Figure 8 shows boiling curve and boiling heat transfer coefficient on the low-fin tube compared with those on the smooth tube at the saturation pressure of 11.7 bar. It is noticeable that boiling hysteresis is enlarged on the low-fin tube compared with the smooth tube. The enlarged hysteresis resulted from the decrease in wall superheat on the finned surface compared with that on the smooth tube because there is temperature gradient along the fin height. Despite the hysteresis, the low-fin tube exhibits higher heat transfer coefficients in both increasing and decreasing heat flux cases. The heat transfer coefficient \( (h_b) \) increased by 61% in increasing \( q^" \) case and by 111% in decreasing \( q^" \) case.

Since the heat transfer area is varied, thermal performance of the low-fin tube can be compared with that of the smooth tube based on the thermal conductance which is defined as multiplying heat transfer coefficient and heat transfer area, \( h_b A_o \). Figure 9 shows the thermal conductance of the low-fin tubes normalized with that of the smooth tube in increasing and decreasing heat flux cases. It is concluded that the boiling heat transfer on the low-fin tube is enhanced by 33% (increasing \( q^" \)) and 74% (decreasing \( q^" \)) over the smooth tube.

Fig. 8. Effect of enhanced structure (low fins) on boiling heat transfer of ammonia.

Fig. 9. Thermal conductance of the low-fin tube compared with the smooth tube.
4. Conclusion

Boiling heat transfer of ammonia was investigated in a flooded evaporator for an adsorption heat pump at the saturation pressures of 6.15, 8.57, and 11.7 bar. Large hysteresis between increasing heat flux case and decreasing heat flux case was observed in the boiling curves, which is ascribed to the low surface energy of ammonia. Higher heat transfer coefficients were obtained with increasing saturation pressure, and the measured heat transfer coefficients were best matched with the previous Stephan-Abdelsalam’s correlation. Since the enhanced tube with low fins exhibited 33% (increasing $q^*$) and 74% (decreasing $q^*$) higher heat transfer performance compared with those on the smooth tube, employing the low-fin tubes in a flooded evaporator is expected to augment thermal performance of the adsorption heat pump system.

Abstract

This paper presents a new ultra-high temperature heat pump, working on the Stirling cycle, with helium as working medium. The heat pump can generate heat up to 200°C from sources as low as -10°C with high energy efficiency. A 400 kW prototype installation at a biogas facility is described, where the heat pump supplies steam and cooling to the CO\textsubscript{2} capture process. The performance of the heat pump is presented across a wide range of source and sink temperatures, in terms of heating capacity and share of Carnot COP. The experimental setup is described in detail, as well as the simulation model used for comparing simulated and experimental data. The performance figures are compared with published data for other heat pump cycles used for high temperature heat pumping. The results indicate that helium heat pumps may be more efficient than vapor compression heat pumps for temperature ratios above 1.3 K/K (sink temperature/source temperature).

1. Introduction

A prototype of a new stirling-cycle heat pump is installed in a test rig at the biogas facility IVAR near Stavanger, Norway. The pilot installation is shown in Fig.1.

This paper presents the performance of a novel high temperature difference heat pump. The performance is measured at a non-commercial installation of the heat pump, operating with a heat source varying between...
5°C and 45°C and with heat sink temperatures between 140°C and 190°C. The heat pump performance and COP are simulated across a wide range of temperatures and measured at the temperatures that were possible at the plant.

The first sections give a description of the heat pump, the thermodynamic process, the process layout and the instrumentation.

The next sections present the results from testing the heat pump at different loads and the comparison between the measured parameters and simulated values. The discussion and conclusions are given in the last section.

2. HoegTemp ultra high-temperature heat pump

The ultra-high temperature heat pump HoegTemp (Fig.2) from Enerin, is a Stirling-cycle heat pump with helium (refrigerant R-704) as working medium. As the Stirling cycle relies on compression and expansion of a gas, Stirling-cycle heat pumps are not characterized by boiling points and condensing temperatures of their refrigerant, but rather by the ratio of absolute temperatures for the source and sink.

Fig. 2. HoegTemp heat pump
The HoegTemp is a 4-circuit piston compressor heat pump of the double-acting gamma configuration. Each circuit consists of a pair of heat exchanger modules, a displacer cylinder, where a displacer piston pumps the working medium through the heat exchangers, and a power cylinder volume, where a power piston compresses and expands the working medium in the whole circuit. The power piston separates two circuits, hence the term double-acting. A pair of circuits is shown in Fig. 3. The process components are also referred to in figures 8 and 9. The heat exchanger modules consist of a source heat exchanger and a sink heat exchanger, separated by a regenerative heat exchanger, where heat is stored in steel wire.

The heat pump operates on the Stirling cycle, and due to the cylinder configuration, the two circuits of a circuit pair undergo slightly different processes, as shown in fig. 4.

The maximum heating capacity of the current implementation of the HoegTemp heat pump is 400 kW. The heat can be generated at any temperature between 20°C and 200°C. The heat pump source can be at any temperature between -10°C and 120°C. If the source temperature is higher than the sink temperature, the heat
The pump will work as a heat engine. In future implementations, the source temperature limit may be reduced to minus 250°C, and the sink temperature limit may be increased to +300°C.

Heat is transferred through closed water circuits, both for source and sink. Steam can be generated by a steam generator heated by the pressurized hot-water circuit. The heat pump has separate subsystems for oil lubrication and cooling, working medium handling and process control, diagnostics and data logging.

3. Pilot installation in biogas facility

Fig. 5 shows a P&ID of the steam generating installation. Heat is transferred to and from the heat pump through closed liquid circuits. Water is a very suitable heat transfer fluid at the temperatures of interest, but other fluids can also be used.

The cold or source side circuit (purple lines) uses pure water, and delivers heat from the external source by receiving and returning water at different temperatures. A shunt valve is used to recirculate a fraction of the water, thereby achieving two objectives:

- Control the heat pump inlet temperature
- Vary the mass flow \( \Delta T \) relationship independently from requirements set up by the external source

The hot side (sink side, grey lines) circuit uses water under pressure in a closed loop to transfer heat from the heat pump to a steam generator, without any direct contact with the external sink. The steam generator is a shell and plate design heat exchanger, where the hot side (hot side circuit) runs inside the plates, while the cold side (feed water, steam) runs between the outer shell and the plates. A pump is used to circulate the hot side circuit, pump work is predominantly caused by pressure loss in the heat exchangers of the heat pump.

Feed water (green lines) from an external source is pumped into the steam generator at the same rate that water is evaporated. Steam (red line) is finally delivered to the external heat sink at a pressure regulated by a control valve. Heat delivered from the hot side circuit is used for preheating of incoming feed water, evaporation of feed water and to a certain amount superheating of steam. It must be assumed that full crossflow conditions are not achieved in the steam generator.
3.1. Instrumentation and measurements

A complete overview of the system from the point of view of measurements is given in figure 6, with descriptions in table 1.

3.2. Accuracy estimates

The main energy streams are measured as follows:

\[ \dot{Q}_x = F_x \left(h(T_{x2}, p_{x2}) - h(T_{x1}, p_{x1})\right) \]  

(1)

If the accuracy of an instrument is generically defined as \( V = \bar{V} (1 \pm \dot{V}) \), where \( \bar{V} \) is the apparent value, \( \dot{V} \) is the relative deviation and \( V \) is the actual value, the total accuracy for the calculated energy flow is

\[ \dot{Q}_c = F \left(1 \pm \dot{F}\right) \left(\bar{h}_2(1 + \dot{h}_2) - \bar{h}_1(1 + \dot{h}_1)\right) \]  

(2)

which becomes
\[ Q_c = \bar{F} \tilde{h}_2 (1 \pm \bar{F})(1 + \bar{h}_2) - \bar{F} \tilde{h}_1 (1 \pm \bar{F})(1 + \bar{h}_1) \]  

(3)

The latter can be transformed into

\[ Q_c = \bar{F} \tilde{h}_2 \left( 1 + \sqrt{\bar{F}^2 + \tilde{h}_2^2} \right) - \bar{F} \tilde{h}_1 \left( 1 + \sqrt{\bar{F}^2 + \tilde{h}_1^2} \right) \]  

(4)

The following equation can be used instead of eqn. (4).

\[ Q_x = \bar{F} \left( \tilde{h}_2 - \tilde{h}_1 \right) + \sqrt{\left( \tilde{h}_2 \sqrt{\bar{F}^2 + \tilde{h}_2^2} \right)^2 + \left( \tilde{h}_1 \sqrt{\bar{F}^2 + \tilde{h}_1^2} \right)^2} \]  

(5)

It is assumed there is a linear relationship between temperature and enthalpy for small temperature spans (i.e. the uncertainty range of the temperature sensor)

For the cold side circuit

\[ \dot{Q}_c = F_c \left( h(T_{c2}) - h(T_{c1}) \right) \]  

(6)

For the hot side circuit

\[ \dot{Q}_h = F_h \left( h(T_{h2}) - h(T_{h1}) \right) \]  

(7)

The coefficient of performance of the heat pump is calculated as

\[ COP = \frac{Q_h}{W_{el}} \]  

(8)

The relationship with Carnot efficiency is calculated by the mean temperature of the water-side of hot and cold side heat exchangers

\[ COP_{ideal} = \frac{T_{h1} + T_{h2}}{T_{h1} + T_{h2} - T_{c1} - T_{c2}} \]  

(9)

4. Simulated performance

4.1. Main energy flows

Figure 7 shows the main energy flows in the heat pump. The electric power \( W_{el} \), the recycled heat \( Q_L \), and the useful heat \( Q_H \). The main losses are electric losses in the variable frequency drive, \( Q_{VFD} \), the electric motor, \( Q_{motor} \), and friction, \( Q_{friction} \).
During the development of the process a simulation model of the engine was developed and refined as the design evolved. The simulation model was made in Sage, which is a software package specially designed to simulate Stirling engines. Sage is developed by David Gedeon [1]. The development and use of a simulation model for an earlier heat pump, is described in detail in a previous paper by Tveit et al [2]. Sage is a 1-dimensional finite element model, where each component is divided into a small number of elements (typically 3 to 9 elements each). Inputs to the model are the principal dimensions of each gas volume in terms of cylindrical equivalents, such as diameter, length, number of tubes, Bernoulli factor *k*, surface area and wall thickness, and the operating conditions such as shaft speed, average pressure and surface temperatures. The model calculates all heat flows and pv work. Internal heat transfer may be modelled, but the authors have chosen to model such losses outside of the simulation model.

The root model consists of three pistons, connected to a crankshaft, defined by geometry, the average charge pressure of each circuit, and the circuit model, shown in fig.8. As can also be seen in fig.3 Displacer-1 separates CompVol-1 and ExpVol-1, Displacer-2 separates CompVol-2 and ExpVol-2, and PowerPiston separates PowerVol-1 and PowerVol-2 in the circuit model ‘GammaCircuits’.

The circuit model (fig.9) consists of two similar circuits, each with a compression volume and an expansion volume, connected by the heat exchangers and ducts, both circuits connected to each side of the power piston, via gas ducts. The gas flow is denoted with numbers: for Circuit 1, the connections are 6-7-20-21-9-10-29-30, and the components are shown principally in fig.3.

The simulation model takes into account certain losses, e.g., gas friction losses in the tube heat exchangers, hysteresis losses between gas and wall surfaces, but not the mechanical losses and heat losses by convection and radiation of the exposed surfaces. Internal heat transfer between parts are not included in the model either.

4.3. Decoupled losses

A model for decoupled losses, was developed, along the methods described by Lundqvist [3]. The main loss factors are defined as:

- Losses in the electric drive train: $Q_{\text{VFD}}, Q_{\text{motor}}$
- Mechanical losses outside the cylinders: $Q_{\text{friction}}$
- Mechanical losses inside the cylinders: $Q_{\text{friction}}$
- Direct heat transfer from hot to cold heat pump volumes: $Q_{\text{internal}}$
- Heat loss to the ambient: $Q_{\text{amb1}}, Q_{\text{amb2}}$

Internal heat transfer has been modelled as linear conduction, with temperature gradient and cross section. External heat transfer has been modelled as free convection and radiation.
Mechanical friction has been simulated by Daido Bearings, the bearing manufacturer for the rotating bearings. The crossheads and piston rod seals have been modelled like linear bearings, and the dry piston guide rings and piston rings, have been treated as linear dry bearings. The efficiency of the electric motor and VFD has been found from the specifications.

4.4. Simulated performance at expected operating conditions

![Fig. 10. Simulated COP for the HoegTemp heat pump](image)

Fig. 10 shows the simulated performance of the process, simulated with source temperature 30°C (average between in and out flow temperatures of the water circuit, 35°/25° would be typical) and sink temperatures ranging from 60°C to 250°C (defined as average between in and out flow temperatures of the water circuit, ΔT 10-20° would be typical), at a shaft speed of 500 RPM, which is very close to the simulated maximum COP of the heat pump, and at a shaft speed of 750 RPM, which is the rated operating point, with a heat output, $Q_H$, of 400 kW across the sink temperature range.

5. Testing at the biogas facility

During operation, the available heat source temperature varies with the ambient temperature, and with the plant operation. The installation allows a reduced source temperature, as long as it is above 5°C to avoid freezing. The maximum expected source temperature is 50°C in the summer.

The plant needs saturated steam at minimum 2 barG, but the test cell is designed to allow heating of the steam generator with higher temperature hot water, or even a higher delivery pressure, that may be throttled to 2-3 barG. The piping and systems have been designed for 16 barG and 200°C. For testing purposes, it is possible to test the heat pump with sink temperatures below 133°C (2 barG), by cooling the steam generator with cold water.

During early testing, the available source temperatures will be 5-15°C, and heat generation will be tested at 130°C to 180°C. Steam will be generated at both 2-3 barG, and at up to 7 barG.

The installation is not ready at the time of writing, so measurements are not available yet.

6. Comparison of simulated results to other high-temperature heat pumps

The simulated performance of the Enerin HoegTemp heat pump is compared to other high-temperature heat pumps in figure 11. For reference, the performance of the stirling cycle heat pump from Single-Phase Power was documented by Høeg et al [4], the performance of heat pumps described in an overview by Bless et al [5], and the peak performance points of cooling machines with natural refrigerants, presented by NTNU [6], have been included. As the Carnot COP and also the COP of a stirling cycle heat pump, depends on the temperature ratio between sink and source temperatures, the chart is presented in terms of temperature ratio rather than the
more common temperature lift. A temperature lift from 5° to 105°C corresponds to 1.36 K/K, while a
temperature lift from 70° to 170°C corresponds to 1.29 K/K, and the heat pumps would have different COPs,
and different share of Carnot COP.

\[
\text{Temperature ratio} = \frac{T_{\text{sink,in}} + T_{\text{sink,out}}}{T_{\text{source,in}} + T_{\text{source,out}}}
\]  

(10)

In order to compare the relative efficiency of the heat pump to other types of heat pumps and cooling
machines, the cooling COP relative to the cooling COP of a carnot heat pump, is plotted against the ratio of
sink temperature to source temperature, in fig.12. In the authors’ opinion, this ratio more accurately assess the
relative efficiency of different cycles, especially at high temperature lifts (large temperature fractions).

Fig. 12. Share of Carnot COP as function of temperature ratio

Fig. 11. Second law efficiency of the HoegTemp heat pump, compared to vapour compression heat
pumps
7. Conclusions

The comparison shows that stirling-cycle heat pumps may be more efficient than vapour compression heat pumps when the ratio of sink to source temperature is above 1.3 K/K. That could be 114°C heating from a 25°C source, or a circuit at 162°C/154°C to make 4 bar steam, with a source of 65°C/50°C waste heat.

Optimization of SPF or CO$_2$ emissions? Impact of control strategies on a bivalent waste water heat pump system for high energy standard buildings

Simon Callegari*, Fleury de Oliveira, Pauline Brischoux, Pierre Hollmuller

Groupe Systèmes Energétiques, Université de Genève, Bd Carl-Vogt 66, CH – 1211 Genève 4, Switzerland

Abstract

While heat pump (HP) systems could be a main solution to achieve the energy transition, their operation in actual condition of use still face specific issues, in particular when integrated in multi-energy systems with fossil complement. Based on detailed monitoring (hourly data, entire year), this paper concerns the monitoring and simulation of the heat production system of a new low energy multifamily buildings complex in Geneva - Switzerland, comprising a centralized HP on waste water (200 kW$_{th}$) and complementary gas boiler (600 kW$_{th}$). For SPF optimization reasons and in order to take advantage of the lower space heating temperatures, a seasonally differentiated operation mode was planned for the HP, with a lower temperature production setpoint in winter than in summer (when only domestic hot water is needed). However, this does in fact limit the operation of the HP to short periods, and leads to a lower HP share (45%) than expected. By way of numerical simulation, we show that alternative operation modes could induce a higher share of HP production, up to 70%. Despite a possible drop in SPF (from 3.2 in the current situation to 2.7 when maximizing the heat pump production), we highlight that this could actually lead to a better system performance in terms of CO$_2$ emissions, when taking into account the related reduction in gas consumption of the complementary gas boiler, as well as the actual hourly electricity mix for the HP.

Keywords: waste water; heat recovery; HP performance; bivalent systems; in situ monitoring; simulation; system analysis; CO$_2$ emissions.

1. Introduction

1.1. Context and issues

In the canton of Geneva, CO$_2$ emissions from the energy system represent about 4.2 t/capita, of which 2.2 are emitted by the building heat supply sector, 1.1 by the transport sector (excluding the airport), and 0.8 by the electricity sector [1]. As a result, the greatest potential for reducing CO$_2$ emissions lies in the building heat supply sector, which also accounts for nearly half of the final energy consumption delivered to consumers. In 2018, the energy consumption of this sector (climate adjusted) amounted to 5’300 GWh or 10.6 MWh/capita, and was mainly based on fossil fuels.

One of the options to valorize local renewable resources is the use of heat pumps (HP). In 2018, this technology covered 1.7% of the heat demand of the Canton of Geneva [1]. However, a set of recent prospective scenarios [1, 2] shows that the development of HPs, in combination with other production methods such as medium-depth geothermal energy, the development of district heating networks, as well as the reduction of the demand for the building stock, would allow a reduction of CO$_2$ emissions related to this sector to about 1 t/capita by 2035, respectively 0.2 t/capita by 2050.

* Corresponding author.
E-mail address: simon.callegari@unige.ch.
In this respect, it is however crucial to know and control: i) the actual performances of HP systems, in condition of use; ii) the effective thermal demand of high and very high energy performance buildings (in terms of heat load and temperature). These points are particularly crucial with regard to multifamily buildings, which represent 79% of the heated surface of Geneva’s residential building stock, against 21% for single family houses [3].

The issue of using HPs for multifamily buildings is addressed in [4], which analyzes the potentials and constraints of various cold sources (air, unglazed solar panels, geothermal boreholes, lake, river, groundwater) for different types of buildings (new and existing). In new constructions, with reduced space heating (SH) demand and distribution temperature, the important share of domestic hot water (DHW) turns out to have a significant impact on the HP performance.

