there is no rotation whether of the main rotor or the fan and there is no mass flow of working fluid or process fluid. The temperature level of sink and source are almost equal at the inlet as well as at the output. The test run starts by ensuring mass flow of sink and source just after 07:30h (Figure 4b) while at around 8:30h the fan, which provides the mass flow of the working fluid, is switched on. This can be seen by the electric power of the fan in Figure 4c. It is essential, that the mass flow of the working fluid is already built up before transferring thermal power at sink and source because otherwise the pressure increase necessary for the process can’t be ensured by the fan. Last step is to start up the main rotation which generates the temperature lift between sink and source, Figure 4b. This can be seen just a few minutes after 08:30h, the mass flow of the working fluid is already ensured. The COP at this time is not representative because there is still a certain amount of heat necessary to heat up the whole machine. As can be seen in Figure 4a, the temperature of sink and source generally increases over time while the temperature difference between sink outlet and source inlet increases as well. General increase is caused by heating up the system by internal electrical components and an external heater mounted on the pipe system at the test rig. The temperature difference, means the temperature lift between sink and source, increases because of the increasing rotational speed of the rotor.

![Figure 4: Ramp up – Temperature (a), rotational speed and mass flow (b), thermal and electrical power (c) and COP (d)](image)

The second time section displays the performance of the RHP at almost constant boundary conditions, shown in Figure 5. After the ramp up the temperatures for sink and source at the inlet are kept constant. Also, mass flow and rotational speed of the main rotor are set to a certain level. For this test 1400rpm are defined for the main rotor and approximately 460l/min are the flow rate of sink and source. Since the test rig is a circuit of limited volume, the controller is not finally optimised yet and as much heat as possible is tried to be recovered, some small drifts of temperature and thermal power occur. Nevertheless, the temperature at sink outlet is kept at around 120°C, which demonstrates the possibility of providing high temperatures while the COP results in around 4 and COP_process is around 5.7-6. The thermal power at the outlet is 500-550kW. A small deviation of thermal power and COP can be seen a few minutes before 13:00h, where the rotational speed of the fan engine was increased slightly and the inlet temperatures have been adjusted.
The last section, Figure 6, describes variations and the shutdown of the system which means that it shows how the temperature is lowered and finally the rotational speed of the rotor decreases until it stops. Also, at the beginning variations of the rotational speed of the fan and how they affect the Joule-cycle and the system are shown. Starting at 14:00h, the temperatures correspond to the level of the steady state shown earlier. A few minutes after 14:00h the rotational speed of the fan is reduced which can be seen by the decreased power consumption of the fan-engine. Because of fluid mechanics, lowering the fan speed goes along with reducing mass flow and pressure increase. This results in lower flow velocities and less flow losses but also less heat transfer in the heat exchangers. Consequently, the transferred heat also decreases, as can be seen in Figure 6c. As a result, however, the COP increases because the ratio of thermal power and electrical power consumption increases. In particular, the COP_process increases since the fan works more efficient. After lowering the rotational speed of the fan, the first temperature step downwards takes place at around 15:00h. At this time more heat is dissipated via the external heat exchangers of Fan1 and Fan2. Sink outlet temperature decreases from 120°C to 100°C and also inlet and outlet temperatures of sink and source are dropping around 20K. Since this is a dynamic process the thermal power and the COP calculation are showing values for unsteady conditions. The heat capacity of the rotor and the whole system would have to be included at this point because the temperature level of all components is decreased. After this drop the system is in a steady state condition after a few minutes again. About half an hour later the next temperature drop takes place and the system temperature is lowered again 20K. Heat output and COP show the same characteristics as before and after a few minutes steady state operation is reached again. Looking at the COP in general, it almost does not depend on the temperature in steady state. In the next steps the temperature is further lowered and just a few minutes before 17:00h the fan is switches off and there is no more thermal power delivered, all temperatures equalise and finally the values for COP are not representative anymore. Before the last step, where the pumps for the process fluids are switched off, the engine for the main rotor is switched off and the rotational speed is reduced. The peak of the main rotor power consumption at 17:00h can be explained as follows. For a final shutdown when the rotor has to stop, valves in the housing are opened to allow ambient air to flow into. Basically, till all tests a vacuum is provided inside the housing to reduce ventilation losses of the rotor. In this case, just before the engine is switched off, the valves are opened, air flows into the housing and so the power consumption of the main rotor is for a short time higher than usual.
3. Application Cases

3.1. Distillation

For the calculation of the thermodynamic processes, the same values for the CHP and RHP were assumed regarding the temperatures of the source and sink, the mass flow and the thermal power. The results are based on [18], where more detailed analyses are given. The spread given in the calculations is assumed to be the same for both source and sink. Since the refrigerant R1336mzz(Z) has a strongly overhanging wet vapor region (see also Helminger [19]), superheating after the evaporator is also applied in the calculation. Furthermore, in the CHP process, no peripheral losses such as the power of the control system or auxiliary devices that influence the process or COP are included.