In order to use the warmest possible heat sources, and with the idea that the majority of the heat demand is in winter, geothermal and hydrothermal energy are a priori well placed, since their temperature remains relatively constant during the year, unlike the outside air. However, in many cases, legislation prohibits geothermal boreholes or water collection in subsurface aquifers (protection of drinking water resources). In this respect, waste water of the proper buildings is an interesting resource, both because of its temperature level which is higher than for low enthalpy geothermal resources, and because of its local and temporal availability matching the heat demand of the buildings, especially for the heat supply of DHW.

1.2. Objectives and structure

This paper concerns the monitoring and simulation of the heat production system of a new low energy multifamily buildings complex in Geneva, comprising a centralized HP on waste water (200 kWth) and complementary gas boiler (600 kWth) with heat distribution by a local district heating.

After a brief description of the buildings and heat production system, we present the heat production balance over an entire year of operation, followed by a detailed analysis and characterization of the related subsystems (waste water pit, HP, gas boiler). CO₂ emissions are assessed by taking into account the hourly Swiss electricity mix. Finally, numerical simulation shows that alternative operation modes could induce a higher share of HP production, with a drop in SPF but a better system performance in terms of CO₂ emissions.

2. System description

2.1. Buildings

Constructed between 2014 and 2019, the residential complex under consideration consists of 7 buildings, 4 of which comply with the legal requirement of "high energy performance" (HEP) for new constructions, and 3 comply with a "very high energy performance" (VHEP) requirement, equivalent to the Minergie label [5]. In total, the complex includes 335 apartments totaling a heated area of 29’192 m², as well as 1’245 m² for extracurricular activities. The buildings are built according to an identical structure and shape (ground floor + 8 floors). Their thermal envelope differs by triple glazing for the VHEP buildings instead of double glazing for the HEP buildings, as well as by a tested airtightness for the VHEP buildings.

2.2. Heat production

The schematic diagram of the heat production is shown in Fig. 1. The waste water from the 7 buildings is collected in a central pit (approx. 37 m³), in which a filtration system retains and removes the solid waste. Heat extraction is realized by submerged heat exchanger, which is connected to the evaporator of the heat pump (HP) by way of a glycol water circuit. The cooled waste water is evacuated by a siphon from the bottom of the pit. The heat production of the HP (200 kWth) is transferred to a buffer storage (2 x 10’000 l). A condensing gas boiler (600 kWth), located downstream of the buffer, allows for complementary heat production. Except for the building that houses the boiler room and whose substation is directly connected to the primary circuit, the heat is transferred to the other six building substations by way of two heating networks (DH1 for the HEP buildings, DH2 for the VHEP buildings), which consist of classical 2-pipe distribution system. Within the substations (not depicted here), the hydraulic configuration allows for production or preheating of the domestic hot water tanks (DHW), with serial connection to the space heating (SH) distribution system.
The heat production system operates according to following alternative modes:

- **HP production** (Fig 1, left), which is engaged when the heat pump and its buffer can meet the demand (load and temperature).
- **Boiler production** (with the HP isolated from the distribution system - Fig 1, right), which is activated when the HP and its buffer can no longer meet the demand (in terms of load or temperature). In this case, in order to prevent the boiler from heating up the HP buffer via the return flow of the networks, the HP is isolated from the gas boiler and the DH networks, and operates in a closed loop for recharging of the buffer.

So as to improve the performance of the HP production and to limit the distribution losses, the system control includes temporary temperature rises (batches) several times a day for meeting the demand for domestic hot water (DHW), and differs between summer (DHW only) and winter (DHW + SH):

- In summer, the HP produces at its maximum temperature of 63°C, for covering of the DHW demand. The boiler only ensures the weekly rise in temperature for the treatment of legionella (heat production at 75°C during 2h), in which case the HP operates in closed loop with its buffer, which is maintained between 45 and 60°C (with an HP production at 63°C).
- In winter, the HP produces at 45°C, for covering of the SH demand along with preheating of the DHW tanks. As soon as there is a demand for DHW from any of the substation, the boiler ensures the production at 65°C for loading of all DHW tanks. During these periods, the HP operates in closed loop with its buffer, which is maintained between 40 and 55°C (with an HP production between 45 and 60°C).

### 2.3. Monitoring

The following data are collected from the centralized control system, in 20 minute time step, and aggregated into hourly and daily values: i) electricity for the HP, including associated circulating pumps (on evaporator and condenser side); ii) heat production by the HP and the gas boiler, as well as associated flow rates and temperatures (including HP buffer temperatures); iii) heat supply for SH and DHW production in each building, as well as associated flow rates and temperatures; iv) waste water temperatures (inlet and outlet of the waste water pit). In parallel, the inlet and outlet temperatures of the HP evaporator are collected by data-loggers placed by us.

### 3. Heat production balance

Within this study we focus on the year 2018, corresponding to the first full year of operation of the 4 HEP buildings (A, G, E, F - DH1), during which the VHEP buildings were still under construction. During that year, the heat demand (1'162 MWh, or 66.8 kWh/m²) is split between 59% for DHW and 41% for SH. The production (Fig. 2) is covered at 45% by the HP with an annual COP of 3.04 (including auxiliaries on the evaporator and condenser side), the 55% complement being covered by the gas boiler (with an efficiency of 86% on the upper heating value). While the HP provides the entire DHW production during the summer (except for the weekly anti-legionella temperature rise), in winter it essentially provides SH as well as DHW preheating, the boiler providing the DHW production.

The last 3 buildings were completed and connected to the heating network in the following year (2019). During that year, the HP was temporarily taken out of service due to repeated blockages of the waste water pit by unwanted materials from the construction site [6], reason why we do not include 2019 in this article.
4. Waste water pit

4.1. Temperatures

Operation of the waste water pit and its relationship to the HP is analyzed on the period ranging from February to December 2018, for which all the temperature data is available (in particular at HP evaporator as well as within the pit). In order to avoid intermittent operation, which make the analysis of the measurements more difficult, only the hours during which the HP operated continuously (60 min) are retained (corresponding to 85% of the HP production over the period). Finally, the filtered measurements are aggregated and analyzed in daily values (Fig. 3, left).

Analysis of this figure leads to following observations:

- The temperature at the top of the pit (waste water inlet) varies between about 28°C in summer and 18°C in winter, with an annual average of 24.5°C. Based on a DHW share of 46% (as measured over a subsequent period, see further down), the latter value is about 7 K lower than the value resulting from the mixture of DHW (at 55°C) and cold water (at 12°C), which could be due to heat losses in the buildings and in the ground, especially in winter.
- In the pit, we observe a relatively important temperature drop (12.4 K in annual average) between the top of the pit (waste water inlet) and the bottom of the pit (waste water discharge, after exchange with the HP evaporator).
- Finally, the temperature at the evaporator inlet (corresponding to the heat exchanger outlet) has an average 7.6°C, i.e. 4.4 K below the bottom of the pit.

4.2. Flowrates

By transferring the daily power extracted from the evaporator (and therefore from the pit) to the temperature loss between the top and bottom of the pit, we can estimate the flow of waste water transiting through the pit.
during HP operation. Except for a few peaks, this calculated flow is around 5 to 10 m³/h, with an average of 6.5 m³/h, i.e. 1.6 m³/h per building. For the sake of comparison/validation, hourly monitoring of the DHW consumption yields values between 0.5 and 1 m³/h per building (during day-time), and weekly readings of total water consumption yield an average share of 46% for DHW and 54% for cold water. Assuming that the cold-water consumption follows the same profile as the DHW, the total day-time water consumption would amount to about 1 - 2 m³/h per building, compatible with the value of 1.6 m³/h used here.

By comparison, the nominal flow rate in the evaporator is 36 m³/h (5.5 times higher than the 6.5 m³/h estimated for the waste water of the 4 buildings, in period of HP operation), corresponding to an evaporator inlet / outlet temperature differential of 2.2 K (i.e. 5.5 times lower than that observed between the top and bottom of the pit).

4.3. Characterization of the heat exchange

The average annual operation of the heat exchange between the pit and the HP evaporator can be characterized by way of a counterflow heat exchanger [7], which links the heat exchange efficiency ε to the flowrate ratio \( V_{ratio} \) and to the number of transfer units \( NTU \) (ratio between the heat exchange factor and the heat flowrate of the pit):

\[
\varepsilon = \frac{1-\exp(-NTU(1-V_{ratio}))}{1-V_{ratio}\exp(-NTU(1-V_{ratio}))}
\]  

(1)

Where:

\[
\varepsilon = \frac{T_{pit,in} - T_{pit,out}}{T_{evap,in} - T_{evap,out}}
\]  

(2)

\[
V_{ratio} = \frac{V_{pit}}{V_{evap}}
\]  

(3)

\[
NTU = \frac{H}{\varepsilon_{water}V_{pit}}
\]  

(4)

With the average annual operation conditions described above (Fig. 3, right), the efficiency of the waste water heat exchanger amounts to 65%, which corresponds to a \( NTU \) of 1.1, i.e. a heat exchange factor \( H \) of 8.5 kW/K.

4.4. Alternative scenarios

All other things remaining equal (load absorbed at the evaporator of 94 kW, pit inlet temperature of 24.5°C, heat exchange factor \( H \) of 8.5 kW/K), the model in question allows to evaluate the performance of the waste water / HP heat exchange, for various alternative configurations (Fig. 4):

- **4 Bld**: This configuration, which corresponds to the situation observed above, concerns the 4 buildings connected in 2018, with a waste water flow during HP operation of 6.5 m³/h, for a flow in the evaporator of 36 m³/h. It results in the observed evaporator inlet temperature \( T_{evap,in} \) of 7.6°C, respectively an evaporator average temperature \( T_{evap} \) of 6.5°C (where \( T_{evap} = (T_{evap,in} + T_{evap,out})/2 \)).

- **7 Bld**: This configuration corresponds to a waste water flow rate of 11.3 m³/h (all 7 buildings), for an unchanged evaporator flow rate. It results in an evaporator inlet \( T_{evap,in} \) of 10.9°C, i.e. an evaporator average \( T_{evap} \) of 9.8°C.

- **7 Bld + Veq**: This configuration is identical to the previous one for waste water, however with a reduced flowrate in the evaporator (11.3 m³/h, equal to the one of the waste water). As a result, the evaporator inlet \( T_{evap,in} \) rises to 13.5°C. However, the reduction of the evaporator flowrate results in an increased temperature drop in the evaporator (7.1 K, identical to that of the waste water), i.e. to an average evaporator temperature \( T_{evap} \) of 10.0°C, almost identical to the previous case.

- **7 Bld + 2 S**: This configuration corresponds to 7 buildings (without balancing of the evaporator flowrate), but with a doubled heat exchanger surface (i.e a doubled heat exchange factor \( H \)). It results in an evaporator inlet \( T_{evap,in} \) of 16.2°C, respectively an evaporator average \( T_{evap} \) of 15.1°C.
• **7 Bld + Veq + 2 S**: This last configuration combines the balancing of the flow rates and the doubling of the exchange surface, resulting in evaporator inlet $T_{evap.in}$ of 19.0°C, respectively an evaporator average $T_{evap}$ of 15.4°C, again almost identical to the previous case.

![Graph](image)

Fig. 4. Temperatures of waste water pit and HP evaporator, for various configurations.

With the connection of the last 3 buildings, the temperature in the evaporator should be around 3.3 K higher than the one observed in 2018. In principle, this performance could be further improved by 5.3 K with doubling of the submerged heat exchanger surface.

5. **Heat production units**

5.1. **Heat pump**

The dynamic of the $\Delta T$ (condenser outlet – evaporator inlet) and COP of the HP (including auxiliaries) is presented in Fig. 5. HP operation at a high $\Delta T$ mainly occurs in the summer, for DHW supply at 63°C. In the winter, the operation at a lower $\Delta T$ is mainly related to the production of SH at 45°C.

![Graph](image)

Fig. 5. HP performance (including auxiliaries) and temperature difference between condenser and evaporator ($\Delta T$), daily values (COP filtered when the heat pump operates 60min/hour, $\Delta T$ weighted by the energy supplied by the heat pump).

The 2018 SPF is 3.04 including electricity for the auxiliaries (circulation pumps on evaporator and condenser side). This value is related to an energy-weighted temperature average of 7°C at the evaporator and 56°C at the condenser, representative of the average HP operation. The corresponding thermodynamic HP efficiency hence amounts to 45% (ratio between the actual SPF and the Carnot SPF, the latter corresponding to the maximum theoretical performance, for the same operating point).

For comparison, according to the HP data sheet, operation at 14°C / 60°C announces a COP of 3.67 (195 kW thermal supply, 53.2 kW electrical consumption), corresponding to a thermodynamic efficiency of 51%. However, note that latter values do not take into account the electricity of the circulation pumps on the evaporator and condenser side.
5.2. Gas boiler

Based on manual readings of the gas and heat production meters (taken between April 2019 and January 2020), the boiler efficiency is 86%, as calculated on the higher heating value of 11.39 kWh/m³ of natural gas. This efficiency, which may seem low for a condensing boiler, is related to the relatively high operating temperatures of the boiler, mainly due to heat production for DHW, which limits the possibility of heat recovery by flue gas condensation. For the 2018-2019 period, the energy-weighted average temperatures for the boiler supply and return are 61°C and 50°C respectively. For comparison, the manufacturer announces an efficiency of 88% at a temperature regime of 70/50°C, respectively 92% at a regime of 60/40°C.

6. CO₂ balance

6.1. CO₂ content of gas and electricity

While the CO₂ content of gas is well established (228 gCO₂-eq/kWh on higher heating value [8]), the same is not true for electricity, whose origin is subject to debate. In this study, we use the Swiss consumption mix emission factor, calculated on an hourly basis [9]. This calculation takes into account domestic production and inflows into Switzerland from its neighboring countries. To do so, it uses hourly data of the production mix of the different European countries, by type of production, as well as hourly cross-border flows. On the basis of economic considerations with respect to merit order of the various types of production, it takes into account the impact of Swiss imports on the production mix of neighboring countries. Finally, the CO₂ content of the resulting electricity mix is calculated from the carbon intensity of each type of generation. During the winter of 2018, there were occasional peaks of more than 500 gCO₂-eq/kWhel, mainly due to fossil electricity imports from Germany. These peaks are much smaller in daily values, rarely exceeding 300 gCO₂-eq/kWhel. Finally, given a low-carbon electricity in summer, the annual average is 107 gCO₂-eq/kWhel. Note that this value is very close to those observed over the previous two years (105 and 108 gCO₂-eq/kWhel).

6.2. CO₂ content of the heat mix

The CO₂ content of the heat production is calculated in hourly values, based on the above data. It is represented in daily and annual values in Fig. 6. It can be seen that the dynamic of the emissions is strongly correlated to the heat demand, and is essentially linked to the use of the gas boiler, whose emissions largely dominate those of the HP. Thus, although the HP covers 45% of the annual heat production, it represents only 10% of the CO₂ emissions. In total (HP + boiler), the latter amounts to 224 tCO₂-eq (or 163 gCO₂-eq/kWhth).

Fig. 6. CO₂ emissions, dynamic and balance (daily and annual values).

In other words, given an efficiency of 86%, the carbon content of the heat production by the boiler is 265 gCO₂-eq/kWhth. Given a relatively constant COP of around 3, the carbon content of the heat production by the heat pump is 7 times lower, namely 35.4 gCO₂-eq/kWhth. As a consequence, up to an electricity carbon content 7 times higher (820 gCO₂-eq/kWhel), the HP heat production would still have a lower carbon content than that of the gas boiler.
7. Evolution and optimization potential

As we have just seen, the CO₂ content of the kWh produced by the heat pump is much lower than the one produced by the boiler, which argues a priori for the most intensive possible use of the HP. However, it turns out that with the current settings, the HP produces less in winter than in summer, despite a higher heat demand (see Fig. 2). In order to evaluate the system optimization potential in relation to the HP operation settings, we conduct an hourly numerical simulation, based on the values measured in 2018. The model also allows to evaluate the evolution of the heat production mix with the connection of the 3 additional buildings (not yet present in 2018).

7.1. Simulation model

The simulation model takes up, in a simplified way, the essential elements of the heat production system, namely: i) the HP and its buffer; ii) the gas boiler; iii) the primary distribution circuit (internal to the boiler room) and the outlet of the district heating / building substations. The algorithm, which is integrated in a spreadsheet, is executed in hourly time step.

The inputs to the model are as follows (in hourly values):

- At source level, the evaporator inlet temperature \( T_{\text{evap,in}} \), which is given by a sinusoidal between 5°C at the end of January and 12°C at the end of July, in accordance with what has been observed.
- The instantaneous heat demand, given in terms of load \( Q_{\text{dem}} \) by the demand measured at the substations, and in temperature \( T_{\text{dem}} \) by the temperature measured at the outlet of the boiler room / inlet to the district heating network (note: for simplification purposes, the thermal losses of the district heating network, as well as the phase shifts linked to the transit time to the substations, are not taken into account).

The main characteristics and parameters of the model correspond to the observed values, and are summarized as follows:

- The HP is characterized by a fixed electrical power of 50 kW, and a thermodynamic efficiency of 45%, which allow at each moment to calculate the COP and the heat production \( Q_{\text{dem}} \), according to the temperatures at the condenser and evaporator \( (T_{\text{HP}} \text{ and } T_{\text{evap,in}}) \).
- The buffer is represented by a non-stratified one-node model, characterized by a thermal capacity of 20 m³ and a single temperature \( T_{\text{buffer}} \). Depending on the imbalance between production \( (Q_{\text{HP}}) \) and demand \( (Q_{\text{dem}}) \), the buffer is used for storing/retrieving of the excess/missing heat. Its operating range is limited by upper and lower temperature setpoints, which determine the on/off switching of the HP (see the control concept below).
- The gas boiler is characterized by an efficiency of 86% on the higher heating value.

The operating modes are as follows (in order of priority), and correspond to the observed operating modes:

- HP + buffer charge: this mode is activated when the HP production is sufficient to meet the demand (in terms of load and temperature), the excess heat being stored in the buffer.
- HP + buffer discharge: this mode is activated when both: i) the HP production allows to meet the demand temperature, but not the load; ii) the buffer temperature is sufficient to meet the demand.
- Buffer discharge alone: this mode is activated when the HP is stopped (buffer setpoint reached) and the buffer temperature is sufficient to meet the demand.
- Boiler on: this mode is activated when neither the HP nor the buffer can meet the demand (temperature and/or load). In this case, the HP and the buffer are isolated from the primary distribution circuit, and operate in a closed loop, for recharging of the buffer.

Finally, in accordance with what is observed at the level of monitoring, the control setpoints are adapted according to the season: i) in summer, the HP produces at its maximum temperature of 63°C, and the buffer is maintained between 45 and 60°C; ii) in winter, the HP produces at a temperature 5 K higher than that of the buffer, which is maintained between 40 and 55°C.

7.2. Validation

Initially the simulation is carried out on the basis of the demand observed in 2018, corresponding to the first 4 constructed buildings, connected to heating network DH1 (buildings A-F-G-E).

As shown in Fig. 7 the simulation reproduces very well the share of the heat production between HP and boiler. In the case of the boiler, the difference observed on the last 2 months of the year is due to the recent connection of an additional substation (building B), which is not accounted in the demand used for the
simulation. The consistency between simulation and measurement is also very satisfactory regarding the electrical consumption of the HP, with a simulated SPF of 3.10, against 3.04 for monitoring.

![Graph](image)

**Fig. 7.** Heat production (total and HP) and HP electricity, integrated daily values, monitoring (dashed lines) and simulation (solid line).

### 7.3. Sensitivity analysis

For the sake of comparison with the base case simulated above, we perform a sensitivity analysis for following HP operation scenarios:

- **Reference**: this is the basic scenario described above, in which: i) the HP and the boiler operate in alternating mode (the HP and its buffer being decoupled from the distribution network when they cannot meet the load and temperature of the demand); ii) the HP control setpoints are adapted according to the season (with lower production temperatures in winter than in summer).
- **Alternate**: in this scenario, the HP and the boiler also operate in alternate mode, but the HP control setpoints are maintained all year round at their high values (summer setpoints of the base case).
- **Series**: in this scenario, the heat pump and the boiler operate in series, the heat pump continuing to deliver heat to the network when its temperature is high enough, the additional load being provided by the boiler. In this scenario, the production setpoints of the HP are maintained throughout the year at their high values.
- **Series + 60°C**: this scenario corresponds to the previous scenario, but the network temperature never exceeds 60°C (except for the weekly rise for the anti-legionella treatment).

Fig. 8 represents the network demand and the heat production of the HP, for these various operation modes. Moreover, the various scenarios are simulated on the one hand for the demand of the first 4 buildings (as was the case in 2018), and on the other hand for a demand multiplied by a factor of 1.75, representing in a simplified way the demand of all 7 buildings. The following qualitative observations can be made:

- While in the **Reference** scenario the HP production drops during the winter, it remains at a slightly higher level in the **Alternate** scenario, when the summer setpoints are maintained throughout the year as.
- Winter HP productivity increases significantly in the **Series** scenario, with the HP operating in series with the boiler, and reaches its full potential when the network temperature is maintained below 60°C (**Series + 60°C**): the winter productivity ceiling of 3 MWh/day corresponds to 20 hours of operation at 150 kW, i.e., the available capacity for an evaporator temperature of 5°C and a production at an average of 50°C.
- When taking into account the demand of all 7 buildings, the HP productivity increases slightly (in MWh/day), but covers a proportionally smaller fraction of the demand. We observe in particular that the HP can no longer provide 100% of the summer DHW demand. Indeed, with 7 buildings, the demand linked to DHW batches typically reaches a daily peak of 400 kW, which can no longer be fully met by the HP.
Fig. 8 represents a set of annual performance indicators (boiler share in the heat mix, CO₂ content of total thermal kWh, SPF of the heat pump), for the various operating modes above, as well as for a 100% boiler scenario. The following conclusions are drawn:

- With 4 buildings to be supplied with heat, the Reference scenario allows to reach a coverage rate of 45% via the heat pump, but this rate might drop to about 30% with the connection of the 7 buildings. These rates could in principle increase significantly with the operation of the heat pump in series with the boiler, and a high production temperature maintained throughout the year: thus the Series and Series + 60°C scenarios both show coverage rates of about 70% (for 4 buildings), respectively 50% (for 7 buildings).
- Given the low CO₂ content of the heat produced by the heat pump, the carbon content of the heat mix falls in a totally correlated way with the fall in the boiler coverage rate, despite a slight fall in the COP of the heat pump (which goes from about 3.2 in the Reference scenario to about 2.7 in the other scenarios).
- The linear correlation between the carbon content of the heat mix and the boiler coverage rate is explicitly shown in Figure 9.

Note: in this model, the evaporator inlet temperature is in all cases defined in accordance with the monitored values of the reference case. As has been seen in section 4.4, such is strictly speaking not correct for 7 instead...
of 4 connected buildings, in which case we would theoretically expect the evaporator temperature to be about 3.3 K higher. Latter would have a slight positive impact on the annual SPF and on the HP share of the heat production, but would not drastically change the insights gained by this analysis.

8. Conclusions

This paper concerns the monitoring and simulation of the heat production system of a new low energy multifamily buildings complex in Geneva, comprising a centralized HP on waste water (200 kW) and complementary gas boiler (600 kW) with heat distribution by a small-scale district heating network. For SPF optimization reasons and in order to take advantage of the lower space heating temperatures, a seasonally differentiated operation mode was planned for the HP, with a lower temperature production setpoint in winter than in summer (when only domestic hot water is needed). However, this does in fact limit the operation duration of the HP to short periods, and leads to a lower HP share than expected.

By way of numerical simulation, we show that alternative operation modes could induce a higher share of HP production, up to 70%. Despite a possible drop in SPF (from 3.2 in the current situation to 2.7 when maximizing the heat pump production), this could actually lead to a better system performance in terms of CO2 emissions, when taking into account the related reduction in gas consumption, as well as the actual hourly Swiss electricity mix consumed by the HP. At this point, it is however important to emphasize that the current performance of the system is already much better than in the case of 100% fossil fuel production, especially as the heat demand remains low overall.

As a complement, future simulation work could include additional scenarios concerning issues like: i) enhanced flue gas heat recovery by coupling with the HP evaporator, which could also enhance latter’s COP; ii) sensitivity analysis concerning HP sizing, in link with possible HP cascading.

Abstract

The improved performance of variable-speed heat pump systems has resulted in their widespread adoption globally. Heat pump rating methods such as AHRI 210/240-2023 (2020) were originally developed to characterize fixed-speed heat pump performance. Recently, load-based testing methods such as CSA EXP07:19 have been developed as a response to evidence that such fixed-speed tests don’t represent realistic performance of variable-speed systems. EXP07 laboratory test results differ significantly from AHRI 210/240 ratings, yet neither approach has been validated as representative of field performance. This paper describes a field test in which six heat pumps are installed in three unoccupied test houses in Lincoln, Nebraska (a climate with a wide range of weather conditions, with heating and cooling design temperatures of -17°C and 34°C respectively. Each house has separate ducted and ductless systems, instrumented to collect performance data; the systems alternate operation weekly. After field testing, the same units will be tested in a certified laboratory using both AHRI 210/240 and an updated load-based method, SPE-07-23 facilitating comparison between the laboratory and in-situ performance. This will allow a fair assessment of the representativeness of each rating method.

1. Introduction

Interest in efficient, variable speed air conditioners and heat pumps has gained momentum around the world as efforts to decarbonize building systems increase and performance of variable-speed systems continues to improve. In many markets, however, air source heat pumps have a lingering negative reputation among contractors and consumers, particularly in cold climates where historically poor sizing and installation practices have led to low efficiency [1-2]. Inaccurate efficiency ratings increase the potential for poor product choices, disappointed customers, and unexpected high bills. When a contractor or consumer chooses a product based on an efficiency rating, they should reasonably expect that the ratings will realistically represent that product, especially when comparing efficiency ratings of similar products. The impact of unpredictable performance ratings can reinforce existing bias, reflect negatively on utility and other publicly supported market transformation programs, and offers little motivation for manufactures to improve product performance. A 2019 study conducted for the Northwest Energy Efficiency Alliance [3] suggests that when a test procedure is updated to better represent current equipment, new energy savings can be gained from “better characterizing the energy use of the product.” The savings result from eliminating the less-reliable ratings that mischaracterize units as highly efficient, and the authors conclude that improving heat pump ratings (specifically the use of EXP07) is a high priority representing a high magnitude of new energy savings.
In 2015 the Canadian Standards Association (CSA) formed a development committee to develop testing and rating procedures that would better represent installed performance of variable capacity heat pumps (VCHPs). The relevance of Heating Seasonal Performance Factor (HSPF) and Seasonal Energy Efficiency Ratio (SEER) ratings [4] as realistic performance metrics to represent savings was increasingly called into question, and concerns included substantial variations in equipment performance when installed in climates that differ substantially from those used for the ratings. Further, in-field monitoring consistently suggested that current ratings do not predict installed performance well [5-6-7-8]. Many utilities and state/provincial agencies are increasing their market transformation efforts and funding to promote efficient HVAC installations, and are increasingly motivated to find rating metrics that reduce investment risk and improve evaluation results.

The development committee focused on variable-speed equipment, which depends on on-board firmware to operate, and for which field-measured performance has appeared to vary the most from published ratings. The result of this effort is a test procedure that includes the effects of on-board control algorithms and a wide range of outdoor conditions, driving a performance metric across a wide range of climates. CSA published EXP07:19 [9] as a technical review document; the updated version of the procedure based on technical review comment resolution has been published by CSA as SPE-07:23 [10]. Significant improvements have been incorporated with the primary intention of improving repeatability and reproducibility, yet it is expected that results of testing using SPE-07:23 will be generally similar to those using EXP-07:19.

Initial results of lab testing on numerous models using EXP07:19 have varied significantly from those units AHRI ratings of SEER and HSPF [11-12], with large variability in the load-based test results even among models with identical AHRI ratings, and very different relative rankings in relative efficiency levels for both heating and cooling performance. The load-based testing inherently includes the built-in control algorithms of variable-speed systems, whereas conventional tests require the use of “locked” or fixed-speed compressor and fan modes. The built-in controls appear to play a large role in the discrepancies in at least some cases. Although the load-based rating procedure has primarily been promoted for voluntary use (e.g. for qualified product lists and to differentiate high-performing products), stakeholders have suggested that better understanding of test-to-test repeatability, lab-to-lab reproducibility, and lab-to-field representativeness is needed to fully characterize the differences between load-based and fixed-speed testing.

Fixed-speed testing has an advantage in the rating process because steady-state operation makes measurements easier and reduces uncertainty. Load-based testing is conducted under “quasi-steady state” conditions, and depends on the behavior of built-in control algorithms, so uncertainty in the results will likely always be higher and repeatability lower. The high degree of lab familiarity with traditional fixed-speed tests (and by contrast, unfamiliarity with load-based methods) increases the potential for misunderstandings or diverse interpretations of testing procedures that can lead to discrepancies in results of load-based tests. An initial evaluation of repeatability and reproducibility [13] has shown that there is significant room for improvement. At the same time, many of the concerns raised by participants and stakeholders have been addressed during the comment process resolution leading to the updated SPE-07:23. Further study of repeatability and reproducibility using SPE-07:23 will be an important step in understanding these improvements and characterizing the differences between SPE-07 and more traditional test and rating methods. The focus of this paper is a further study, currently underway, that will focus on the representativeness of load-based and fixed-speed test methodologies to in situ field performance.

The authors of this paper are unaware of any systematic field validation of this nature that have previously been undertaken on any past versions of AHRI 210/240 and its precursors over several decades. Several studies have examined factors that introduce bias in the SEER and HSPF ratings [7-14-15]. Field studies and program evaluations generally cannot be taken as a direct comparison to standardized efficiency ratings. Many have found performance that varies from rated values, but such results can be influenced by numerous external factors including occupant behavior, indoor air conditions, duct leakage, load differences, and installation practices such as air flow and refrigerant charge. Recently, with the 2023 edition of AHRI 210/240 [16], an effort has been made to correct assumptions regarding the heating load lines used in different climates (related to both building thermal performance and equipment sizing assumptions) for both single and variable-speed equipment, and the assumed static pressure of duct systems has been increased from an unrealistically low 50 Pa (0.2 in.w.c) to 125 Pa (0.5 in.w.c) for most common ducted system types. These changes will result in new metrics of HSPF2 and SEER2, that will generally be numerically lower than those of HSPF and SEER. Both of these changes should reduce systematic bias in the new metrics, making them incrementally more representative of field conditions. However, the continued use of fixed-speed testing that ignores built-in equipment control algorithms is likely to miss some important performance variations.

Although the lab tests using CSA EXP07 revealed substantial differences between the fixed-speed ratings and load-based tests [12] and provided some evidence that these differences were largely driven by the
behavior of built-in equipment control algorithms in the load-based testing, to date there has been no clear proof that load based testing results in ratings that better approximate real-world performance. This paper describes an effort to address this gap.

2. Representativeness Study Overview

The study is divided into two phases, a field segment (Phase I, currently underway) and a laboratory segment (Phase II). Phase I studies the performance of six heat pumps installed in a field in a simulated occupancy home environment. Phase II will test the same heat pumps in an accredited lab, using both SPE-07:23 and AHRI 210/240: 2023 [16]. Comparing the test and rating results will provide insight into which method (if either) more closely matches the performance of the actual systems in the field. Equally important, the detailed field monitoring and lab test results may provide insight into what aspects of performance drive the differences between the rating methods, as well as differences between both methods and the field performance. The intent is to examine the differences between the rating methods and provide insight into how either or both methods might be improved to represent real-world performance more closely. Ratings are always models based on limited testing and assumed applications, and as such are inherently simplifications; they are typically used for purposes such as comparing different products, roughly predicting product performance, and demonstrating regulatory and/or voluntary program compliance. But systematic biases and other significant errors in rating methodologies have the potential to dilute and confuse those purposes.

Phase I is being conducted in Lincoln, NE in a residential neighborhood using three identical, unoccupied mobile homes as test houses. Each test house is outfitted with two heat pumps, one ducted and the other ductless, that are being used in alternate weeks to heat or cool each house. The heat pumps were installed and set up to run in cooling mode, with data collection beginning in mid-August 2022, and were subsequently changed over to heating mode in late October. In March 2023 the tested systems will be uninstalled and shipped to the laboratory for Phase II. This time span will include a wide range of load conditions for both heating and cooling operation.

During Phase II, the laboratory will conduct the test procedure using a modified version of SPE-07:23. The modifications will be to approximate both the load line and thermal mass capacitance of the actual houses as measured during Phase I, so that the test method can be calibrated to the buildings used in the study. The laboratory will also conduct a set of heating and cooling tests from AHRI 210/240-2023, with manufacturer cooperation to access any required proprietary test modes. The lab testing may include additional testing such as the optional H4_Cold test [16] at -15 °C (5 °F), the Min/Mild and/or the H4_Max/Cold tests as detailed in the DOE cold climate challenge specification [17].

3. Field Study Method

3.1. General approach

Each test house has two heat pumps installed; operation is alternated between the two systems approximately once each week, to capture a range of operating conditions for each. The test houses have been calibrated to approximately match the heat transfer and thermal mass characteristics of SPE-07. The test houses are operated with internal gains, and latent internal gains during cooling, to approximate occupied conditions. Detailed measurements of heat pump operating parameters are recorded, as well as conditions in the house, and outdoor conditions at the site, allowing measurements of equipment capacity and input power over the entire range of operating conditions at a 1-second time interval. All the recorded data is uploaded to a server for access and analysis.

3.2. Test house description and characterization

The test houses consist of three manufactured homes of identical design, built in 2021 at the same factory, sited in the same neighborhood and orientation to the compass. Each house has 113 m² floor area on one story (Figure 1), with low-slope vaulted ceilings and are insulated to current code requirements for manufactured homes. They are set on concrete blocks, raised off the ground level approximately 1 m. The existing heating system is an electric forced-air furnace of 15 kW nominal capacity, with a supply duct running the length of
the “belly” (enclosed joist/truss area) and a single branch duct running to each room; a single return register is located in the utility room.

![Plan View of Test House](image1.png)

Fig 1: Plan View of Test House.

The houses were tested and calibrated prior to the test period, with enclosure thermal transfer (UA) and mass capacitance measured, as well as enclosure and duct leakage. Each home has one ducted and one ductless heat pump installed. The ductless heat pumps are high-wall mounted. The ducted heat pump air handlers are mounted off the floor, with return air at the bottom and a single supply duct that terminates inside the service closet near the return grille of the central system, as shown in Figure 2.

![Ducted Indoor Unit](image2.png)

Fig. 2. Ducted Indoor Unit.

Each heat pump is controlled by a wall-mounted thermostat on an interior kitchen wall, near the entrance to the utility room. During the test period, the air handler fan of the pre-existing central furnace remains on, to promote air mixing. In addition, there are two ceiling fans, four box fans and two stand fans to mix the air throughout the house.

3.3. Test house calibration

The test method of SPE-07 relies on a model of the building load and shallow thermal mass typical of a residential building. The model is scaled to equipment capacity. The laboratory test mimics the thermal response of the modeled building as the equipment capacity varies during each load-based test condition. Measurements and modifications were made to bring the UA and mass capacitance of the test homes close to
the SPE-07 lab test values. The test method of AHRI 210/140 has no built-in assumptions about either parameter, so no conflict results from targeting those of SPE-07.

The UA can be defined as:

\[ UA = \frac{Q_{\text{heat loss}} - c}{\Delta T} \]  

Where:

- \( UA \) is the U-value times the area of the building in W/K
- \( Q_{\text{heat loss}} \) is the heat loss of the house in W,
- \( \Delta T \) is the difference between indoor and outdoor temperature in K, and
- \( c \) is the temperature-independent heat loss (internal gains)

To estimate the UA of the test houses, the houses were heated with electric resistance heaters at night to reduce transients and solar effects. By measuring the energy input and indoor/outdoor temperature differences, the UA can be estimated as the slope of a linear regression of those two variables. Figure 3 shows an example of a UA calculation for one house that is tested over a period of 26 nights.

![Fig. 3. Plot of Target CSA UA and Measured House UA.](image)

The target UA for SPE-07 based on equipment nominal cooling capacity of 5.2 kW is 199 W/K. Measurements of the three houses ranged from 160 to 169 W/K, so modifications were made to increase the heat transfer. Some insulation and air barrier materials were removed from the belly (crawlspacce) of the homes, and in each house four double-low-e glazing panels were replaced with sheet galvanized steel.

The target thermal capacitance for SPE-07 for a 5.2 kW capacity heat pump is 317 Wh/K. The capacitance of the houses was estimated by using the preexisting electric furnace and measuring the cycling rate of the furnace under a range of heating load conditions. The capacitance [18] is then calculated using:

\[ C_s = \frac{Q_{h,s,D}}{4 \cdot N_{\text{max}} \cdot \Delta T_{db}} \]  

Where:

- \( C_s \) is the thermal capacitance in Wh/K,
- \( Q_{h,s,D} \) is the heater capacity in W,
- \( N_{\text{max}} \) is the maximum cycling rate in hours\(^{-1}\), and
- \( \Delta T_{db} \) is the thermostat deadband in K

\( N_{\text{max}} \) can be determined using the following relationship [18]:

\[ N = 4 \cdot N_{\text{max}} \cdot X \cdot (1 - X) \]  

Where \( X \) is the run time fraction, which is the heat on time divided by total cycle time.
By logging the behavior of the on/off heating cycles, as shown in Figure 4, across a range of load conditions (changing outdoor temperatures), the value of $N_{\text{max}}$ can be determined empirically for each house as the slope of the linear regression formed by the cycling rates $N$ vs the product of the run fraction and its complement $X \cdot (1 - X)$, for each cycle, divided by 4. The plots for each test house are shown in Figure 5. The coefficients of determination $R^2$ are 0.96, 0.96 and 0.98 respectively for House 1, 2 and 3, indicating a strong correlation.

![Fig. 4. Measurement of Cycle Times and Thermostat Deadband to Calculate Thermal Capacitance.](image)

The value of $C_s$ for the three houses were estimated to be 282, 296, and 298, slightly lower than the target of 317, and $N_{\text{max}}$ was estimated between 4.9 and 6.8 for the three houses. In order to increase the shallow mass capacitance and increase the cycle time, 16 sheets of drywall were added to each house, divided into three rooms, and standing vertically and separated to increase surface exposure (Figure 6). The 16 sheets were estimated based on a comparison of interior surface area of a house contained within a residential home testing laboratory facility, which had been previously used to conduct validation testing and compare mass capacitance response using EXP07:19 [19].