Application - Distillation process

In addition to the results presented so far with specified boundary conditions, as can occur in industrial processes, the two heat pump processes are compared below for the specific application case of a distillation process in whisky production. In this application, the ethanol-water mixture is evaporated in the still (distillation column). This takes place at 85 °C to 95 °C and is usually realised with saturated low-pressure steam. In this application, an inlet temperature of 120 °C and an outlet temperature of 90 °C are required. In principle, the distillation process (latent heat) is also possible at constant temperature. This process can also be implemented with process water, but the spread must be correspondingly large (30 K). At the same time, the heat of condensation and cooling that must be dissipated in the downstream condenser can be used as a source. This application thus has the advantage that both the cooling of the source and the heating of the sink can be used. Figure 7 shows the integration schematically. The boundary conditions are the

- Temperature at the inlet of the source with 85 °C,
- Temperature at the outlet of the source with 55 °C,
- Temperature at the inlet of the sink with 90 °C,
Temperature at the outlet of the sink with 120 °C

The spread is 30 K, whereby the lift for the evaluation according to source inlet to sink outlet temperature is 35 K and 65 K for source outlet to sink outlet temperature. The thermal power is also given in this case with 700 kW and is assumed to be the same in both designs. Figure 8 below show the thermodynamic cycle for the RHP and CHP for the given boundary conditions where a COP of 4,7 for the RHP and for the CHP a COP of 3,7 can be calculated.

3.2. Cooling

Many industries need to dissipate enormous amounts of heat for the cooling of engines/generators/processes, this heat can often not be used directly due to a relatively low temperature level. With the Rotation Heat Pump, it is possible to both provide the cooling with high temperature spreads, this energy is used as a source, and to provide heat again at a high temperature level. E.g., for self-consumption for heating support or for feeding into a district heating network. Heat and cold can thus be provided with one system.

3.3. Pasteurization

In the pasteurization process, products must be heated in the first step and then cooled again. Until now, these processes have often been considered separately. However, it is much more energy-efficient to use the heat available during cooling and to use it for heating at the beginning by means of a temperature lift in a Rotation Heat Pump.
3.4. Hydrogen production

In hydrogen production, water is separated into Hydrogen (H\textsubscript{2}) and Oxygen (O\textsubscript{2}) by an electrolysis process. The water provided must be cooled and fed back into the process. To make hydrogen production as efficient as possible, it makes sense to use this heat for other processes. Depending on the operating temperature of the production process, many electrolyzers use temperature levels of around 40-70°C which is to less for direct using most of the time. Combined with a Rotation Heat Pump, a large spread at the source can be achieved to cool the water and then feed the heat into e.g., a district heating network or a production process at higher temperature levels.

3.5. Steam generation

Steam can be obtained directly from the hot water by pressure reduction in a steam drum. This eliminates the need for an additional heat exchanger and allows the full temperature level to be utilised, as steam is fed directly into the system via a steam lance. Pressure control units allow precise control of the steam pressure as well as the hot water to prevent evaporation in the heat pump. The amount of used steam is fed back into the system in form of feed water via a feed water tank.

4. Results and discussion

The presented results of a high temperature test run show that due to the flexibility of the Joule-cycle the temperature level is not essential to operate a RHP efficiently. During the ramp up time it is necessary that mass flow of the working fluid is already ensured before the main rotor speed is increased. Otherwise, it is not possible to overcome the pressure difference caused by the thermal power transferred at the heat exchangers. This pressure increase is mainly depending on the thermal power and the temperature lift. Temperature lift is mainly produced by the rotational speed of the main rotor. By adjusting the rotational speed of the rotor, the temperature lift can be controlled as well as the thermal power for given conditions can be adjusted. Of course, different control strategies can be obtained for this system by having those parameters to control. This is already in progress and will be tested as soon as possible in a first step on digital twins and finally at the test rig combined with the RHP. Having different control strategies also tests will be adapted and can be much more dynamical. Changes in temperature, mass flow, rotational speed and other parameters can then be made easily under exact control. This will allow a much more detailed analyse of the system under dynamic boundary conditions. Probably the sampling rate of the logging must be adjusted to get finer results since now it is set to 5 seconds. In addition, accuracy of sensors should be considered and analyzed in a next step.

Table 1 shows the COP for the given operating points before. They are based on theoretical calculations with 700 kW thermal power at the sink. Most of the values of conventional heat pumps used for the specification of the temperature spread usually refer to the inlet temperature of the source and the outlet temperature of the sink. This approach is referred to as case 1 in the results. Another possibility is to calculate the temperature spread from the outlet temperature of the source and the outlet temperature of the sink. Case 2 describes this value.

</table>

The results show that the COP has a strong dependence on the temperature lift or on the temperatures used for calculating the temperature lift (source inlet/source outlet).

At a spread of 30 K, the difference between the two technologies becomes clear, with the RHP achieving much higher COP values than the CHP. This is possible due to the sensitive heat transfer as it occurs in the Joule process in the RHP.
Table 1 shows that the RHP achieves comparatively higher COP values as the temperature level rises. The reason for this is the Joule process implemented in the RHP, which enables very efficient compression due to the always gaseous working fluid at different temperature levels. The 2-phase process in the CHP is limited in terms of the maximum temperature level by the refrigerant. The COP decreases in the subcritical cycle in the CHP close to the critical temperature [6]. This effect does not occur in the RHP, since the working fluid permanently runs through the cycle in a supercritical state. Specifically for distillation, the RHP has a COP of 4.68 and the CHP a COP of 3.72. This can be explained by the high spread in combination with the high temperature level (120 °C sink outlet, 90 °C sink inlet, 85 °C source inlet, 55 °C source outlet).