The project schedule did not allow repeating the measurements with the final modifications in place, but data adequate to estimate the building heating and cooling loads and the equipment cycling behavior are being captured throughout the test period, so a more complete picture of the houses’ dynamic response will be understood by the end of the test period. These parameters in the SPE-07 lab tests during Phase II will then be matched to the measured houses’ performance.
The airtightness of each house was measured with a blower door, with results ranging from 3.1 to 3.9 air changes per hour at 50 Pa. The leakage impact on heating and cooling load is integrated into the overall UA value of each house and the houses are tight enough that wind effects should be small.

Fig. 6. Drywall Used to Increase Thermal Capacitance

3.4. Heat pump selection

The design heating load was estimated at 5.5 kW at the heating design temperature of -15 °C. This was done by analyzing billing data of identical homes, and with standard load calculations. The design cooling load was calculated to be 5.2 kW at a design temperature of 35°C. Heat pump models from manufacturers who are engaged in the project were selected, so that the manufacturers will be able provide testing support during Phase II to ensure that the proprietary test modes required for AHRI 210/240 testing can be accessed properly. Five of the selected systems are variable-speed, and one (a ducted system) has a 2-stage compressor. The variable-speed systems are all considered “cold-climate” systems according to the NEEP cold-climate air-source heat pump listing specification [20], whereas the 2-stage system (Unit B in Figure 7) has a steeper drop of heating capacity at colder ambient conditions, typical of more conventional heat pumps. It was important to choose systems that are not significantly oversized, so that they will typically run at full speed operation near design conditions and modulate well across a range of heating and cooling load conditions. Figure 7 shows the systems’ heating and cooling capacities, compared with the estimated heating and cooling design loads. Because the UA measurements were done on the houses in advance, actual heating loads could be estimated with reasonable confidence, whereas cooling loads are driven by solar gain, which could not be measured in advance of test period.

Fig. 7. Installed Heat Pump Heating and Cooling Capacities and Design Loads.
The heat pumps were installed carefully following manufacturers’ specifications, with line lengths selected to require no adjustment to refrigerant charge amount. Line lengths were calculated to account for the interior volume of the mass flow sensors and bypass piping. Most systems’ outdoor units came pre-charged, so that no refrigerant was added during installation. Two of the systems were charged at the site. Both had charge weighed in, and the charge amount was confirmed by comparing the liquid line subcooling measurement to the manufacturer specification.

Figure 8 shows a typical ductless outdoor unit installation, and one steel window panel, which was used as a location for mechanical penetrations.

3.5. Example test results

The systems were operated in cooling mode from 19 August and switched over to heating on 25 October, 2022, and are expected to run through early March 2023. The outdoor temperatures have ranged from 39.4 °C (103 °F) to -25 °C (-13 °F), providing a range of operating conditions that exceeds the normal design conditions. The units within each test house were alternated at intervals ranging from 3 days to a week. Figure 9 shows an example of two of the units operating from noon until 8:00 AM the following morning, during which a peak 39 °C ambient temperature occurred. The power to unit D (House 1) modulated over a wider range during the hottest hours, while unit F (House 3) appears to modulate more smoothly, and uses about 70% of the energy of unit D. Unit D appears to manage the supply air temperature within a narrow range when the cooling load is large. Analysis is still in progress, so calculated values (e.g., capacity) are not available at the time of writing.

Fig. 9. Systems D and F in Cooling Mode During a 20-hour operating period with a 39 °C Peak Ambient Temperature.
Each of the houses has almost 100 sensors connected to a data acquisition system (DAQ), which is cloud-connected, allowing real-time monitoring. The sensors provide a comprehensive set of measurements within the house, such as temperatures in important locations, and of the heat pumps. Electrical power is also monitored at end uses, including the heat pumps and air handlers, and for the house overall, so that internal heat gain is known. The set of monitored variables facilitates characterization of the houses’ cooling and heating loads, as well as the capacity and efficiency of the heat pumps. Heat pump capacity is characterized both on the air-side (by measuring the air flow rate and the indoor coil entering and leaving temperature and humidity) and on the refrigerant side (by measuring refrigerant mass flow rate and characterizing enthalpy entering and leaving the indoor coil with temperature and pressure measurements). This provides redundant measurement of the key variable, heat pump capacity.

Coriolis mass flow sensors are used to measure refrigerant mass flow. Cutting into the liquid line was considered to be too invasive; for most systems it would involve substantial modification of the outdoor unit, and removal then replacement of the refrigerant. Instead, the mass flow sensors were installed in the line set, which carries vapor or mixed-phase refrigerant, depending on the mode of operation and the location of the expansion devices. Mass flow sensors can only measure single-phase refrigerant, so the sensors were located to provide vapor flow measurements.

Some systems do not have a pressure port that allows measurement of the high side pressure during cooling mode, which is needed to calculate liquid line enthalpy (that can be assumed to equal the enthalpy at the evaporator inlet). Because the outdoor unit could not be modified, additional pressure ports could not be added. In these systems, the pressure is inferred by measuring temperature at several locations in the condenser, finding the region of saturation, and using the saturation pressure at that temperature. Figure 10 shows two indoor units with the Coriolis mass flow sensors installed in the refrigerant lines near an indoor unit.

![Fig. 10. Ducted (left) and Ductless (right) Indoor Units, Showing Refrigerant Mass-flow Sensors.](image)

The houses each have temperature and humidity sensors measuring the air condition in several locations throughout the house. Each house also has temperature sensors on the: (1) interior surface of the drywall; (2) the outward-facing surface of the drywall; and (3) in the middle of the wall cavity. These trios of sensors are located on: (a) an interior wall; (b) a south facing wall; and (c) on a north-facing wall. A temperature sensor is also located at the location of the thermostats controlling the heat pumps. Outdoor conditions – temperature, humidity, wind and solar irradiance – are monitored with a weather station, and each outdoor unit is also outfitted with radiant-shielded temperature sensors in the air intake of the outdoor unit. Finally, condensate from the evaporator in cooling mode is measured with a tipping-bucket type sensor.

Table 1 gives a list of typical measurements in each house.
Table 1: List of measurements in each house

4. Future Comparison of Lab and Field Performance

Properly comparing field performance and the two types of rating approaches requires that each system be run through the entire SPE-07 and AHRI testing process. From that process unofficial efficiency performance metrics can be calculated for each tested system, which may or may not correspond closely to the catalogued ratings. Further, because the load-based approach in SPE-07 inherently includes a virtual model of the building load and mass capacitance (scaled to the size of the tested system), this virtual model will be adjusted to match the actual test houses, to make the comparisons more meaningful. The initial characterization testing of the three houses showed that they were quite close to the SPE-07 virtual building model, providing an initial validation that the SPE-07 virtual building model is reasonable.
Finally, to compare the field- and lab-tested performance fairly, the field performance of each tested system will be characterized by a performance curve, primarily capacity and input power over a range of outdoor temperature conditions. That performance curve will then be fitted to the prototypical climates that have been defined for each test method, to create field equivalent performance metric results for each rating procedure, that can be compared with the unofficial efficiency performance metrics from the laboratory testing. The performance curve can also be fitted back to the actual weather from the field test sites, to determine how closely the simplified curve approximates the actual seasonal performance during the test period.

Besides simply making numerical comparisons of the unofficial rating results, the analysis will examine where in the testing processes there may be the largest discrepancies, and whether there are other factors that create systematic bias or other errors in one or both ratings methodologies.

5. Conclusions

This project is unique because it will provide field data that can be directly compared to multiple lab test methods. Having six heat pumps tested in nearly identical homes, under identical use patterns but without occupant behavior, enables researchers to evaluate how effective current and future test procedures are at generating representative ratings. Much of the lab testing to date [8-11-12] has shown that conducting tests under a heat pump’s built-in algorithms sometimes reveals performance issues for variable speed and single speed heat pumps alike. As heat pumps increasingly become microprocessor controlled, it is imperative that we learn what conditions are most sensitive to the effects of built-in control algorithms. This research project will be able to inform improvements that can be made to both load-based and fixed-speed test methods, to provide ratings that better inform contractors and end users which product will perform better for their climate conditions. In addition, more representative test procedures can lead to better input parameters for simulations that are used for electrical utility forecasting and grid resilience, energy code compliance, engineering analysis and system designs.

In-situ monitoring of a groundwater heat pump for a low-temperature district heating network: energy performance, issues and challenges

Pauline Brischoux\textsuperscript{a,\*}, Stefan Schneider\textsuperscript{a}, Pierre Hollmuller\textsuperscript{a}

\textsuperscript{a}University of Geneva, 66 Bd Carl-Vogt, 1205 Geneva, Switzerland

Abstract

With the development of district heating networks and the need for decarbonization, heat pumps in district heating are expected to play a major role in the upcoming years. To facilitate the implementation of such systems by sharing lessons learned, this study presents monitoring results of a large-scale heat pump supplying a low-temperature district heating network (LTDH) in Switzerland. Detailed monitoring over a whole year of operation reveals an annual heat production of 8 GWh, of which 85\% is covered by the heat pump with an annual SPF of 3.69 (pumping and auxiliaries excluded). However, about 25\% of the heat for space heating is produced with very low energy performance. Analyzing the influence of temperatures and flow rates on the heat pump energy performance brings to light potential optimizations of the system and improvements for future LTDH. In particular, the results raise crucial questions related to heat pump sizing and domestic hot water production methods with LTDH, as well as reaffirm the importance of optimizing substations return temperatures when the main heat generator is a heat pump.

1. Introduction

1.1. Context

In 2015, around 45\% of the total European energy consumption was due to the heat supply of buildings for space heating and domestic hot water, and was based at 66\% on fossil fuels [1]. This sector hence represents a huge potential for the reduction of greenhouse gas emissions.

District heating networks (DH) have long been recognized as a means to decarbonize the heat supply in dense urban areas, as it allows the use of waste heat, which would otherwise be rejected in the environment, and facilitates the integration of renewable energies.

However, renewable energy sources such as geothermal heat, solar heat, surface or underground water are often available at low temperature, unfit for direct use. Thus, their integration into buildings heat supply often requires a temperature lift with a heat pump (HP), either centralized or decentralized.

Therefore, with the development of DH and the need for decarbonization, HP are expected to play a major role in the upcoming years. Heat Roadmap Europe 2050 (HRE2050) prospective scenario [2] shows that DH could cost-effectively cover 50\% of the total heat demand by 2050, compared to 12\% currently, with 25\% of the heat supplied by large-scale HP (520 TWh/year with a COP of 3 and a total capacity of 40 GW\textsubscript{th}).

Large-scale HP are already in use across Europe for the supply of DH networks. A study made in 2017 [3] identifies 149 units (≥ 1 MW) across 11 European countries, installed between 1981 and 2016, for a total capacity of 1.6 GW\textsubscript{th} (25 times lower than the HRE2050 scenario). This study also shows that many large-scale HP were commissioned in the last decade in several countries such as Finland, France, Denmark and Italy.

* Corresponding author.

\textit{E-mail address:} pauline.brischoux@unige.ch.
Despite their use on many systems since the 1980s, there are still barriers to the implementation of HP in DH networks [4], such as the lack of knowledge compared to other technologies (like biomass or gas boilers) and investment cost. Therefore, documentation on existing projects could increase confidence of stakeholders, increase energy efficiency as well as reduce operation and maintenance costs of such systems. IEA HPT Annex 47 [5] produced a short description of 44 case studies of HP in DH networks to show examples of implementation. However, detailed information on the challenges/issues encountered are not always provided.

1.2. Objectives

The present study consists in analyzing the energy performance, in actual conditions of use, of a large-scale HP supplying a low temperature district heating network (LTDH). The aim is to determine whether the HP achieves the expected performance and to identify possible areas for improvement. This provides insight not only on this specific system, but also for the optimization of other existing or future HP in LTDH systems.

Based on detailed monitoring data over an entire year of operation, we first compute daily and annual energy balances of the HP to get an overview of its energy performance. Then, we proceed to an hourly analysis to examine the influence of various parameters on the HP performance, such as temperature levels and flow rates. Finally, based on the results of this study, we make recommendations regarding the use of large-scale HP in LTDH.

2. Case study

2.1. Description

The case study is an eco-district located in the canton of Geneva, Switzerland. It hosts around 1’350 dwellings and various activities, totaling 170’000 m² of conditioned floor area. A local low temperature district heating network (LTDH) distributes heat to the buildings for space heating (SH) and domestic hot water (DHW). Because all connected buildings meet high energy performance standards, the LTDH supplies heat at a low temperature level (50°C). At fixed time, twice a day, the temperature of the network is raised from 50°C to 65°C to heat up DHW tanks within the buildings over a 2-hour period. Compared to a network operating at a constant supply temperature of 65°C, these DHW batches lower DH heat losses and increase the energy performance of the heat production.

As shown in Fig. 1, the LTDH is mainly supplied by a 5 MWth heat pump (HP), whose heat source is shallow groundwater. Before reaching the HP, this cold water at approximately 12°C supplies a district cooling network, recovering waste heat from the nearby industries, thereby increasing the resource temperature for the HP and improving its efficiency. As a result, the HP source temperature ranges between 12°C (during the winter) and 16°C (during the summer). The HP delivers heat directly to the LTDH and the surplus is stored in two buffer tanks of 20 m³ each (i.e. a total volume of 40 m³) to add inertia to the system.

In addition to the HP, the LTDH is also connected to Geneva’s high-temperature district heating network (HTDH), as complementary or back-up source. The objective is to cover at least 80% of the annual heat demand with the centralized HP, and reach a HP seasonal performance factor close to the nominal values presented below, pumping and auxiliaries excluded.

The HP has two variable-speed compressors, operating in parallel for SH mode or in series for DHW mode (to reach higher outlet temperatures). It admits condenser inlet temperature ranging from 20°C to 45°C, though it only stops when the temperature reaches 50°C to prevent damage. According to the manufacturer [6], the nominal coefficient of performance (COP) of the HP for each operation mode is as follows:

- DHW: COP of 3.62, for inlet/outlet condenser temperatures of 45°C/65°C
- SH : COP of 4.60, for inlet/outlet condenser temperatures of 35°C/50°C

It should be noted that these values are given for an evaporator inlet temperature of 12.5°C, i.e. the temperature of the water at the pumping site. The increase in temperature of this resource due to the heat supplied by the district cooling customers allows in principle to reach slightly higher COP.
2.2. Monitoring

To evaluate the actual energy performance of the HP, we analyze monitoring data for a whole year, from June 2019 to June 2020. This time interval corresponds to the first year of operation of the HP and has the advantage of including all possible types of operation, namely:

- A summer period (from June to August 2019) where the HP operates only 4 hours per day (two 2-hour batches) for the preparation of DHW at 55°C-65°C.
- Mid-season periods (from September to October 2019 and from March to May 2020) during which the HP operates not only in DHW mode during the batches (at 55°C-65°C), but also in SH mode intermittently (at 50°C).
- A winter period (from November to March 2020) during which the HP operates almost continuously to maintain the LTDH at 50°C for SH of buildings, and at 55°C-65°C for DHW batches 4 hours per day.

Except for a few breakdowns in February and March 2020, partially due to high condenser inlet temperatures exceeding the HP limits of operation, the HP runs during most of the period. It stops voluntarily at the end of the heating season (mid-May) to test the behavior of the LTDH when the HTDH covers the entire heat demand during the summer.

Data is collected from the system with a 10-min time step and aggregated on an hourly, daily and annual basis. As indicated in Fig. 1, it includes, but is not limited to: i) energy meters, with their corresponding flow meters and temperature sensors, on the evaporator and condenser of the HP, as well as on the HTDH supply; ii) electricity meters on the HP compressors; iii) temperature sensors in the buffer tanks, in particular at the bottom of each tank, as well as on the DH return.

Since the high temperature DHW batches occur at fixed time each day, it is possible to dissociate the heat produced in DHW mode from SH mode (i.e. outside the batches) based on the timestamp. The DHW batches start at 5:00 and end at 7:10 each morning and evening.

The energy performance of the HP is evaluated on an hourly (COP) and annual basis (SPF) as the ratio of the heat produced at the condenser to the electricity consumption of the HP compressors (i.e. pumping and auxiliaries excluded).

To check the validity and consistency of the data, we calculate the hourly and daily energy balances between the load side (condenser) and the source side (evaporator and electricity) of the HP. Following the observation of the data, the limit is set at ±10% error on the HP balance. Results exceeding the limit are excluded from the analysis. Similarly, outlier COP values are excluded (COP > 7 and COP < 1).
3. Results and discussion

3.1. Energy balance

Fig. 2a shows the daily and annual energy balance between energy source (HP evaporator, electricity and HTDH) and heat production per operation mode (SH / DHW).

The total heat production varies from 7 MWh/day in summer to nearly 50 MWh/day in winter. The heat production in DHW mode, i.e. during the high temperature batches (55°C-65°C), has a seasonal effect: it goes from 7 MWh/day in summer to about 12 MWh/day in winter. It is important to note that this corresponds to the heat production during this period of the day, and not the buildings DHW demand, because the HP stops at the end of each DHW batch and lets the DH temperature come back down to SH level before turning back on. Therefore, part of the heat produced during the DHW batches is used after the batch for SH. This control logic is visible on typical days presented later in Fig. 5.

The total heat production amounts to about 7.98 GWh, with a HP coverage of 85%, thus meeting the target of 80% despite the HP breakdowns (February-March). The HP produces 6.78 GWh of heat with an electricity consumption of 1.84 GWh, leading to an annual SPF of 3.69. Over an entire year of monitoring, the ratio of heat produced during the DHW batches, i.e. between 55°C and 65°C, to the total heat produced is close to 52%. Outside the heating season, from June to early October 2019, the SPF value of 3.25 is lower than the annual SPF (Fig. 2b). It corresponds to the operation of the HP in DHW mode only. During the heating season, from October 2019 to June 2020, the SPF is higher (3.77), indicating that the COP of the HP in SH mode is higher than in DHW mode, as specified by the HP manufacturer. In this regard, the highest daily SPF match the days with the highest share of SH.

![Fig. 2a](image)

![Fig. 2b](image)

3.2. Measured and expected energy performance

Comparing hourly values of the measured COP with the expected COP provides a more accurate assessment of the HP performance, per operation mode (SH / DHW), than the daily or seasonal SPF presented before. In this regard, Fig. 3 shows, for each operation mode, the distribution of the measured hourly COP in bins of width 0.25, as well as the corresponding cumulative heat output, aggregated from the lowest to the highest COP. Vertical lines represent the measured SPF, as well as the expected COP provided by the manufacturer. These results confirm that the COP in DHW mode is generally lower than in SH mode.
In SH mode, the COP varies greatly, from 2.2 up to 5. A large share of the measured COP (41%) exceeds the expected COP of 4.60 provided by the manufacturer. The corresponding heat production represents nearly half of the heat production of the HP in SH mode. On the other hand, more than a third of the measured COP are below 4, representing about 25% of the heat production. For the whole period, the SPF (4.28) is only 7% below the nominal COP (4.60). Operation with high COP thus largely compensates for operation with very low COP. Hence, while the annual performance in this mode is close to expected, it could exceed expectations thanks to optimization measures.

In DHW mode, the COP is more stable as it varies from 2.8 to 3.5, but never reaches the COP announced by the manufacturer (3.62). While 45% of the measured hourly COP are below 3.25, most of the heat production (74%) is done with a COP between 3.25 and 3.5. Overall, the SPF is equal to 3.32, which is 8% less than the nominal COP (3.62).

![Fig. 3. Distribution of measured hourly COP per bins of width 0.25 (histogram), cumulative heat production aggregated from the lowest COP to the highest (black dots) and comparison with the manufacturer’s data (vertical lines).](image)

It should be noted that the results presented in Fig. 3 are based on available hourly data. As explained earlier, some data are either missing or inconsistent and have been excluded from the analysis. In the end, the valid hourly data presented correspond to a total heat production of 4.4 GWh, i.e. 64% of the HP heat production during this period.

With an annual electricity consumption of 1.84 GWh (Fig. 2), the HP is one of the main electricity consumer of the district since it represents about 30% of the total electricity demand (including heat pump and auxiliaries, as well as buildings’ electricity consumption). Thus, even though the measured performance of the HP is close to the expected performance, there is a potential for optimization in both operation modes that could lead to significant electricity savings. To identify causes of low COP, the following sections focus mainly on SH mode. Reasons behind COP higher than the nominal COP in SH mode or lower than nominal COP in DHW mode could not be identified from the available information.

### 3.3. Factors of influence

To explain the performance gap between theoretical and measured COP and to identify optimization strategies, we first investigate the influence of the inlet and outlet temperatures at the evaporator and condenser.
The only temperature which can explain variations in COP within a given operation mode (SH / DHW) is the condenser inlet temperature, because: i) the evaporator inlet temperature is stable in SH mode, i.e. about 13°C, and varies only slightly in DHW mode (from 13°C to 16°C); ii) the condenser outlet temperature, i.e. the production temperature, is a setpoint for each operation mode (50°C in SH mode, 55°C at the beginning of the DHW batch and 65°C for the rest of the DHW batch). According to the system diagram in Fig. 1, the condenser inlet temperature results from two elements: i) the temperature at the bottom of the buffer tanks of the heating plant and ii) the DH return temperature.

Fig. 4a shows the measured hourly COP as a function of the temperature difference (ΔT) between the condenser inlet and the evaporator inlet, as well as the average temperature at the bottom of the storage tanks (color). As expected, the COP is higher in both operation modes when the ΔT is lower. The COP in SH mode is very sensitive to the ΔT; it varies from 2.2 for a ΔT of 28°C, to about 5 for a ΔT of 18°C. Furthermore, when the ΔT is lower than 23°C, there are significant variations in the COP, ranging from about 4 to 5 for the same ΔT. On the other hand, the COP in DHW mode is relatively unaffected by the ΔT since it varies from 2.8 to 3.5 over a wider range of ΔT, from 20°C to 38°C. In both modes, except for COP greater than 4 in SH mode, there is a clear correlation between the buffer tank temperature and the COP: the lower the temperature at the bottom of the tanks, the higher the COP. Besides, in DHW, the bottom of the tank reaches temperatures up to 50°C, which corresponds to the temperature at which the HP shuts down to prevent damage.

Not presented here, the same analysis with the DH return temperature instead of the buffer tanks temperature shows that, in SH mode, there is no systematic correlation between the DH return temperature and the COP. Whereas in DHW mode, results are similar to those of the buffer tanks temperature. Hence, the temperature at the bottom of the tanks is the main source of increase of the return temperature to the HP in SH mode. In DHW mode, the condenser inlet temperature is influenced both by the DH return temperature and by the temperature at the bottom of the tanks.

However, the variations of the condenser inlet temperature alone do not explain why, in SH mode, the hourly COP varies between 4 and 5 for the same ΔT of about 20°C (Fig. 4a). As shown in Fig. 4b, this is due to variations in condenser flow rate. The highest COP (4.8 to 5) occur for condenser flow rates of 90 m³/h or more, while the lowest (below 4.5) correspond to flow rates below 75 m³/h. Intermediate values are associated with the transition phase between these two flow rates.

Therefore, the COP of the HP is mainly influenced by: i) the condenser flow rate (Fig. 4b) and ii) the condenser inlet temperature, itself mainly influenced by the temperature at the bottom of the buffer tanks (Fig. 4a). The performance of the HP in SH is highest for flow rates above 90 m³/h and low condenser inlet temperatures (< 35°C).

Fig. 4. Influence of the condenser flow rate and the temperature at the bottom of the buffer tanks on the hourly COP of the heat pump.
3.4. Typical Days

To understand more precisely the mechanisms involved in the degradation of the COP in SH, Fig. 5 presents typical days of operation of the HP during the winter. The location of the temperature sensors used to produce this figure is shown in the schematic of Fig. 1, where the colored circles correspond to the color of the lines. During those days (December 6th to December 8th), the HP operates at all times, except for approximately an hour and a half after each DHW batch, where it stops until the LTDH temperature lowers back to SH temperature levels (50°C).

The system dynamics indicates that low COP in SH generally occur before the DHW batches, while they are the highest after, following the temporary shutdown of the HP. During SH cycles c2 and c3, there is a significant degradation of the COP, since it goes from 5 at the beginning of the cycle to about 3 at the end. First, the condenser flow rate decreases from 90 to 70 m³/h. Then, while the condenser flow rate is greater than the DH flow rate, the temperature at the bottom of the buffer tanks increases significantly (up to 50°C), thereby increasing the condenser inlet temperature. In SH cycle c4, the degradation of the COP is less important than for the two previous cycles (c2 and c3) because the temperature at the bottom of the storage tanks remains low (around 34°C). There is only a reduction of the condenser flow rate in the middle of the cycle (between 1:00 a.m. and 3:00 a.m.). The only SH cycle illustrated here for which the COP of the HP is stable is cycle c1, during which the condenser flow rate remains high (equal to about 90 m³/h) and the temperature at the bottom of the tanks stays in the 30-35°C range. It is important to note that, in SH mode, the DH return temperature is stable. This indicates that, at this time of year, the degradation of the COP in SH is not due to high return temperatures from the DH substations. In DHW mode, the DH return temperature often reaches 50°C or more at the end of the batches, which can damage the HP and force it to shut down.

During the mid-season, the COP degradation phenomenon is amplified due to high imbalance between demand and HP production. Furthermore, the increase in condenser inlet temperature is not only due to an increase in buffer tank temperature, but also to high return temperatures of the DH substations.

![Graph showing typical days of operation of the HP during the winter.](image)

Fig. 5. Typical days of the system for December 6th to December 8th 2019. Gray background indicates the DHW batches. Refer to Fig. 1 for the location of temperature sensors.

In summary, the COP degradation phenomenon observed throughout the year can be caused by two elements:

- The high HP capacity compared to the demand which leads to: i) a reduction of the condenser flow rate to adapt to the demand, and ii) an increase of the buffer tanks temperature caused by storage of excess heat production.
• The substations and buildings control for SH which results in high DH return temperatures, in particular during the mid-season. Possible reasons are: i) a non-optimal control of the building SH circuits, which leads to high return temperature on the secondary side of the substations, thereby causing high return temperatures to the DH; ii) an excessive flow rate on the primary side of the substations, which leads to a low temperature difference between the inlet and outlet on that side, and thus to high return temperatures, regardless of the return temperature of the SH circuit on the secondary side.

3.5. Discussions and recommendations

The use of a HP with such a high capacity when the DH demand is low leads to an unsolvable problem. When the condenser flow rate is higher than the DH flow rate, the bottom of the tanks quickly heats up and increases the condenser inlet temperature. If the DH flow rate is increased, for the same heat demand, then the DH return also heats up. A solution would consist in lowering the production temperature of the HP: either punctually when the demand becomes too low during a SH cycle, or in a more systematic way by applying a heating curve to the DH supply temperature as a function of the outdoor temperature. This would allow to keep a relatively high flow rate at the condenser and to increase the DH flow rate while keeping DH return temperatures low.

It should be noted that the maximum capacity of the HP is 5 MW. However, the maximum heating power measured over this period is only about 2.5 MW in SH mode, while it reaches 4 MW in DHW mode. This difference between the two operation modes seems mainly related to the DHW batch system, gathering the whole daily DHW production in only 4 hours. Therefore, even if these batches avoid supplying the network constantly at 65°C, it raises an interesting point as for the sizing of the HP required for such a strategy, and thus of the necessary investment.

More generally, this analysis leads to the following recommendations, related to this case study in particular, but also to other HP in DH:

Control logic:

• Adapt the DH supply temperature to the outdoor air temperature to prevent operating with flow rates below the HP’s operating limits, and thus degrading the HP performance. However, special attention should be paid to the network flow rates as such implementation leads to reduced temperature difference between DH supply and return, i.e. to higher DH flow rates. Therefore, to be beneficial, the increase in HP COP must compensate the additional electricity consumption for pumping.

• Stop the HP sooner and operate on the DH inertia to avoid reducing the flow rate and/or overheating the buffer tanks. The disadvantage of this solution is that heat pumps need time between each cycle to preserve their lifespan. It is thus challenging to decide when to switch it off, knowing it cannot turn back on immediately. Furthermore, if the HP stops shortly before a DHW batch, then the network temperature will decrease below 50°C. It will therefore take longer to reach the 65°C setpoint at the beginning of the DHW batch. As a result, it may prevent the DHW tanks within the buildings from being fully charged and thus cause comfort issues.

• Optimize DH substations to prevent high return temperatures, as pointed out in [7, 8], as high return temperatures reduce the HP energy performance and force it to shut down when it exceeds the operating limits. Such optimization might not only increase the HP performance, but also the overall efficiency of the district, if the faults identified also affect the energy performance of the buildings. For example, as shown in previous work [9], some buildings seem to have a high cut-off temperature of their SH system (> 15°C) despite their highly insulated thermal envelope. This suggests that some buildings are over-heated. Optimizing the control of the heat distribution system for these buildings would thus avoid having very low SH demand when the outdoor temperature is relatively high.

Sizing and system concept:

• Use several smaller HP instead of one high capacity HP, to better adapt to the DH demand and prevent overproduction compared to the demand, especially if the storage volume is low. This could however make the system control strategy more complex than with a single HP, because it is then necessary to manage several HPs.

• Install bigger volumes for thermal storage compared to the minimum capacity of the HP, to allow the HP to operate longer without overheating the storage and degrading the COP. Needless to say, there are economical and spatial constraints to such solution.
• **Use another strategy for DHW preparation**, as the DHW batch system leads to high return temperatures and causes HP breakdowns. It adds complexity to the system, both in terms of control strategy and equipment sizing compared to a substation that has the possibility to charge DHW tanks at any time of day. In addition, there has been complaints from building occupants regarding the lack of DHW, usually happening in the afternoon. Because supplying the DH network at 65°C at all time would mean achieving an annual SPF of 3-3.5 rather than 4-4.5, other, more energy efficient solutions should be explored. For example, installing booster heat pumps [10, 11] or flat substations [12, 13] with instantaneous water heating would allow to operate the network at lower temperatures than 65°C at all times, thanks to the limited risk of legionella bacteria proliferation. Both options would grant constant access to DHW preparation, thus an improved comfort for the occupants.

4. Conclusions

This study concerns the analysis, in actual conditions of use, of the energy performance of a large-scale heat pump supplying a low temperature district heating network. One of the specificities of this concept is that the district heating network is maintained at 50°C, and at fixed time, twice a day, its temperature is raised from 50°C to 65°C to heat up domestic hot water tanks within the buildings (batch).

Monitoring results show that the heat pump reaches an annual SPF of 3.69 (pumping excluded) and covers about 85% of the district heating demand. While the heat pump energy performance is close to the expected values (6-8% lower), the heat pump electricity consumption represents about 30% of the total electricity demand of the district, it is thus a consumption worthwhile to optimize.

The analysis of detailed monitoring data indicates that low energy performance is associated with low condenser flow rate and high return temperatures. This is mainly due to the high capacity of the heat pump compared to the demand and the storage volume, which leads to: i) a reduction of the condenser flow rate to adapt to the demand, and ii) an increase of the buffer tanks temperature of the heating plant, caused by storage of excess heat production. Furthermore, in mid-season, high return temperature from district heating substations in space heating also participate to the reduction of the heat pump performance, likely due to substations malfunctions. In domestic hot water mode, all substations of the district tend to have a high return temperature, partially due to the complexity of the domestic hot water batch strategy (control, equipment sizing, storage stratification etc.).

To prevent unexpectedly low energy performance of large-scale heat pumps in district heating, it is necessary to consider, but is not limited to, the following aspects: i) heat pump(s) and buffer tank sizing, which should allow to cover the highest demand, but also the lowest to avoid overheating the buffer tank; ii) control of the system, such as the use of a heating curve on the supply temperature of the network to operate the heat pump(s) at the lowest temperature possible, as well as to prevent high capacity heat pumps from operating at flow rates below operating limits; iii) substations monitoring and optimization, which allows to reduce the district heating return temperature to the heat pump(s), thereby increasing the energy efficiency and avoiding heat pump(s) shutdowns; iv) domestic hot water production strategies, as the batch system used in this case study has proven to be more challenging than anticipated, adding complexity to control and sizing of the system (heating plant and building substations) to guarantee the operation of the heat pump, the energy efficiency of the system and occupants comfort.

Because heat pump in district heating systems are expected to develop massively in the upcoming years, it would be interesting to explore alternative solutions to this concept, in actual conditions of use, such as the use of decentralized solutions for the domestic hot water production.

Abstract

Decarbonization of industrial processes is one important step towards a sustainable future. The usage of high-temperature heat pumps to provide heat for industrial processes is a promising way towards that goal. Heat pumps used for such high temperature applications have a large difference between condenser and evaporator pressure and therefore the losses due to irreversible dissipation within the expansion process are high. To make high-temperature heat pumps more efficient and therefore interesting for industrial applications, the ejector, which is an alternative expansion device to replace the conventional throttle valve, is investigated. The flow inside an ejector of a high temperature heat pump is simulated numerically to gain better understanding of the underlying fluid flow phenomena, its applicability to heat pump cycles and to give an outlook on possible cycle efficiency improvements.

To reduce the computational demand of simulating the two-phase flow inside the ejector and to avoid the need for experimental-based fine-tuning as opposed to a full multiphase model, the Homogeneous Equilibrium Model (HEM), which assumes thermal and mechanical equilibrium between both phases, is applied. This model was implemented into the commercial Computational Fluid Dynamics (CFD) software Ansys Fluent. The main flow features are analyzed, and phenomena occurring at unfavorable operating points, obtained through an unsuitable geometry, are identified.

1. Introduction

Performance enhancement of high temperature heat pump systems is an important topic to facilitate a change in industrial energy systems. One way is to do cycle modification with the intentions of decreasing the electrical energy input under the restrictions of as low costs as possible. Therefore, the introduction of a two-phase ejector has become a promising cycle modification recently. Contrary to an ordinary expansion valve, the ejector recovers some of the expansion energy which is normally wasted in throttling processes. It reduces the compressor work by raising the suction pressure to a higher level, which directly leads to an improvement of the COP. Nakagawa et al. \cite{1} experimentally analyzed ejectors and achieved a COP increase of up to 26\%.

Moreover, the ejector technology also leads to an evaporator size reduction as it provides a flash gas bypass. The technology itself is not new, as in 1990 Kornhauser \cite{1} analyzed the thermodynamic performance of the ejector expansion refrigeration cycle using R12 as a working fluid.

To improve the design of ejectors CFD has become a valuable tool to enhance the performance. For a given ejector geometry, there exists only a small bandwidth of operating conditions that is leading to optimum efficiency \cite{3,4,5}.

Smolka et al. \cite{6} developed a Homogeneous Equilibrium Model (HEM) to perform CFD simulations of a two-phase transcritical CO\textsubscript{2} ejector with a commercial CFD code without having to employ a full multiphase
model, as through the assumption of a homogeneous equilibrium, the governing equations can be used in their single-phase formulation. Bodys et al. [7] expanded the model of Smolka et al. [6] to account for thermodynamic metastability effects, which was realized through solving an additional equation for the vapor quality which includes a relaxation factor to be experimentally tuned. This addition to the homogeneous model led to an improvement of the prediction of CO₂ ejectors with subcritical inlet conditions. Yazdani et al. [8] used a mixture model to simulate the two-phase flow of CO₂ in an ejector. The mass transfer between the phases was modeled including both boiling and cavitation phenomena. Additionally, a slip velocity between the phases was included in the model. The analysis did not show a better accuracy in predicting key performance parameters of an ejector than simpler models like that of [7]. Biferi et al. [9] used the HEM of [6] to simulate a supersonic ejector with R134 as working fluid. The simplification of constant material properties except for those of density and speed of sound was made without drawbacks in accuracy.

Zhu et al. [10] showed that their 2D axisymmetric CFD simulation can predict the entrainment ratio with good accuracy (<10% error) compared to their measurements using R141b as working fluid.

In this work the HEM approach is used to model the flow phenomena inside the given R600 (butane) ejector. The extracted data from 2D-axisymmetric CFD simulations is analyzed and compared to experimental results. The results of this paper are partly based on the work of Zenz [11].

2. Heat pump cycle

The ejector in a heat pump cycle fulfills two purposes, first mixing of the high-pressure with the low-pressure flow and secondly pressure recovery by expansion. It consists of a primary inlet where the fluid is in a liquid state, a secondary inlet also called suction inlet where the fluid is in a gaseous state and one outlet with mixed conditions. As there are different types of ejectors it must be noticed that the presented design can be characterized as a two-phase supersonic constant pressure mixing ejector. A high-pressure fluid enters through the primary inlet and accelerates in the motive nozzle which entrains a low-pressure fluid through the secondary inlet. After a mixing process and static pressure recovery in a diffuser, the fluid leaves the ejector at a pressure that lies between the two inlet pressures. In the motive nozzle the fluid reaches supersonic speed while at the beginning of the diffuser the Mach number is close to 1 so that no further acceleration occurs, and pressure recovery is obtained.

The idea of an ejector in a heat pump cycle is to replace the expansion valve which has the purpose of converting the potential energy of the high-pressure fluid into kinetic energy as it is accelerated. Therefore, the pressure level at the compressor inlet is increased which leads to lesser electric energy needed and as a result to an increase of the COP. In Figure 1 the heat pump cycle, using an ejector, is depicted. Based on the ejector technology applied, the vapor entering the compressor from the separator at state 1 lies at a higher-pressure level than that of the evaporator. The low-pressure vapor leaving the evaporator (10) enters the ejector through the secondary inlet (5) and is entrained by the high-pressure stream coming from the condenser and entering the ejector through the motive nozzle (4). After pressure recovery inside the diffuser, the mixed two-phase refrigerant leaves the ejector at a higher-pressure level (7) and is separated into vapor (1) and liquid (8) phases.

![Fig. 1. Heat pump cycle and log(p)-H diagram. (see [11])](image)

The ejector can be characterized by three key parameters. The first one is the entrainment ratio:
\[ X = \frac{m_{\text{sec}}}{m_{\text{prim}}} \]  

(1)

with \( m_{\text{sec}} \) being the secondary inlet mass flow and \( m_{\text{prim}} \) the mass flow entering the motive nozzle at the primary inlet.