Beside the specific shown case for a distillation process different application cases are shown where the high temperature spread provides a significant advantage for the process. Those applications provide for example cooling of a specific system or a high temperature difference at the process fluids is beneficial. A very interesting topic for high temperature heat pumps is also steam production which can be realized by using a steam drum. As a next step the combination and testing of a Rotation Heat Pump with a steam production system will be the aim.

4.1. Outlook for very high temperatures

The demand on thermal power at temperatures higher than 150°C up to 250°C in the industry is enormous. While right now temperatures of 150°C are possible by using a Rotation Heat Pump, it is already the aim to provide also these temperature-levels. Therefore, a completely new design of the rotor is developed which uses new technologies of manufacturing. The new method is based on a diffusion bonded system which includes heat exchangers and also the pipe system for water and the working fluid (only one solid block). A massive simplification is possible because all sealings at the rotor can be removed and so this method allows simple mass production. While also the size is reduced by more than 50% the efficiency can be increased by around 30% (due to smaller delta T in heat exchanger and reduced pressure drop). Following Figure 9 shows the difference in size and grade of simplification for a rotor providing same thermal power and temperatures. This new design will allow temperatures of up to 250°C and will be included in a prototype till 2024.

5. Conclusions

High temperature heat pumps play an important role to decrease CO₂ emissions since there are a lot of industrial applications using fossil fuels for heat supply now. The possibility to use the Joule cycle in a RHP allows using flexible temperatures and in addition the temperature level is not limited by the working fluid. To demonstrate the performance of a RHP at high temperatures, up to 120°C, a specific test run was set up and analyzed. Those test results were generated using a RHP-K7 in combination with a special test rig described in previous papers. The test data show an entire test day were also the startup period and shutdown time is included and analyzed. During the startup it is clearly shown how the temperature increases with time due to the heating up of the circuits. This takes some time but is not limited by the RHP but more by the electrical
heaters. The RHP could deal with faster changes in temperature which is demonstrated during the shutdown. Also, the effect of increasing the rotational speed of the rotor can be seen and how this influences the process. This is a dynamic process where no steady state conditions are present and the evaluated COP is not correct by using classic formulations. Because the machine and periphery are heated up and can be seen as a thermal storage, energy balances are not fulfilled during this time. After the components have reached steady temperature levels the second time period of testing starts. This mainly includes steady state analyses where the parameters should not be changed. During this period measured sensor values and COP are almost constant without discontinuities. After having this constant test period, the third part describes the shutdown of the machine when the temperature level is reduced in a few steps. This shows that the temperature level can be changed within some minutes. Also, the thermal power can be adjusted in a certain range by increasing or reducing the speed of the fan. If the fan is finally turned off, no more mass flow occurs, and the temperatures all drop to an equal level. This test at 120°C could also be achieved for 150°C at sink outlet, essential is the use of adequate seals for this case to prevent leakage. Since the working fluid is not limiting the Joule-process itself, higher temperatures are feasible but of course some components must be updated.

Abstract

Liquid desiccant air-conditioners (LDAC) with heat pump can perform cooling dehumidification or heating humidification, and have high energy-saving and sterilization performance. Therefore, they are installed in hospitals, nursing homes, and food factories, where humidity control is required. However, lithium chloride (LiCl), a conventional humidity control liquid, is highly corrosive to metals, requiring the use of highly corrosion-resistant materials such for the pipes and the heat exchangers. This leads to the problem that the manufacturing cost of the air conditioner increases.

Therefore, we developed an inexpensive and compact LDAC by adopting a novel ionic liquid (IL) that does not corrode the metals commonly used in air conditioners. In this study, we evaluated the metal solubility and sterilizing property of the ionic liquid. Based on the physical properties of the IL, the humidity control module was improved for the purpose of downsizing and cost reduction of the unit. Moreover, we conducted a performance evaluation of the LDAC in the environmental test room under the condition in which temperature and humidity change rapidly in short period of time to simulate the condition of sudden showers of rain in summer. Test results showed that processed air was supplied at very stable level.

1. Introduction

The development of an efficient air-conditioning system has become more and more important from the standpoint view of realizing a sustainable society. In hospitals and factories where temperature and humidity control throughout the year are required, gas as fuel have been used as heat sources of boilers and absorption chillers. However, there is a lot of heat loss in the boiler and the steam piping, and the energy consumption is high. LDAC is attracting attention as one of the most promising candidates to replace such inefficient air conditioning systems [1-3].

However, the present commercial LDAC uses an aqueous solution of LiCl as the humidity control liquid or desiccant. The LiCl is very caustic/corrosive to metals, in particular, iron or aluminium, both of which are popular resources of materials in the air-conditioner system; this requires expensive special corrosion-resistance pipes and heat exchangers, which causes a critical problem that the manufacturing cost of the air-conditioning system is rather high.

Ionic liquids (ILs) have gained strong interests due to their unique physical and chemical properties and their applied fields have been significantly expanding. ILs show a low volatility, unique solvation capability, and high stability and the liquids have thus been applied in various fields of electro-chemistry, organic and inorganic synthetic chemistry, catalysis, and gas absorption [4-5].

In these backgrounds, we have developed an inexpensive and compact LDAC by adopting a novel IL that does not corrode general-purpose metals such as iron and aluminium. In this study, we evaluated the metal
solubility and the sterilizing property of the IL. Based on the physical properties of the IL, we improved the heat exchanger and the humidity controller. Moreover, we conducted a performance evaluation of the LDAC in the environmental test room under the condition in the rated dehumidification condition and the transient condition.

2. Outline of LDAC

Figure 1 shows an outline of LDAC in the case of dehumidification. LDAC is a device that absorbs and releases water vapor in the air by bringing the outside air into direct contact with a gas-liquid contactor wetted with a liquid humidity control liquid to adjust the humidity and temperature of the air. It consists of a processor and a regenerator. The processor plays a role of supplying the treated air to the room, and can create air of any temperature and humidity by adjusting the temperature and concentration of the humidity control liquid. Also, the temperature and concentration of the humidity control liquid can be independently controlled, and the temperature and humidity of the air can be freely set. On the other hand, the regenerator has a role of concentrating the liquid by heating the humidity control liquid, which has been diluted by absorbing the moisture in the air, and bringing it into contact with the outside air. Humidification is performed by switching between cooling and heating of a heat source such as a heat pump. Various heat sources such as heat pumps, groundwater, exhaust heat, and solar heat are used to cool or heat the liquid. In particular, the use of heat pumps that can heat and cool at the same time will improve system efficiency.

3. Physical properties of IL

In general, humidity control liquids are required to have high humidity control performance, inexpensive, satisfy, and high sterilization properties and so on. LiCl which is mainly used as a humidity control liquid for LDAC, satisfies such requirements, but has the problem of being highly corrosive to metals.

In this study, a novel IL developed by Evonik Industries was used as the humidity control liquid. This IL exhibits high dehumidification performance, thermal and chemical stability, low volatility, comparable heat mass transfer properties [6] and is suitable for LDAC. Table 1 shows comparison of thermophysical properties of humidity control liquid. At the same temperature and the equivalent liquid desiccant mass fraction at which the saturated vapor pressure is identical, the aqueous IL exhibits lower density and surface tension than aqueous LiCl. On the other hand, the viscosity of aqueous IL is higher than that of aqueous LiCl. In the following, the results of evaluating the level of metals dissolved into the IL and sterilization performance in comparison with LiCl are shown.

3.1. Level of Metal ions into the IL

Figure 2 and Fig. 3 show the metal ions of stainless steel and aluminum dissolved into the IL. The test period is 3 weeks and the temperature of the solution is heated up to 70°C. The mass fraction of IL and LiCl are 80wt% and 35wt%, respectively. Saturated vapor pressure at these mass fractions is close to the value when dehumidifying the outside air in summer. The size of the metal sample is 40mm×10mm×3mm. The amount metal ions SUS and aluminum dissolved into the IL is much less than into the LiCl solution and is at a practically acceptable level. This result suggests that commonly used tubes and heat exchangers can be used, which is a great advantage in reducing the manufacturing cost of air conditioners.

3.2. Sterilization performance

In the COVID-19 pandemic, the air cleaning performance of air conditioners is also required as an additional factor. Therefore, we investigated the sterilization and virus inactivation performance of the IL. As an example, Fig. 4 and Fig. 5 show the results of the sterilization effect against Legionella and Aspergillus niger of the IL in comparison with LiCl solution. When each bacterium is brought into contact with the IL, it dies after 1 minute, and the sterilization performance is higher than that of LiCl.

Table 2 shows the inactivation effect of the IL on three types of viruses (feline coronavirus, influenza virus, and feline calicivirus). The IL was added to the liquid containing the virus cell line, and after a predetermined period of time, the amount of virus infection to the cell line was measured. In the case of the purified water for comparison, the amount of viral infection hardly changed after 60 minutes, but with the IL, the amount of viral infection decreased sharply down to the detection limit even after only 1 minute, demonstrating a remarkable viral inactivation effect.

Regarding the hazards of this IL, we conducted an acute toxicity test using mice in accordance with the OECD guidelines, and confirmed that the classification of hazards to health (GHS) is beyond the most mild class.
4. Configuration of humidity control module

In LDAC, the supply air temperature is determined by controlling the temperature of the humidity control liquid, and the air humidity is determined by controlling the concentration of the humidity control liquid. In a typical LDAC, as shown in Fig. 6, the humidity control liquid is first cooled in a plate heat exchanger and then directly contacted with the outside air in an air-liquid contactor. The temperature and humidity of the outside air are regulated by direct contact with this liquid.

In the conventional LDAC systems using LiCl, as the humidity control liquid generates heat when it absorbs moisture, the temperature gradually rises in the downstream direction of the gas-liquid contactor. Since the dehumidifying ability of the humidity control liquid decreases as the temperature rises, it is necessary to flow a large amount of the liquid in order to prevent this, and the capacity of the solution pump and the solution tank have been increased. Therefore, from the viewpoint of the cost reduction and the compactness, it was necessary to reduce the liquid flow rate and the tank size as much as possible.

In this study, as shown in Fig. 7, a sandwich structure was adopted in which tube heat exchangers and gas-liquid contactors were alternately arranged, and dehumidification was performed while cooling the humidity control liquid. As a result, it becomes possible to reduce the liquid flow rate while reducing the temperature rise of the humidity control liquid in the downstream direction. We conducted tests using the tube layout and the type of gas-liquid contactor at various conditions of parameter, determined the optimal combination, and developed a compact integrated humidity control module that combines a heat exchanger and a humidity control mechanism. As a result, the circulation flow rate (liquid volume) was reduced by 90% compared to the conventional machine, and the tank size was also greatly reduced. As showed in Table 1, the IL has lower surface tension and higher viscosity than LiCl. Therefore, it should be noted that a stable and thin liquid film is likely to be formed even at a low flow rate [7].