The second parameter is the suction pressure ratio:

\[ \Pi_S = \frac{p_{\text{out}}}{p_{\text{sec}}} \]  

(2)

with \( p_{\text{out}} \) the absolute pressure at the outlet and \( p_{\text{sec}} \) the total pressure at the secondary inlet.

The last and third parameter is the ejector efficiency as it is defined by Elbel and Hrnjak [12]:

\[ \eta_{\text{ej}} = X \frac{h(p_{\text{out}} - h(p_{\text{sec}}))}{h(p_{\text{prim}} - h(p_{\text{out}}))} \]  

(3)

Using the entrainment ratio \( X \) and enthalpy differences. In other words, the ejector efficiency can be described as the ratio of the amount of expansion work rate recovered to the maximum possible expansion work rate recovery potential of the ejector. Lawrence and Zhang et al. [13] found out that the ejector efficiency ranges from 20% to 30% for transcritical CO\(_2\) heat pump cycles. They also mention that the best system performance may not occur when the ejector efficiency is at its peak for a given geometry.

3. Numerical Model

3.1. Geometry and Mesh

The geometry is designed by using an 1D simulation tool and is already published together with first measurement results by Schlemminger et al. [14].

![Diagram](image_url)

**Fig. 2. Ejector design according to [14].**

The domain is meshed using Ansys 19 Workbench to generate a full hexahedral grid with 167000 cells which is depicted in Figure 3.

The maximum skewness is well below 0.5 and refinements at the walls are included to keep the \( y^+ \) at a reasonable value (area-weighted average = 2.5). The cells are stretched in axial direction which is increasing their aspect ratio in regions such as the mixing chamber and the diffuser, as there exists a clear direction of convective transport and therefore, the number of needed cells can be significantly reduced. Inside the primary nozzle and where the primary and secondary exit meet, the aspect ratio is kept near unity.
3.2. Numerical setup and Boundary conditions

The boundary conditions are chosen accordingly to Schlemminger et al. [14] and are summarized in Table 1. The refrigerant entering the ejector through the motive nozzle is subcooled. However, in [14] it was assumed that a vapor quality of 2.7% was present at the primary inlet. Therefore, a two-phase state corresponding to a vapor quality of 2.7% was used as boundary condition for the value of enthalpy at the primary inlet. With the energy equation being enthalpy-based the temperature is not a variable used by the solver. The whole case is set up as a 2D-domain using Ansys 19 Fluent for steady-state simulations. To setup the Homogeneous Equilibrium Model, the energy equation needs to be solved in the enthalpy-based form. This is done with a User Defined Scalar (UDS), solving an additional transport equation for the enthalpy. Moreover, the material properties are updated by calling an User Defined Function (UDF) that contains the C-code to perform a bilinear interpolation in order to obtain material properties as functions of pressure and enthalpy based on the REFPROP 10.0 database [15]. To model turbulence the k-ω-SST taking compressibility effects into account is used. All equations are solved using first-order upwind schemes, except for pressure, where a second order pressure interpolation scheme is chosen. Second-order schemes are known to be more accurate and less diffusive, but also more numerical unstable. The drawback in accuracy of a first-order scheme over a second order scheme (given they are both of the same type, e.g. upwind schemes) can be compensated by using a denser computational grid. For the two-dimensional simulations performed in this work it was noticed that an increase in cell density comes at less computational cost than the needed measures to bring a simulation using second-order upwind schemes to convergence.

3.3. Homogeneous Equilibrium Model

To lower the computational demand, the Homogeneous Equilibrium Model was used as a two-phase model. In this model the liquid and the vapor phase are assumed to be in a thermal and mechanical equilibrium, meaning that pressure, temperature, velocity, turbulence kinetic energy and turbulence dissipation rate are the same in both phases [6].

All properties are a function of the specific enthalpy and the pressure. Since Ansys Fluent uses the temperature as an independent variable for the energy equation, an enthalpy-based energy equation was implemented, using the specific enthalpy as an independent variable. This was implemented as an UDS in the program.
The general form of a steady state transport equation of an arbitrary scalar $\phi$ (with Favre averaged quantities denoted with tilde and Reynolds averaged quantities denoted with a macron) in ANSYS Fluent has the form [6][16]:

$$\nabla \cdot (\rho \bar{u} \bar{\phi}) = \nabla \cdot (\Gamma \nabla \bar{\phi}) + \dot{S}_\phi, \quad (4)$$

with $\dot{S}_\phi$ being an additional source term and $\Gamma$ the diffusion coefficient of the scalar $\phi$. The enthalpy-based energy equation for the implementation in Ansys Fluent has the following form, according to [6]:

$$\nabla \cdot (\rho \bar{u} \bar{h}) = \nabla \cdot (\Gamma_h \nabla \bar{h}) + \dot{S}_{h1} + \dot{S}_{h2} + \dot{S}_{h3}, \quad (5)$$

with $\Gamma_h$ being the diffusivity of $h$:

$$\Gamma_h = \frac{\lambda}{c_p} + \frac{\mu_t}{\sigma_t}, \quad (6)$$

where $\lambda$ denotes the thermal conductivity, $c_p$ the specific heat capacity at constant pressure, $\mu_t$ the turbulent viscosity and $\sigma_t$, the turbulent Prandtl number.

The source terms represent the mechanical energy $\dot{S}_{h1}$, the irreversible dissipation of kinetic energy variations $\dot{S}_{h2}$ and the dissipation of turbulent kinetic energy $\dot{S}_{h3}$. These source terms have the following form [6]:

$$\dot{S}_{h1} = \bar{u} \cdot \nabla \bar{p}, \quad (7a)$$

$$\dot{S}_{h2} = (\mu + \mu_t) \left\{ 2 \left[ \left( \frac{\partial \bar{u}_t}{\partial x} \right)^2 + \left( \frac{\partial \bar{u}_y}{\partial y} \right)^2 + \left( \frac{\partial \bar{u}_z}{\partial z} \right)^2 \right] + \left( \frac{\partial \bar{u}_x}{\partial x} \right)^2 + \frac{\partial \bar{u}_y}{\partial x} \frac{\partial \bar{u}_x}{\partial y} \right\} + \frac{1}{3} \bar{\rho} K \nabla \cdot \bar{u}, \quad (7b)$$

$$\dot{S}_{h3} = -\bar{\rho} \bar{u} \cdot \nabla K. \quad (7c)$$

For the implementation into Ansys Fluent, using the axisymmetric solver, all source terms need to be implemented in cylindrical coordinates, leading to:

$$\dot{S}_{h1} = \bar{u}_r \frac{\partial \phi}{\partial r} + \bar{u}_\theta \frac{\partial \phi}{\partial \theta} + \bar{u}_z \frac{\partial \phi}{\partial z}, \quad (8a)$$

$$\dot{S}_{h2} = (\mu + \mu_t) \left\{ 2 \left[ \left( \frac{\partial \bar{u}_r}{\partial r} \right)^2 + \left( \frac{\partial \bar{u}_\theta}{\partial \theta} \right)^2 + \left( \frac{\partial \bar{u}_z}{\partial r} \right)^2 \right] + \left( \frac{\partial \bar{u}_r}{\partial \theta} \right)^2 + \frac{\partial \bar{u}_\theta}{\partial \theta} \frac{\partial \bar{u}_r}{\partial \theta} \right\} + \frac{1}{3} \bar{\rho} K \nabla \cdot \bar{u}, \quad (8b)$$

$$\dot{S}_{h3} = -\bar{\rho} \left( \bar{u}_r \frac{\partial K}{\partial r} + \bar{u}_\theta \frac{\partial K}{\partial \theta} + \bar{u}_z \frac{\partial K}{\partial z} \right). \quad (8c)$$

Since the velocities and derivatives in an axisymmetric simulation are zero, the source terms reduce to the following form:

$$\dot{S}_{h1} = \bar{u}_r \frac{\partial \phi}{\partial r} + \bar{u}_z \frac{\partial \phi}{\partial z}, \quad (9a)$$

$$\dot{S}_{h2} = (\mu + \mu_t) \left\{ 2 \left[ \left( \frac{\partial \bar{u}_r}{\partial r} \right)^2 + \left( \frac{\partial \bar{u}_z}{\partial z} \right)^2 \right] + \left( \frac{\partial \bar{u}_r}{\partial \theta} \right)^2 + \frac{1}{3} \bar{\rho} K \nabla \cdot \bar{u}, \quad (9b)$$

$$\dot{S}_{h3} = -\bar{\rho} \left( \bar{u}_r \frac{\partial K}{\partial r} + \bar{u}_z \frac{\partial K}{\partial z} \right). \quad (9c)$$
with the divergence of the velocity, assuming that velocity and derivatives in angular direction are zero:

\[ \nabla \cdot \mathbf{u} = \frac{\partial \tilde{u}_r}{\partial r} + \frac{\tilde{u}_r}{r} + \frac{\partial \tilde{u}_z}{\partial z} \]  

(10)

In the general form of cylindrical coordinates, the z-axis is considered as the symmetry axis. Ansys Fluent specifies the x-axis as the symmetry axis. Therefore, for the implementation in Ansys Fluent all terms in z-direction need to be implemented as x-direction terms.

4. Results

The mass flow rate and entrainment ratio were, in the experiment, measured as \( \dot{m}_{prim} = 0.127 \) kg/s and \( X = 0.46 \), respectively [13]. The simulation over-predicts the mass flow rate by 30% up to 45% and the entrainment ratio by 20% up to 50%, depending on the value of inlet vapor quality. The unsatisfactory prediction of mass flow rates by the HEM was also concluded by Bodys et al. [7] for subcritical inlet conditions (for CO\(_2\) as working fluid). Therefore, they extended the underlying model to incorporate non-equilibrium effects. This led to an agreement between experimental and simulated mass flow rates of less than 10%. However, this model needs to be calibrated by a set of experiments which in not available for the presented R600 ejector.

The influence of vapor quality at the primary inlet on the primary mass flow rate and the entrainment ratio is shown in Figure 4. With an increase of the vapor quality the density decreases and therefore the mass flow changes quickly. However, the entrainment ratio \( X \) increases which suggests that the effect of the lower primary inlet mass flow is dominant over the effect on the physical process of entrainment.

![Fig. 4. Primary inlet mass flow rate \( \dot{m} \) (left) and entrainment ratio \( X \) (right) for subcooled primary inlet condition and different levels of primary inlet vapor quality. (see [11])](image)

Figure 5 shows the variation of static pressure along the ejector axis and wall compared to six measurement points obtained by the experiments published in [14]. In the mixing zone a deviation of the calculated pressure from experimental measurements is noticeable. This is also the location in which oblique shock waves occur. This might have affected the measurement results. However, specific potential errors in measurements due to condensation at the drilled hole for the pressure measurement, as well as thermal effects cannot be quantified.
Figure 5 shows the static pressure along the ejector axis and the wall, as well as experimental pressure measurements from [14]. (see [11])

Figure 6 shows the Mach number along the axis of the ejector. The oscillations in the mixing chamber correspond to supersonic shocks which can be noticed in the contour plot showed in Figure 7.

The velocity is decreasing, and no shocks are appearing at the beginning of the diffuser, which is a must have condition to guarantee the desired pressure recovery. This behavior can also be seen in the contour plot of the Mach number in Figure 7.
How sensible the ejector design reacts to minor geometry variation in the motive nozzle can be seen in Figure 8. The primary nozzle throat and exit diameter are increased while keeping the converging and diverging angle constant, and the secondary nozzle cross-sectional area is decreased. In contrast to Figure 7 higher Mach numbers are reached and the flow stays supersonic until reaching the beginning of the diffuser, where a crucial shock occurs. As a result, boundary layer separation occurs and a recirculation region at the beginning of the diffuser forms. This leads to a performance drop with a decrease of the entrainment ratio to $X = 0.082$. Although, the simulation model is not able to capture non-equilibrium effects, qualitative conclusions on the suitability of an ejector geometry can be drawn. This model is especially interesting for drawing relative comparisons between different ejector geometries.

5. Conclusion

For the evaluation of the ejector performance in a high-temperature heat pump a CFD analysis was conducted.

A homogeneous equilibrium model was implemented in Ansys Fluent to allow for computationally affordable calculations of the two-phase flow. The benefit of the model is, that it does not need experimental fine-tuning, which is difficult, given that currently heat pumps featuring an ejector are still a topic of research and not commercially available. Even though the mathematical model is not capable of capturing metastability
effects, and therefore mass flow rate predictions are sometimes unsatisfactory, the model can still be used to make interesting qualitative observations. Furthermore, geometry shape optimizations can be extracted. Besides the limitations of the HEM approach, comparisons between different ejector geometries can be drawn. Concerning future work, a broader range of experimental data for ejectors operated under heat pump conditions is needed to calibrate more reliable numerical models. This is of importance as the main quantities of interest for heat pump cycle simulations, the mass flow rates and entrainment ratio, are found to be strongly affected by non-equilibrium thermodynamics. For further work, a subcooled state in the motive nozzle flow should be achieved in the experiments since the given ejector was originally designed for those conditions.

Heat Pumps and Thermal Storage for Domestic Dwellings

Neil J Hewitt*, Babak Kamkari and Patrick Keatley

Ulster University, 2-24 York Street, Belfast, BT15 1AP, Northern Ireland, UK

Abstract

IEA HTP Annex 55 Comfort and Climate Box aligned with the UKRI funded Comfort and Climate Box to review the challenges and research necessary to deliver at scale heat pump and thermal storage solutions for single family homes across the partnering nations. Building on the deliverables to IEA HTP Annex 55, an updated review of the state of the art is presented here and how that was implemented in a small sample trial in social housing in Northern Ireland. Early results of this field trial indicate strong participant satisfaction with the air source heat pump and thermal store with reduced heating costs when allied to a modest upgrade to building thermal fabric i.e., improved glazing, insulation etc. and larger hydronic radiators to facilitate lower temperature heat delivery.

1. Introduction

IEA HTP Annex 55 Comfort and Climate Box and the subsequent UKRI//BEIS funded Comfort and Climate Box (EP/V011340/1, CCB, facilitating UK participation) targeted the implementation of typically air source vapour compression heat pumps and accompanying thermal storage in single family homes. It could be argued that such a focus was restrictive to global participation, but it was recognised that a focus had to be applied to deliver an in-depth analysis of the CCB concept to address concerns, that often are ultimately related to capital cost.

The Annex therefore identified several criteria that required inputs to deliver significant heat decarbonisation and integration with non-dispatchable and variable renewable electricity resources, such as:

- Affordability
- Suitability
- Compactness
- Efficiency
- Plug & Play, maintenance
- Integral design
- Smart Grid ready
- Controls & monitoring
- Appreciation

These factors were considered as the backbone of the research and implementation required to provide the necessary confidence for governments and other agencies to successfully promote the decarbonisation of space heating with electrically driven vapour compression heat pumps and thermal storage. Initially, observations were obtained from the participating countries of Austria, Belgium, Canada, China, Germany, Italy, the Netherlands, Sweden, Turkey, the UK, and the USA, but relevant results from other countries were also

incorporated. The purpose of this paper is then to update the reports that addressed aspects of these issues and to report on the implementation of this research that led to a demonstration of air-source heat pumps and thermal stores in social housing (alongside a modest retrofit) as a cost-effective decarbonisation approach to space and water heating in homes.

At the core of this approach to the decarbonisation of space and water heating in single family homes is the vapour compression heat pump. New (and existing) working fluids that decrease/eliminate global warming potential, and indeed reduce capital costs, are noted. In terms of single-family home systems, the role of hybrid heat pumps may seem attractive. Natural gas is seen as a contributor to decarbonisation in the short-term and its replacement (by biomethane and/or hydrogen) in the longer term is being considered. The price of natural gas is a current challenge and the scale of switching to more decarbonised sources much be at such a scale that the decarbonised gas sources are not costed at international gas prices. An example of this is the US Henry Hub price for natural gas. The US (and Canada) was largely insulated from European price increases resulting from war in Europe due to availability of low-cost “fracking” (hydraulic fracturing) gas. Natural Gas prices are also of course two-sided. Lower natural gas prices may hinder heating decarbonisation with heat pumps but now, electrification of heating (aligning with large scale renewable energy resources such as wind and solar) has gained a significant driver beyond decarbonisation, and it is incumbent upon us to deliver this opportunity. Regarding hybrid heat pumps therefore, Beccali et al [1] noted existing gas boilers can be utilised in “parallel” or in “series” alongside various ground source and air source heat pumps, both with and without thermal storage. Series or parallel approaches lend themselves to demand side management in terms of reducing electrical load at peak electricity demand times, with obviously the parallel approach facilitating a significant electricity load reduction that of thermal storage, but perhaps with a less time limiting factor i.e., the gas boiler can operate at peak electricity demand times and/or low (renewable) electricity supply times. Sun et al [2] noted that such “smart” hybrid heat pumps could avoid heat pump oversizing (reducing capital cost), avoid/minimise electricity distribution network capacity challenges (facilitating technology introduction), and overcoming social barriers to new technology adoption.

Vapour compression heat pumps need to be cost effective. Examples of how to achieve this is in the technology itself, selling heat as a service and demand response electricity market services. Regarding the technology, optimal sizing and impact on the electricity network is critical, as noted with gas boiler hybrid heat pumps. Unfortunately, not all countries with electrically driven vapour compression heat pump aspirations have sufficient capacity at local low voltage electrical distribution network level. Therefore, advanced high coefficient of performance (COP) heat pumps can be aided with the wider deployment of (5th Generation) heat networks (waste heat, renewable heat from excess renewable energy, geothermal heat etc.). So called “booster” heat pumps have upgraded heat for domestic applications with Thorsen et al [3] demonstrating an average seasonal COP of 5.25 and improved heat pump economics. Østergaard et al [4] noted that if district heating networks are operated in conjunction with lower heat distribution temperatures in the buildings, the overall efficiency of building/heat pump/heat network is significantly improved, with, again, cost savings as in some cases, little must be done to the building heating distribution system as the older hydronic radiators work sufficiently well at lower temperatures.

Regarding utilisation of the heat pump and thermal store as heat as a service and/or demand side response (electricity grid balancing), selling heat as a service to lower the barriers for heat pumps is noted by Kircher and Zhang [5]. A host purchases heat from a heat pump owned by an aggregator. The aggregator purchases power (at scale) and with the aid of thermal storage can address demand side response requirements of the local electricity market, whether renewable energy driven, electricity network constraint driven etc. It is claimed that the value of the heat pump investment is nearly doubled, i.e., a strong return on investment is possible. However, there is a concern over “data”. While “the internet of things” facilitates significant data flows, the question must be “what is the minimum amount of data that can be securely interrogated to deliver demand side response?”. The question arises as we become “smart”, we also may become vulnerable to cyber-attack. The fear is not when something is turned off (which is very inconvenient and possibly personally challenging), but when a significant number of devices are turned on at the same time, thus potentially initiating long-term damage to an electricity network. The electrification of heating (and transport) will require an amount of control and an expectation that by a given time, heat (and power) will be provided. Thermal storage (and/or hybrid heat pumps) are an example of peak electricity demand avoidance. Other approaches (e.g., for electric vehicle charging) are more time manageable where we expect our car to be charged overnight for example. Smart domestic electricity load controllers will therefore “manage” electrical demands through an
understanding (whether a fixed concept of a maximum electrical demand or through a “floating” concept associated with available local electricity network capacity) or our needs and, for example, reduce/turn off demands for short periods when we (the end user) do not notice. Thus, our fear of a cyber-attack to turn everything on could destroy infrastructure.

However, on the positive side, the role of integrated renewable energy i.e., photovoltaics, solar thermal or indeed their combination in PVT, can be aligned to heat pumps and thermal storage. Typically (but not always the case), winter solar energy is limited (when we want it the most) and summer solar energy can be excessive. Affordable seasonal thermal storage that is also sufficiently dynamic for diurnal/demand side response operations would be an advantage. Returning to “solar-assisted” heat pumps, Gaonwe et al [6] describes the likely types, while Yang et al [7] addresses the traditional solar thermal approach, heating a storage vessel and the heat pump utilising this storage as a heat source utilising TRNSYS modelling. This model accounted for the UK geographical extremes in temperature encountered in the UK (represented by an additional 21 days in space heating requirements but still represented a 30% increase in COP when using solar assisted united compared to an air-source heat pump. Regarding financial supports, at an electricity market level, we see several markets addressing aggregated technologies to coordinate demand side response/management for the greater integration of variable, non-dispatchable renewable electricity. These include CAISO, ERCOT, Hawaii, Australia’s NEM, GB’s Smart Systems and Flexibility Plan, EU MCs, including Denmark’s community renewables ownership model, etc). An example is the Tennet-Veissmann Viflex project where domestic heat pumps, thermal storage, and photovoltaics (PV) manage the electricity network in areas of high PV penetration. OpenADR is also being considered as a mechanism for standardised Demand Response control. In the UK, Gupta and Morey [8] assessed a domestic heat pump, PV and battery arrangement for single family homes noting 2-hour intervention times and their impact on electricity demand and export. Automation was deemed too be very important, as was transparency of financial transactions. Agile electricity tariffs were deemed advantageous.

3. Heat Pumps and Thermal Storage – What is emerging as best practice?

The Kigali Amendment to the Montreal Protocol requires developed countries to reduce their use of HFCs by 85% by 2036. This would challenge the use of the most popular air-source heat pump working fluid, namely R410A. Several alternatives are being explored namely R452B, R454B, R454C etc. e.g., Shen et al [9]. However, the question arises as to what is a low global warming potential (GWP) refrigerant? Very low GWP refrigerants refer to the natural fluids such as CO2, Ammonia, Propane etc. with GWP’s of less than 3. Low GWP refrigerants is accepted as those below 150 (on a 100-year basis), although there appears to be no absolute definition. Unfortunately, when taking the more extreme requirement of low GWP, there appears to be currently one no HFC, HFO replacement for the current incumbent R410a. Therefore, propane (R290) is of interest and Schnabel et al [10] demonstrated that for a charge of 200g of R290, a 10kW heat pump could achieve a COP of 3.5 across a 35°C temperature lift. With R290 having a Lower Explosion Limit of 2.1% volume per volume, 200g of propane would be “safe” in a space as low as 0.11m3. Regarding alternative refrigerants to R410a for air-source heat pumps, the following refrigerants have been modelled (Table 1) for different heat pump configurations (Figure 1). These are not always drop-in replacements but are being considered for domestic heat pumps, given the challenges of finding a suitable (<150 GWP) direct replacement for R410a.

The choice of system is interesting. Capital cost of domestic heat pumps has come under pressure and development of lower cost units is very worthy of effort. Energy Poverty and Fuel Poverty are themes at the time of writing that imply heat pumps and thermal storage for single family homes i.e., the pathway to space heating decarbonisation, may become the preserve of the wealthy. For mass adoption, capital costs must reduce and/or schemes for ownership spread that cost over the lifetime of the system. However, improving COP is also welcome.

The performance of the alternative refrigerants is evaluated in three different heat pump cycles i.e., basic, liquid line-suction line internal heat exchanger (LL-SL IHX) and flash tank heat pump cycles. For all cycles, the condenser temperature is set at 60°C, and the evaporator temperature changes ranging from 0°C to 10°C to calculate the COP, Volumetric Heat Capacity (VHC), discharge temperature, and pressure for systems working with different refrigerants. In the current analysis, the subcooling and superheating values are set at 0°C and isentropic efficiency has been considered for the compressor operation based on the pressure lift.
Figure 2 shows the variation of COP with evaporator temperature in different heat pump cycles working with alternative refrigerants. As expected, the COP increases by increasing the evaporator temperature. For the basic cycle at an evaporator temperature of 0°C, the R32 provides the best COP followed by R32, R454C, R452B, R1234ze(e), R515A, R454B, R513A, R1234yf, and R410A. The difference between the maximum (R32) and minimum (R410A) COPs is about 7%. The COP ranking differs with changing the evaporator temperature or cycle configuration. For example, at an evaporator temperature of 10°C, R1234ze(e) performs marginally (1%) better than R32. Also, it is observed that the COPs may improve slightly by adding a LL-SL IHX to the cycle at the expense of higher discharge temperature. However, employing a flash tank can considerably enhance the COP compared to the basic cycle. Volumetric heat capacity reveals that R32 has the highest VHC followed by R452B, R454B, and R410A. Pure HFO refrigerants (R1234ze(e) and R1234yf) has considerably lower VHC values compared to R32 due to low vapor density.

By adding R32 to HFO refrigerants the VHC improves as is seen for R454B (69% R32 and 32% of R1234yf) with 153% improvement in VHC compared to that of R1234yf (Figure 3). Figure 4 illustrates the variation of discharge temperature of the compressor versus evaporator temperature in different heat pump cycles working with alternative refrigerants. The maximum discharge temperature corresponds to the pure R32 and reduces by decreasing the share of R32 in the mixed refrigerant. The minimum discharge temperature belongs to R1234yf. It is seen that the discharge temperature increases with raising the evaporator temperature. The value of temperature rises in the case of LL-SL heat exchanger running with R32, R452B, and R454B are not realizable in practice, and they are shown just for comparison. The figure shows that depending on the refrigerant type, employing the flash tank decreases the discharge temperature by 9 to 17% compared to the basic cycle. Figure 4 also depicts the discharge temperature for different alternative refrigerants employed in basic, LLSL IHX, and flash tank heat pump cycles at evaporator temperatures of 0, 5, and 10°C. As expected,
the pressure lift decreases by increasing the evaporator temperature. At 0°C, the maximum pressure lift is about 5.9 which is related to R1234ze(e) and R515A, and the minimum pressure lift is 4.8 obtained by R410A. Thus,

![Figure 4](image_url)

**Fig. 4.** Variation of discharge temperature with evaporator temperature for different heat pump cycles

we can conclude that from these choices, it is challenging to address a direct replacement for R410a that possesses a GWP <150. Therefore, new systems will emerge, or existing systems will re-emerge that can address low GWP (and safety) while, in the best traditions of the automotive mass manufacturing industry were saving in weight equate to manufacturing savings, retain of exceed the size of R410a units. About the control of alternative cycles, such as a flash tank, this requires additional expansion valves to manage superheat at the intermediate compression stage. There are the challenges of expansion valve sizing in that there is typically reduced pressure drops than those encountered with a traditional heat pump cycle. However, managing flow rate to maintain the usual minimum superheat is normal with a digital valve e.g., a stepper motor and pre-programmed refrigerant saturation temperature curves.

Finally, R290 and moving beyond F-Gas regulations to the future phase out of working fluids proposed by the European Chemicals Agency, we see proposal to cut perfluoroalkyls, leaving the domestic air-source heat pump sector with for example, R32 and R290 as their main choices. The US EPA has also banned certain working fluids. Utilising the data provided by OST (Switzerland), Air-Source Heat Pumps (ASHPs) are tested under conditions of both EN14511 (COP at certain temperatures, humidities etc.) and EN14825 (seasonal COP). The available data is summarised in Figure 5 for conventional air-source heat pump cycles.

![Figure 5](image_url)

**Fig. 5.** COP Comparison of Existing Tested Air Source Heat Pumps

In terms of thermal storage, our understanding of electricity network constraints to be combined with our understanding of our heating and hot water needs to provide an optimal system. As previously reported, a 2-hour period was noted for demand response and the greater integration of non-dispatchable, variable renewable energy. For our domestic space heating and domestic hot water needs, water as a medium has flexibility in temperature (for weather compensated heating control), low cost and well understood systems and properties. However, the size of water-based systems (in both retrofit and expensive inner-city terms) along with heat losses, may deem water to have rival storage media. Nair et al [11] reviewed phase change materials (PCMs) for space heating and domestic hot water applications and noted that many organic PCMs are flammable (potentially limiting their application), salt hydrate types are highly corrosive and suffer from supercooling and phase separation, and long-term cycle stability is questioned by some. However, encouraging trials and examples are noted with for example, the then Department of Energy and Climate Change funded trial in 7 homes in the UK starting in 2013. Using an Air Source Heat Pump and a phase change material storage, an
average heating bill saving of 50% compared to fossil fuels was achieved [12]. There remain numerous studies on laboratory-based systems and thus the need to verify PCM based systems in the field.

4. Field Trials in Northern Ireland

Ulster University has been developing heat pumps for 50 years. Initial interest was in heat pump performance in a controlled environment during an energy crisis of the 1970’s. This evolved into the challenge of compressor lubrication and oil transport, its effects on heat transfer and of course, compressor longevity based on refrigerant/lubricant solubility and miscibility. This work continued as we moved from CFC’s to HCFC’s and HFC’s, with HFC’s typically utilising Polyol Ester lubricants (POEs) and combined system performance comparisons, material compatibility and lubrication aspects. New heat exchangers such as all-welded compact plate types saw improvements in performance. Natural fluids also were noted and indeed their challenges as drop-in replacements for, for example, R407c heat pumps, where R290’s lack of compatibility with POEs lead to compressor failures. Compressors for domestic heat pumps moved to scroll types (again with new lubrication concepts needed) and future developments such as the vapour injection for higher temperature lift applications where developed. R410a heat pumps where introduced and new working fluids such as R1233zd(E) are being evaluated for different applications, including industrial heat pumps. Therefore, it was correct to not only assess the heat pump system, but how it would be used in homes and how it would need thermal storage to address the electricity network, renewable energy integration and perhaps of increasing importance, the role of the end-user in the success of heating decarbonisation.

In understanding heat pumps and thermal storage in single family homes, Shah et al [13] utilised an air course heat pump and 600 litres of water to heat a “hard-to-treat” home, purposely built on a campus of Ulster University. This house, as part of “Terrace Street” was home to a family and was monitored for temperature, electricity consumption, gas consumption (when the boiler was required) with a heavily monitored heat pump and thermal store. The occupier and their family were free to heat the home as appropriate and the gas boiler was available for comparisons as well as a back-up during system modifications. In general, the occupants were happy with the level of heat provided but no formal test was carried out as the then objective was to observe what performance was required to maintain thermal comfort.

Overall COP of the high temperature heat pump could have been better and spurred our interest in an overall system methodology i.e., building improvements (a “Fabric First” approach) followed by a heat pump of appropriate size. About the size of thermal store, we had anticipated a time frame that approached 4 hours rather than a shorter time. The 3-to-4-hour time frame addressed the peak time for electricity usage (typically 4pm to 7pm) in the UK but was later proved to be not as important as the shorter term changes in for example, wind derived electricity from the network (as demonstrated by the 48 time periods incorporated into the current All-Ireland electricity market structures). A secondary (but important factor) was the heat losses associated with such a large (but still well insulated) water storage tank. Thus, smaller storage systems with less heat loss were required and therefore air source heat pumps and compact thermal stores applied to homes with improved building fabric (typically glazing and insulation).

Interreg VA Spire 2 and UKRI EPSRC CCB and Lot-NET projects provided the means to work with the Northern Ireland Housing Executive (one of the largest social housing providers in the UK) to deliver the solutions and the analysis of the installation of air source heat pumps and thermal storage into retrofitted homes in the west of Northern Ireland. This significance of the area chosen is to reassure those out of our major cities that cost-effective decarbonisation approaches can be delivered in rural communities, and secondly, the west of Northern Ireland is where our dominant wind energy resource is found, and therefore local demand response solution may have to be found soon. UKRI EPSRC CCB and IEA HPC Annex 55 gave confidence in delivering
a viable solution to decarbonisation of our homes. RULET – Rural-Led Energy Transition – is an initiative within the SPIRE 2 project (Figure 6) aimed at reducing or eliminating the risk of low-income households being left behind in the transition to clean, smart, integrated energy systems. Not only where air source heat pumps and thermal storage systems investigated, but also hybrid systems (with oil or gas boilers) to address the householder concerns regarding the “radical, new technology” of heat pumps.

Figure 7 shows typical operational data per home and Figure 8 illustrates the CO₂ seen from the different options across a three-month operating period. As expected, with Northern Ireland producing nearly half of its electricity from wind power, the heat pump has the lowest emissions. Furthermore, as part of the trial, a local electricity supplier agreed to provide an Economy 7 tariff i.e., a reduced cost from 12:00 to 07:00 daily as a prelude to flexible tariffs. Householders were generally pleased with their running costs.

![Figure 6. Rulet Heat Pump and Thermal Storage Installations](image)

![Figure 7. Household electricity consumption profiles](image)

![Figure 8. CO₂ Emissions for the Selected Options](image)
However, the most important aspect during this energy crisis is that of running costs. Figures 9 and 10 illustrate the current running costs and the projected running costs for the Winter period 2022/2023.

The small-scale trial has illustrated that an air source heat pump with thermal storage can meet the demands of householders, at least at a similar cost basis and, with the help of flexible tariffs, could reduce the running costs further. However, what of capital cost? For this field trial, approximately £18,000 was spent per home, with a building fabric upgrade of glazing and insulation being approximately £9,000 per home, the PCM thermal store of 6kW was £6000 and the 5kW (thermal) air source heat pump was £3,700. With 880,000 homes in Northern Ireland (not all requiring this level of retrofit prior to heat pump installation), Ogunrin et al [14] estimated approximately £2bn would be required for the building fabric upgrade alone. However, the kWh not used is the best kWh. Aggregation systems that use the heat pump and thermal storage as a renewable electricity integrator must become part of the value-added aspects of heat pump deployment.

Regarding reducing heat pump capital costs, in addition to mass production, smaller machines due to reduced heating demands and moving away from air to waste heat/geothermal heat networks, the use of lower cost components and natural working fluids that have lower pressures and no doubt other innovations not requiring copper and steel may make systems cheaper, while maintain reliability. Water for thermal storage with vacuum insulation tanks may be more cost effective.

Finally, the move towards R290 in the field of domestic air-source heat pumps is typically beneficial. A 5% increase in seasonal COP has been noted in Figure 5 and this would translate in an equivalent reduction in electricity demands.

5. Conclusions

Air source heat pumps and thermal storage are a solution to decarbonisation of space and domestic water heating. We have seen (albeit informally) that residents are happy with their decarbonisation solution, especially as in many cases is saves on running costs. The heat pumps and accompanying thermal stores need to be smart. The use of an Economy 7 tariff was successful, but a 10-hour tariff would be more beneficial. A flexible tariff following excess wind generation, thus reducing wind derived renewable electricity curtailment and constraint and operated by aggregators, should benefit electricity distribution companies (better utilisation of existing network capacity and lower rates of new builds), the aggregators themselves, and the end-users (the residents and as such, prosumers with lower tariffs). This help with affordability. Retrofit, even at a basic level improved building suitability. Compactness may be challenged by refrigerant changes. Efficiency will be improved with new components, a move to R290, and a move away from air-source. Finally, integral design of heat pumps, thermal store and building will see improved results.

Abstract

High-temperature heat pumps (HTHP) with supply temperatures above 100 °C are becoming increasingly important for the electrification and decarbonization of industry. However, their adoption is slow because there is still a lack of knowledge about their capabilities, design, control, and optimal integration, resulting in few practical implementation examples. This study investigates the technical and economic feasibility of HTHP integration based on case studies from the Swiss industry. ELSA (Estavayer Lait SA), Cremo SA, and Gustav Spiess AG support the research and provide access to industrial process data. ELSA, Switzerland’s largest industrial dairy on a single site, is interested in a HTHP supplying steam for cleaning-in-place processes. Cremo SA manufactures dairy products and sees opportunities to integrate a HTHP in a milk permeate drying plant that consumes a large amount of 3 bar steam. Gustav Spiess AG produces meat products and sees potential for integrating a HTHP into sausage cooking processes for steam generation at about 115 °C. In addition, other Swiss industrial companies in the food, biotech, and chemical sectors also show interest in HTHPs for applications such as distillation, sterilization, drying, and steam generation. This study presents suitable HTHP integration concepts based on case studies with quantified efficiency gains, energy savings, CO₂ reduction, and cost-efficiency results. It also includes an up-to-date review of HTHP suppliers derived from participation in the IEA HPT Annex 58 that shares results and knowledge with international experts on HTHPs.

1. Introduction

1.1. Application potential of industrial HTHPs in Switzerland

Switzerland has been pioneering in developing and commercializing heat pumps (HP). The first European HPs were realized in Switzerland (e.g., in 1877 at the salt works at Bex) [1]. In 2021, HP sales increased to an all-time high of 33’704 units (20% growth compared to 2020) [2]. Especially in the small-capacity range for single- and multi-family houses, HPs are an established technology for space heating and domestic hot water, with a market share of over 90% in new buildings. Above 100 kW heating capacity, 169 HPs were sold (around 0.5% of all units) since, in larger heating capacity ranges, oil and gas boilers still dominate process heat generation [3]–[5]. Therefore, replacing fossil heating systems with electrically-driven industrial HPs is
a possible scenario to reduce CO₂ emissions from industry. High-temperature heat pumps (HTHP) with supply temperatures above 100 °C are increasingly important to replace fossil fuels in industries [6]–[8]. The most relevant application areas for HTHPs are the food/beverage, chemicals, and pulp/paper industries for processes like drying, evaporation, sterilization, or similar thermal processes with available waste heat from about 30 °C to 70 °C and process heat demand from 80 °C to 150 °C [9]. Based on annual energy consumption of around 43 TWh in Switzerland [10], a 30% share of process heat and steam below 150 °C [11], and a moderate conversion rate of 40% to HPs and HTHPs [12], the addressable energy savings potential from the use of HTHPs in the Swiss industry can be roughly estimated at 2'893 GW/a which is approximately 6.7% of the total process heat demand [13] (Table 1).

</tr>
</tbody>
</table>

Compared to natural gas, which has an emission factor of 0.201 kg CO₂ per kWhₘₖ of useful heat [14], the consumer electricity mix available in Switzerland is 0.128 kg CO₂/kWhₘₖ [15]. On this basis and with an average COP of 3.0 to 4.0 for an industrial HTHP at about 40 K to 60 K temperature lift from heat source inlet to sink outlet (assuming 45% Carnot efficiency [6], [7], [16]), the generated CO₂ emissions per useful heat are about 0.032 to 0.043 kg CO₂/kWh, which is 5 to 7 times lower than for a gas boiler (assuming 90% boiler efficiency). Assuming that integrated HTHPs would run with 5'000 operating hours per year on average, this results in a total heating capacity of 579 MW and, with specific investment costs (incl. installation, without integration, valid for 500 kWₘₖ HP size) of approx. 450 to 700 EUR per kW heating capacity [17], a potential market of 260 to 405 million EUR for Switzerland. Assuming an average heating capacity per HTHP unit of 1 MWₘₖ is equivalent to installing around 579 HTHP units.