5. Specifications

Figure 8 shows the appearance of the developed LDAC, and Table 3 shows the specifications. The processor and the regenerator have the same shape. As a heat source, not only hot and cold water from a heat pump chiller, but also hot water discharged from a factory, well water, etc. can be used. Compared to the conventional models of line-up, this unit has about 20% reduction in manufacturing cost, about 25% reduction in installation area, and about 90% reduction in the amount of humidity control liquid.

The LDAC shown in Fig. 8 has a rated air volume of 4,500 m³/h, but customers in the industrial field require a variety of processing air volumes. Therefore, as shown in Fig.9, we made it possible to customize and incorporate it inside the air handling unit (AHU) used for general air conditioning. As a result, we have been able to respond to a wide range of processing air volumes according to customer needs.

6. Performance tests of the LDAC

The performance tests of the developed LDAC were conducted in the climatic environmental testing room in the research and development division of Chubu Electric Power Co., Inc. Rated humidification performance, dehumidification transient performance were measured. 100kW heat pump chiller was used as a heat source.

6.1. Rated dehumidification performance test

Table 4 shows the results of the rated performance test. This test was conducted under typical Japanese summer outdoor air conditions, assuming application to a commercial building. The measured value of the dehumidification capacity was close to the target value, confirming that stable performance were obtained.

6.2. Dehumidification transient performance test

This test was conducted for the purpose of verifying the humidity control during sudden weather changes. In manufacturing processes such as pharmaceutical and painting processes, it is important to maintain a stable state even under drastic change in ambient conditions.

Figure 10 shows changes in temperature and humidity processed by the developed LDAC in a situation simulating the condition in which temperature and humidity change rapidly in short period of time such as sudden showers of rain in summer. By control temperature and concentration of the IL suitably, test results showed that the processed air was supplied at very stable level. The averaged temperature, humidity, and humidity ratio during the test were 26°C, 44%, and 9.2g/kgDA, respectively. The temperature change of the supply air was ±0.6 °C and the humidity change was within ±1%.

Fig.10  Supply air temperature and humidity characteristics when a shower is assumed
7. Primary energy consumption

Table 5 shows the result of estimating primary energy consumption and CO₂ emission of the conventional system and that of the developed LDAC system when the system is introduced to a hospital in Japan. The conventional system consists of a gas steam boiler and an air-cooled heat pump chiller. A substantial reduction in energy consumption of 72% and CO₂ emission of 49% from that of the conventional system can be expected when the new system is introduced. It is noted that although the LDAC system using LiCl considerably increases the power consumption of the pump compared to the developed system, the impact on the increase of primary energy consumption and CO₂ emission is not so large.

-Estimate condition-
Building: Hospital (floor area: 2,000m²)
Air conditioning operation: 24h/day, 365day, flow rate 10,000m³/h
System Efficiency: Heat pump chiller (cooling COP:4.07, heating COP:4.06), Gas boiler 70%
Calorific value: Electric 9.70MJ/kWh, Gas 45MJ/m³
CO₂ emission factor: Electric 0.449kg-CO₂/kWh, Gas 2.29kg-CO₂/m³

8. Summary

We have developed an inexpensive and compact LDAC by using a novel IL that does not corrode general-purpose metals. The developed LDACs were already installed in hospitals, nursing homes, offices, food supermarkets, and beer factory as energy-saving and hygienic air conditioners. The results obtained during the research and development of this system are as follows:

- The amount of SUS and aluminum dissolved in the IL is much lower than that in LiCl solution. In addition, the IL has a higher sterilization effect against bacteria and viruses than LiCl solution.
- A sandwich structure in which tube heat exchangers and gas-liquid contactors are alternately arranged was developed for the direct contact of air to liquid. Consequently, the liquid flow rate can be reduced by 90% compared to the conventional unit.
- By appropriately controlling the temperature and IL concentration, extremely stable processing air can be supplied even under conditions where the outside air conditions change rapidly.
- It is expected that the energy consumed by conventional air conditioning system such as heat pump chiller and boiler, can be reduced 72% by introducing the new system.

Abstract

Adsorption heat pumps can provide process heat to the industry by converting wasted heat from the plants to more useful heat of high temperature. Ammonia is suitable for a working fluid of the adsorption heat pump for decarbonization since it has zero global warming potential (GWP) and ozone depletion potential (ODP). Thermal performance of the ammonia adsorption heat pump is closely related to the boiling heat transfer in a flooded evaporator of the heat pump. Boiling heat transfer of ammonia on the plain stainless steel tube with an outer diameter of 15.87 mm was investigated at three different saturation pressures of 6.15, 8.57, and 11.7 bar (corresponding saturation temperatures of 10, 20, and 30 °C). Considerable hysteresis between increasing heat flux and decreasing heat flux cases was observed. Measured boiling heat transfer coefficients were compared with previous correlations, and Stephan-Abdelsalam’s correlation showed best agreement with the measurement. Boiling heat transfer on the enhanced tube with low fins was also examined, which exhibited large enhancement of the boiling heat transfer coefficient.

Keywords: Adsorption heat pump; Ammonia; Pool boiling; Flooded evaporator; Hysteresis

1. Introduction

The decarbonization of thermal energy associated with building and industry sectors is essential for attaining the 2050 Net-zero goal. Thermally driven heat pumps such as absorption and adsorption heat pumps are regarded as one of the key technologies improving the energy efficiency in heating and cooling section, and eventually replacing conventional fossil fuels \cite{1}. An adsorption heat pump can be operated with lower grade waste heat and is free from greenhouse gas emission because it utilizes natural refrigerants like water and ammonia \cite{2}. Although ammonia is toxic and flammable, it has lots of advantages of high latent heat, chemical stability, and higher operating pressure above atmosphere \cite{1}.

Numerous previous studies have revealed basic heat transfer characteristics of ammonia in the heat exchange devices such as boiler and flooded evaporator. Spindler \cite{3} thoroughly reviewed pool boiling heat transfer data of ammonia and compared them with general pool boiling correlations. Experimental data include pool boiling on a single tube \cite{4}, heat transfer enhancement techniques \cite{5-6}, boiling phenomena on tube bundles \cite{7}, and spray evaporation \cite{8}. Zheng et al. \cite{9} investigated the effect of lubricant oil on shell-side boiling heat transfer coefficient and concluded that the heat transfer coefficient first decreased with increasing oil concentration, then increased with a further increase in concentration. Abbas et al. \cite{10} also reviewed various empirical correlations for outside boiling on single tube and bundles in ammonia. They concluded that existing correlations are to be cautiously applied because there is a wide disparity among them. Fernandez-Seara et al. \cite{11} compared the heat transfer coefficient of spray evaporation with that of pool boiling on a horizontal plain tube in ammonia. They also showed boiling heat transfer improvement on an integral finned tube in a flooded evaporator \cite{12}. They reported that a large hysteresis between increasing heat flux and decreasing heat flux was initially observed but diminished as the time passed (10 hours).

Despite abovementioned previous studies, there are still lots of unresolved phenomena about pool boiling of ammonia in a flooded evaporator. More elaborate investigation is required to understand the complicated phenomena of ammonia including boiling incipience, hysteresis, and effect of surface structures in the flooded evaporator. The present study is aimed to investigate the hysteresis in boiling curves of ammonia and to clarify the effect of low fin structure on boiling performance, and to compare the measured data with previous correlations.

2. Experimental Setup

2.1. Experimental apparatus

The test chamber was made of stainless steel with a wall thickness of 6.5 mm to withstand an internal pressure as high as 20 bar, which corresponds to the saturation pressure of ammonia at 49.4 °C. The length of the test chamber is 796 mm, and the internal diameter is 254.4 mm. The chamber is filled with ammonia, and the liquid level of the ammonia pool reaches approximately to the center of the chamber. The test tube was located at the bottom-center of the liquid pool as shown in Fig. 1. The test tube was likewise made of stainless steel with an outer diameter of 15.87 mm, and the inner diameter was 13.39 mm. Smooth tube and enhanced tube were prepared to investigate the effect of surface geometry on boiling heat transfer performance. Important geometric parameters are designated in Fig. 2 and corresponding values for smooth and enhanced (low fin) tubes are tabulated in Table 1. A smooth tube has machine-roughened surface, whose arithmetic average roughness ($R_a$) was measured as 0.296 μm using the surface roughness tester. The enhanced tube has low fins with a height of 1.33 mm. The fin pitch was 0.977 mm (26 fins per inch), and wall thickness ($t_w$) was 0.63 mm. Since the tube was compressed by the fin rolling machine during the fabrication process, the outer and inner diameters of the enhanced tube were reduced to 13.07 mm and 11.81 mm, respectively. The outmost diameter including low fins was maintained to be 15.73 mm, which is nearly the same as the outer diameter of the smooth tube.

The chamber temperature was maintained using eight tubes embedded in the chamber, where water and ethylene glycol mixture flows. Four tubes are in the vapor region of the chamber and utilized to condense the ammonia vapor generated from the test tube. The remaining four tubes are located at the liquid region of the chamber and employed to maintain the saturation temperature of the liquid pool of ammonia. The liquid temperature of the ammonia pool was measured at two points using T-type thermocouples, and the internal pressure of the chamber was acquired from the pressure transducer. The temperature of the test tube was controlled by circulating hot distilled water through the tube. Inlet and outlet temperatures of the test tube were measured with precise RTD sensors with 1/10 DIN accuracy (±0.03 °C tolerance at 0 °C). The hot distilled water was circulated by a gear pump and the flow rate was measured with Coriolis mass flowmeter. The flow rate through the test tube was maintained to be 3.8 kg/min over the entire tests. Two reinforced glass windows were equipped at the top and bottom regions of the chamber to observe the boiling and condensation phenomena at the liquid and vapor regions, respectively. A high-speed camera with a frame rate of 2,000 fps was utilized for capturing the bubble nucleation on the heated tube. The entire test chamber was thermally insulated with fiberglass insulation tapes having low thermal conductivity of 0.05 W/mK.

2.2. Experimental procedure and data reduction

Ammonia is filled into the test chamber in the following procedure. The internal pressure of the test chamber is lowered down to the absolute pressure of 3–5 mTorr using a rotary vacuum pump. Once the non-condensable gas is completely extracted from the chamber, the valve to the vacuum pump is closed. Then, the valve to the ammonia cylinder is open, and the liquid ammonia is injected into the chamber. When the liquid level of ammonia gets to the center of the chamber, the valve is closed to finish the filling process. The boiling experiment was conducted at three saturation pressures of 6.15, 8.57, and 11.7 bar, which correspond to the saturation temperatures of 10, 20, and 30 °C, respectively. Once the internal temperature and pressure are maintained at the designated saturation temperature and pressure using eight temperature control tubes, the hot water begins to flow through the test tube. At the initial step, hot water temperature is merely 2.5 K higher than the saturation temperature of ammonia pool. Once the inlet and outlet temperatures of the test tube reach steady state, all data including temperature, pressure and flow rate are stored for 10 min, and the hot water temperature is increased to the next level stepwise.

Evaporation or boiling heat transfer rate, \(Q\) is obtained from the following energy balance equation.

\[
Q = \dot{m}c_p \Delta T = \dot{m}c_p(T_i - T_o)
\]  

\(T_i\) and \(T_o\) refer to the inlet and outlet water temperature of the test tube, respectively. The heat transfer rate, \(Q\) is also expressed as multiplying overall heat conductance and log-mean temperature difference as shown in Eq. (2).

\[
Q = UA \Delta T_{lm}
\]  

The LMTD (log-mean temperature difference) is defined as,

\[
\Delta T_{lm} = \frac{\Delta T_i - \Delta T_o}{\ln(\Delta T_i/\Delta T_o)}
\]
here, \( \Delta T_i = T_i - T_{\infty} \), \( \Delta T_o = T_o - T_{\infty} \)

\( T_{\infty} \) refers to the liquid pool temperature surrounding the test tube. Boiling heat transfer coefficient, \( h_b \) can be acquired from the following thermal resistance relation.

\[
\frac{1}{UA} = \frac{1}{h_i A_i} + \frac{\ln(D_o/D_i)}{2\pi k L} + \frac{1}{h_b A_o}
\] (4)

Total thermal resistance comprises thermal resistance of internal convection, conduction thermal resistance through the tube wall, and thermal resistance of boiling heat transfer. Convective heat transfer coefficient of internal water flow through the test tube was obtained from the Gnielinski correlation [13].

\[
Nu_D = \frac{(f/8)(Re_D-1000)Pr}{1+12.7(f/8)^{1/2}(Pr^{2/3}-1)}
\] (5)

\( 0.5 \leq Pr \leq 2000, \quad 3000 \leq Re_D \leq 5 \times 10^6 \)

Since Reynolds numbers in the present study range from 5,282 to 14,531, the correlation is applicable to obtain the internal convective heat transfer coefficient. Then, boiling heat transfer coefficient \( (h_b) \), the remaining unknown in Eq. (4), can be acquired. The average wall temperature on the test tube is calculated in the following equation.

\[
\bar{T}_w = \frac{(T_i + T_o)}{2} + Q \times \left( \frac{1}{h_i A_i} + \frac{\ln(D_o/D_i)}{2\pi k L} \right)
\] (6)

2.3. Uncertainty analysis

T-type thermocouple employed to measure the liquid pool temperature has an uncertainty of \( \pm 0.5 \) °C. 1/10 DIN-class RTDs to measure inlet and outlet temperatures of the test tube are extremely accurate with an uncertainty of \( \pm 0.03 \) °C at 0 °C. The uncertainty increases with temperature according to the following relation.

\[
U(T) = (0.3 + 0.0005 \times T)/10
\] (7)

where, \( T \) is measured temperature in °C. The resultant uncertainty of LMTD (log mean temperature difference) are calculated to be from 1.9% to 14.4%. The mass flowmeter has an uncertainty of \( \pm 0.1\% \), and the pressure transducer has an accuracy of \( \pm 0.08\% \), both of which are provided by manufacturers. As a result, the uncertainty of obtained heat transfer rates ranges from 1.1% to 20.5%, and the uncertainty of boiling heat transfer coefficients is 16.1% in average.

3. Results and Discussion

3.1. Hysteresis in boiling curve

Figure 3(a) exhibits the boiling curve on the smooth tube in the ammonia pool at the saturation temperature of 30 °C corresponding to the saturation pressure of 11.7 bar. It is noticeable that there is discrepancy between boiling curves with increasing heat flux and decreasing heat flux. In case the heat flux is increased from low to high, bubble generation is observed only in some areas of the tube until the heat flux
reaches 11,000 W/m². It seems that boiling incipience is delayed until the superheat is large enough to sustain the bubble generation. The large superheat required to generate the bubble is attributed to the superior wettability of ammonia on the stainless steel surface owing to the small surface energy. Ammonia is highly wettable on most of metal surfaces, resulting in the low contact angle less than 10°. The low contact angle is responsible for the suppression of bubble nucleation because it decreases the initial radius of the vapor embryo. The small initial radius of the embryo results in the increase of the wall superheat for attaining bubble nucleation. In contrast, in case the heat flux decreases from high to low, nucleate boiling is preserved over the entire tube surface even at the low heat fluxes less than 10,000 W/m². The bubble generation is facilitated at the low heat flux because the remaining vapor after the departure is large enough to keep the bubble generation at the low wall superheat. Boiling heat transfer coefficients at two cases show maximum 46% difference near the heat flux of 7,800 W/m² as shown in Fig. 3(b). Since the large hysteresis leads to different heat transfer performance according to the heating and cooling paths, consistent operation of actual heat exchangers might be threatened. In real heat transfer applications, it is greatly important to minimize the hysteresis by using surface modification techniques such as wettability control or porous structures.

Figure 4 shows different boiling phenomena at the heat flux near 11,000 W/m² for both increasing and decreasing heat flux cases. At the increasing case, only a few bubbles can be seen at the low heat flux. In contrast, numerous bubbles are observed over the entire tube surface at the decreasing case. Certainly, the increased number of bubble nucleation is responsible for improvement of heat transfer performance at the decreasing case as shown in Fig. 3.
3.2. Effect of saturation pressure

With increasing the saturation pressure in the ammonia pool, thermodynamic properties such as liquid density, vapor density, surface tension, and heat of vaporization are changed. Since the variation of thermodynamic properties affect the boiling heat transfer performance, heat transfer coefficients at three different saturation pressure from 6.15 bar ($T_{sat} = 10 \, ^\circ C$) to 11.7 bar ($T_{sat} = 30 \, ^\circ C$) were compared as shown in Fig. 5. As the saturation pressure increases, boiling curves move to the left, implying that the boiling heat transfer is enhanced. It is known that bubble departure diameter decreases with increasing the saturation pressure owing to the variation of thermodynamic properties. Eq. (8) shows the correlation about the bubble departure diameter proposed by Cole [14].

$$Bo^{1/2} = 0.04Ja$$

$$Bo = \frac{\varrho(\varrho_1-\varrho_2)d_d^2}{\sigma}, \quad Ja = \frac{\varrho_1 c_p(T_w-T_{sat})}{\varrho_v h_{lv}}$$

where, $d_d$ refers to the bubble departure diameter. The bubble departure diameters of ammonia at the wall superheat of 7 °C are calculated to be 1.21, 1.08, and 0.97 mm at three different saturation pressures. Figure 6 clearly shows that the bubble departure diameter increases with increasing the saturation pressure. On the contrary, number of nucleation sites and departure frequency are increased with increasing the saturation pressure. More bubble nucleation sites at higher saturation pressure are also revealed in the captured images in Fig. 6.

Fig. 5. Boiling curves according to the saturation pressure from 6.15 to 11.7 bar (decreasing $q''$).

Fig. 6. Comparison of bubble nucleation according to the saturation pressure from 6.15 to 11.7 bar (decreasing $q''$).
3.3. Comparison with previous correlations

The present data are compared with previous correlations about pool boiling heat transfer coefficients on the smooth tube. Following four correlations (Mostinski [15], Gorenflo [16], Rohsenow [17], and Stephan-Abdelsalam [18]) were selected for comparison.

\[
\begin{align*}
    h_b &= 0.1011 (P_c)^{0.69} q^{0.7} \left[ 1.8 \left( \frac{P_a}{P_c} \right)^{0.17} + 4 \left( \frac{P_a}{P_c} \right)^{1.2} + 10 \left( \frac{P_a}{P_c} \right)^{10} \right] \quad \text{(Mostinski)} \quad (9) \\
    h_b &= h_0 \left( \frac{q}{q_0} \right)^{n(P_c)} F(P_T) \left( \frac{P_a}{P_{sat}} \right)^{0.133} \quad \text{(Gorenflo)} \quad (10) \\
    h_b &= \frac{1}{c_sT_h f_g} \left[ \frac{1}{\mu_l \sqrt{g l (P_T - P_v) \rho_v}} \right]^{-0.33} (q)^{0.67} (Pr)^{-1.7} \quad \text{(Rohsenow)} \quad (11) \\
    \frac{h_b D_b^2}{k_1} &= 207 \left( \frac{q_{bD}}{k_1 T_{sat}} \right)^{0.746} \left( \frac{P_a}{P_T} \right)^{0.581} (Pr)^{0.533} \quad \text{(Stephan-Abdelsalam)} \quad (12)
\end{align*}
\]

Gorenflo and Rohsenow’s correlations exhibit relatively high heat transfer coefficients (upper bound), and Stephan-Abdelsalam correlation provides lower heat transfer coefficients (lower bound). The present data in case of increasing heat flux shows good agreement with the Stephan-Abdelsalam correlation, and the data in the decreasing case are somewhat higher than the Stephan-Abdelsalam correlation, and approach the Mostinski correlation, especially at the low heat flux region.

The following empirical relations are deduced for the pool boiling heat transfer of ammonia at the saturation temperature of 30 ℃.

\[
\begin{align*}
    h &= 0.9168 (q'')^{0.7846} \quad \text{(increasing \(q''\))} \quad (13) \\
    h &= 10.472 (q'''')^{0.5542} \quad \text{(decreasing \(q'''\))} \quad (14)
\end{align*}
\]

![Fig. 7. Comparison with previous correlations at the saturation pressure of 11.7 bar.](image)

3.4. Smooth tube vs. Low-fin tube

The low-fin tube has an outer diameter \((D_o)\) of 13.07 mm as indicated in Fig. 2 and Table 1. The heat transfer coefficient, \(h_b\), is calculated from the tube surface area based on the outer diameter. Total heat transfer rate \((Q)\) is obtained from the following equation.
\[ Q = h_b A_o \Delta T_w \]  \hspace{1cm} (15)