Thus, integrating industrial HTHPs will contribute to energy savings, CO₂ reduction, and a substantial new market. Furthermore, expanding renewable energy and increasing energy efficiency in industrial processes align with the federal government’s Energy Strategy 2050 [18]. Consequently, HTHP technology supports the efforts of Switzerland’s net carbon emissions to net zero by 2050 [19].

### 1.2. Existing challenges for the wider spread of HTHPs

However, HTHPs are just beginning to enter the market of industrial heat production. There is still a lack of knowledge about available HTHP technologies and products (>100 °C supply temperature), methods for optimal integration, proper sizing, control, dynamic behavior, and techno-economic feasibility, resulting in few realized references with operational experience. As highlighted in a white paper [20], demonstration projects with increased knowledge sharing at the international level are needed to drive further HTHP technology dissemination and achieve greater visibility, particularly in process electrification. In this context, the authors of this study participate as Swiss representatives in the IEA HPT Annex 58 on HTHPs to exchange results and knowledge with international experts. In recent studies, the techno-economic feasibility of integrating HTHPs for steam generation in distillation applications was investigated [21], [22], and an up-to-date overview of the latest HTHP developments and products for supply temperatures above 100 °C was presented at the China Heat Pump Conference 2022 [16]. The analysis of the integration of HTHPs into ammonia and pulp production was also presented at CPOTE 2022 [23] and ECOS 2022 [24].

### 1.3. Objectives of this study

This study investigates the technical and economic feasibility of HTHP integration based on case studies in Swiss industrial companies with heat source temperatures from 40 to 80 °C to provide process heat (e.g., steam) at 115 to 150 °C and about 0.5 to 3.5 MW heating capacity. First, a review of current HTHP products and the corresponding working domains (e.g., heating capacity, temperatures) is given. Next, a simple economic model is used at an early planning stage to assess whether a HTHP integration could be economically viable. Then, the investment and operating costs of HTHPs are analyzed for the case studies using a cost model with different
input parameters. Finally, the payback period, the avoided CO₂ emissions, and the energy savings are calculated, and the main influencing factors are discussed in a sensitivity analysis.

2. Market review of industrial HTHPs and operating ranges

The range of industrial HTHP products on the market has grown steadily in recent years (especially since 2018 [6]). Table 2 presents an overview of 33 HTHP products with heat supply temperatures above 100 °C based on information collected in the IEA HPT Annex 58 project [25]. The list includes closed-cycle and open-cycle HPs for mechanical vapor recompression (MVR). It is structured by maximum supply temperature, HTHP supplier, country, compressor type, the working fluid (refrigerant), maximum heating capacity, and technology readiness level (TRL) [16]. The specific investment costs are also given in EUR/kWth. It should be noted that the HTHP suppliers provided the information without third-party validation. Therefore, the data is indicative and may vary in the final installations depending on the application-specific parameters.

Table 2. Overview of HTHP technologies and suppliers sorted by maximum heat supply temperature above 100 °C [16] (Data based on IEA HPT Annex 58 [25]) (Note: The HTHP suppliers provided all information without third-party validation. Therefore, the information is indicative and may vary in final installations depending on application-specific parameters).

Figure 1 shows the industrial HTHP products sorted by their maximum heat supply temperature and heating capacity range. The heating capacities range from laboratory demonstrators of about 10 kW to larger 70 MW units. Illustrated in color are the compressor technologies, including screw, piston, turbo, and others like the rotary vane compressor from ToCircle, the heat transformer from QPinch, or the Rotational HP from Ecop using a noble gas in a Joule cycle. These last examples show various technologies emerging alongside more classical Carnot cycles.

In most cases, turbo compressors are used for large heating capacities. For HTHP applications and high temperature lifts, compressors must be able to handle high pressure ratios. Therefore, the compressor manufacturers offer optimized designs for special applications.

For HTHP application, the steam compressors must preferably offer high flow rates at low suction pressure, high pressure ratios to reduce the number of compression stages, temperature resistance (e.g., need for liquid injection), and long-term corrosion resistance. In particular, a development perspective is small steam compressors for integrating HTHPs in industrial processes with an open cycle or combined in a two-stage cycle with MVR [26].

For example, Spilling’s piston steam compressors operate at suction pressures above 1.4 bar(a) (110 °C) and achieve temperature lifts of up to 100 K with a 3-stage compression design in one unit. Piller’s VapoFans are used in multi-stage MVR applications with suction pressures down to about 100 mbar(a) (45 °C). Enerin and Olvondo provide HTHPs with helium (R704) as working fluid and double-acting piston compressors in a Stirling cycle, which allow flexible operation conditions, high lifts, and supply temperatures above 200 °C.
Some HTHP suppliers provide closed-cycle HTHPs with up to 165 °C supply temperature using HFO refrigerants, e.g., the HeatBooster from Heaten or the ThermBooster from SPH. Other suppliers realize steam-generating HP using natural refrigerants, e.g., Ohmia Industry with ammonia (R717) in a bottom cycle and water (R718) in an open top cycle with MVR, Mayekawa with n-butane (R600), or Johnson Controls (Sabroe) with an R717/R600 cascade system using piston compressors.

Hybrid Energy uses ammonia/water (R717/R718) as the working medium in an absorption/compression cycle. As a result, temperatures up to 120 °C are achieved with high efficiency, and potentially high temperature glides on the heat source and sink. Recently, Fenagy commercialized CO₂ HPs for hot water heating from 30 to 120 °C with heating capacities up to about 1,800 kW.

Other manufacturers of HTHP products not listed in Table 2 and Figure 1 are Ago Calora (absorption-compression cycle, R717/R718, up to 150 °C), Ochsner (HFO refrigerants, up to 130 °C), Oilon (R1233zd(E), up to 120 °C), PureThermal (R1233zd(E), up to 120 °C), or Combitherm (HFO refrigerants, up to 120 °C). Finally, several large-scale HTHPs with > 10 MW heating capacity for industrial applications are supplied, for example, by Friotherm, MAN Energy Solutions, Turboden, Mitsubishi MHPS, or Siemens Energy.

Figure 2 shows the operating maps of some industrial HTHPs as a function of the heat source and sink temperature. In particular, there is a higher share around 50 °C heat source and 120 °C sink temperature. The operating limits are determined by the permissible condensation pressure, evaporation pressure, compression ratios, differential pressure across pistons, compressor speed, discharge gas temperatures, lubrication (e.g., oil temperature issues), and lowest allowable suction pressure.
Overall, Table 1 and Figures 2 and 3 demonstrate the availability of HTHP products and steam compressors and can be used as decision-support data for selecting appropriate HTHP suppliers. A preliminary technical feasibility check for HTHP integration consists of verifying the availability of a HTHP compatible with the temperature levels of the heat source and sink and heating capacity for a given project. In addition, industrial site constraints may further limit the HTHP integration options, such as the choice of refrigerant used (e.g., natural or synthetic), cycle concept (e.g., open, closed, or combinations), and space limitations.

Finally, a Pinch analysis can determine the optimal HTHP integration in an industrial context, which also identifies heat recovery options to increase efficiency and reduce energy consumption. Depending on the application, tailor-made HTHP designs are required (i.e., concepts for large temperature glides in the heat sink versus steam generation with no temperature glide).

3. Case studies and economic model

The following section describes case studies of potential HTHP integrations from the industrial companies ELSA, Cremo SA, and Gustav Spiess AG that support the Swiss project Annex 58 HTHP-CH by giving access to industrial process data. Furthermore, various other Swiss industrial companies (e.g., food, biotech, chemical) and HP suppliers are in contact with the project team showing interest in HTHP integration.

3.1. Case Study at ELSA (Estavayer Lait SA)

ELSA (Estavayer Lait SA) is Switzerland’s largest dairy on a single site, processing around 260,000 t/a of milk into a wide range of fresh dairy products, such as UP/UHT milk, yogurt, quark, and cream. The main heat treatments are pasteurization and sterilization in the temperature range of 65 to 155 °C. In addition to the production processes, CIP processes (Cleaning in Place) require large amounts of water and are an important steam consumer (e.g., 4.5 bar(a), 148 °C) (Figure 3). Today, process steam is generated by a wood chip steam boiler and several natural gas boilers (71.6 GWh/a or 275 kWh/t milk processed).

The process requirement for CIP is keeping the circulating basic and acidic solutions at 75 °C and 60 °C respectively, while the “sterilization” step of processing equipment, taking place after cleaning and, if needed, before the next operation, requires circulating hot water at 90 °C. These requirements could, in principle, be fulfilled with a hot utility below 100 °C; however, retrofitting the CIP stations (comprising 65 heat exchangers in total) for a hot water utility at 95 to 100 °C instead of steam at 4.5 bar(a) would be both expensive and difficult to implement because of the lack of space.

Therefore, to save energy and water, ELSA is interested in integrating steam-generating HTHPs that use waste heat from the NH3 chillers (about 23.7 GWh/a at 40 °C, currently discharged through cooling towers) or drain water (about 490,000 m³/a at 50 °C) as a heat source to replace some of the steam required for the CIP processes (about 22.7 GWh/a steam in 7,200 h of operation corresponding to 3.15 MW). Although the heat sources and sinks have yet to be confirmed, Figure 3 shows potential HTHP integration points for the CIP plants. Measurements are ongoing to determine the mass and heat balance of CIP operations and to check whether a significant share of the consumed 4.5 bar(a) steam could, in practice, be supplied at a significantly lower temperature and affordable costs.

The electricity price for 2023 is around 0.18 CHF/kWh [27] in Estavayer for a large industrial company (Category C7), and the gas price (Type X) is about 0.13 CHF/kWh, including CO2 tax of 0.02 CHF/kWh [28]. These conditions result in a favorable electricity-to-gas price ratio of around 1.4. Compared with natural gas, which has a CO2 emission factor of 0.201 kg CO2 per kWh [14], an average Swiss consumer electricity mix of 0.128 kg CO2/kWhel is considered [29]. The cost multiplication factor for planning and integration is assumed to be 3.0 because the installation environment is quite complex, and space is tight.
Fig. 3. Potential integration points for a steam-generating HTHP at ELSA using waste heat from the ammonia chillers at 40 °C as a heat source (1) or heat from drain water at 50 °C (2).

3.2. Case Study at Cremo SA

Cremo SA in Villars-sur-Glâne processes around 240,000 t/a of milk into various dairy products, including cheese (Gruyère, Vacherin fribourgeois, Raclette), butter, skim milk, milk proteins, and milk permeate powder. Today, the heat is supplied by two 5 MW gas-fired steam boilers (12 t/h steam, baseline consumption). In addition, a district heating network (105 °C/80 °C supply/return) from the nearby waste incineration plant provides heat to an internal hot water loop at 105 °C/60 °C that is connected to spray dryers (for preheating air), a TIXOTHERM™ drying process [30], evaporators, pasteurizers, CIP stations, building HVAC, and tap hot water. In case of a future reduction of the district heating temperature to 80 °C/60 °C, the possibility of a large-scale HTHP is considered (around 5 to 10 MWth) to adapt to the changing heat transfer rate (Figure 4).

Fig. 4. Potential HTHP integration point at Cremo using district heat as a source and upgrading the heat to the internal hot water loop.

Another potential integration point for a HTHP has been identified in the TIXOTHERM™ drying plant (Figure 5), which produces milk permeate powder (containing milk sugars) and currently consumes about 10% to 15% of the total steam demand for heating a Rosinaire™ paddle dryer [30]. Presently, there is only limited heat recovery on the humid exhaust air. Therefore, this case study is a priori suitable for a HTHP integration to supply low-pressure steam at around 1.4 bar(a) (110 °C) to the paddle dryer using humid exhaust air as a heat source (65 °C) and substitute steam generation from the steam boilers.
Figure 5. Potential HTHP integration point at Cremo in the TIXOTHERMTM drying process with a RosinaireTM paddle dryer, where humid exhaust air could be used as a heat source to generate steam.

Figure 6 (left) shows the calculated Composite Curves (CCs) as the initial situation before the integration of a HTHP, indicating a Heat Recovery (HR) potential through direct heat transfer of about 600 kW between air flows and a Pinch temperature at around 70 °C. Furthermore, Figure 6 (middle) shows the corresponding Grand Composite Curve (GCC) with an integrated HTHP, providing a 940 kW condensation capacity at 120 °C and 570 kW evaporation capacity at 38 °C, from which a COP of 2.3 can be derived (see COP-fit formula in Figure 8). Finally, Figure 6 (right) shows the CCs after integrating the HTHP. The example demonstrates a potential reduction of the Hot Utility (HU) by 100% (from 940 to 0 kW) and the unused waste heat by 47% (from 1,204 to 634 kW), and an increase of the HR potential by 249% (from 605 to 2,113 kW).

A challenge is the low evaporation temperature (and thus the large temperature lift of 80 K) and the probably insufficient evaporation capacity if the waste heat is to be recovered exclusively from the drying process. Therefore, additional waste heat sources must be identified at about 35 to 40 °C. The estimated annual operating time of the potential HTHP is about 6,400 hours, which is within the range of various techno-economic studies presented in a literature review [21], [22]. The electricity price for a customer of the size of Cremo is 0.2 CHF/kWhel, and the gas price is 0.11 CHF/kWhth, corresponding to an electricity-to-gas price ratio of about 1.8. The CO2 emission factor of electricity at Cremo is around the average Swiss consumer electricity mix of 0.128 kg CO2/kWhel [29], as the mix contains renewables, just not purely renewables. Furthermore, a discount rate of 2% is used to estimate the discounted payback period of the HTHP investment. The cost multiplication factor for calculating planning and integration costs is assumed to be 2.0.
3.3. Case Study at Gustav Spiess AG

Gustav Spiess AG in Berneck (SG) produces meat products such as sausage, ham, and bacon. Today, a gas boiler provides steam (6 to 8 bar(a)) to heat the pasteurization and cooking/smoking cabinets (Figure 7). The steam pressure is reduced to 1.5 bar(a) (115 °C) to achieve cabinet temperatures of 85 to 90 °C and a sausage core temperature of about 72 °C. Here, integrating a 550 kWel steam-generating HTHP is under consideration, using the waste heat from the NH₃ chillers as a possible heat source at 40 to 50 °C. Typical operation is 12 hours per day, 250 days per year, resulting in an annual operating time of about 3,000 hours. The expected payback period for new energy-related infrastructure investments is about 8 to 10 years. The electricity price for medium-sized customers in the given area is 0.25 CHF/kWh, and the gas price is 0.17 CHF/kWh resulting in an electricity-to-gas price ratio of 1.5, which appears favorable for electricity-powered heating and cooling technologies. The purchased electricity mix is nuclear energy with a low CO₂ emission factor of about 0.012 kg CO₂/kWhel. The cost multiplication factor accounting for planning and integration is assumed to be 2.0.

![Possible integration point of a steam-generating HTHP at Gustav Spiess AG for sausage cooking/smoking processes.](image)

3.4. Economic evaluation and COP estimation

The economic evaluation of the case studies is based on a calculation tool developed in MS Excel, illustrated in Figure 8 [21], [22]. It assumes that the investment of the gas boilers is depreciated and that the gas boilers remain for production safety, redundancy, start-up operation, and peak load coverage. Input parameters to the evaluation tool are electricity price (\(c_{el}\)), gas price (\(c_{fuel}\)), operating hours (\(t\)), heating capacity (\(Q_h\)), temperature lift between the heat source and sink (\(\Delta T_{lift}\)), specific investment cost \((c_{inv,HP})\), maintenance cost factor \((f_{maintain})\), interest rate (\(i\)), the emissions factors of electricity and fuel \((f_{CO2})\), and CO₂ tax refund (subsidies). The output results are the \(COP\), CO₂ emissions reduction \((\dot{m}_{CO2, reduction})\), annual cost savings \((C_{savings})\), and the payback periods \((PP)\). The calculation tool helps to quickly evaluate the economic feasibility as a “go/no-go” decision.

1. First, the efficiency of the HTHP is estimated using the temperature lift (\(\Delta T_{lift}\)) and a COP fit-curve \((COP = 52.94 \cdot \Delta T_{lift}^{-0.716})\) derived from quotes from various heat pump suppliers [21], [22].
2. Next, the investment costs \((c_{inv,HP})\) of the industrial HTHPs are evaluated based on the specific investment costs \((c_{inv,HP} = 3'157 \cdot Q_h^{-0.322})\) according to price information from heat pump suppliers, the heating capacity \((Q_h)\), and a cost multiplication factor \((f_{inv,HP})\) accounting for planning and integration (typically between 1.5 to 4.0 depending on the complexity of integration, e.g., including heat storage, site’s electrical installation, piping, hydraulics, etc.) [21], [22].
3. Then, the annual cost savings are calculated considering the following:
   - electricity cost \((c_{el})\) to operate the HTHP,
   - maintenance costs \((c_{maintain})\) of the HTHP using a multiplication factor \((f_{maintain})\) on capital cost (typically between 1.5% to 6%, in the case studies, 4% is used) [21], [22],
   - saved fuel costs \((c_{fuel})\) (assuming 90% boiler efficiency \(\eta_{fuel}\)), and
   - possible refunds of CO₂ reduction \((C_{CO2})\) (e.g., carbon taxes or subsidies).
4. After that, the payback period of the HTHP investment is evaluated as a trade-off between the investment costs versus the expected annual cost savings resulting from the heat pump investment.
5. Finally, the discount rates \( (i) \) are considered to calculate the discounted payback periods (DPP) [31], depending on the investor’s risk tolerance (e.g., sector, company size, energy intensity, funding source, new technology, etc.) [32]. Typical discount rates for HP investments range from 5% to 15%, according to reviewed literature [21], [22]. The DPP (discounted payback period) is the period after which the cumulative discounted cash inflows cover the initial investment [31]. The DPP can therefore be interpreted as a period beyond which a project generates economic profit. In contrast, the static PP gives a period beyond which a project generates accounting profit.

\[
\text{DPP} = -\ln\left(1 - \frac{\text{CER}_{\text{inv}}}{\text{CER}_{\text{gain}}}\right) \ln(1 + i)
\]

\[
\text{CER}_{\text{inv}} = \sum_i (\text{CER}_{\text{inv,i}} - \text{CER}_{\text{gain,i}}) / (1 + i)^n
\]

\[
\text{CER}_{\text{gain}} = \sum_i (\text{CER}_{\text{gain,i}}) / (1 + i)^n
\]

\[
\text{DPP} = 3.157 \cdot \hat{Q}_A^{-0.322}
\]

\[
\text{COP} = 52.94 \cdot \Delta T_{\text{eff}}^{-0.716}
\]

\[
\text{PP} = \text{CER}_{\text{inv}} / \text{CER}_{\text{gain}}
\]

Fig. 8. Economic calculation, COP, and specific investment costs to derive the payback period for HTHP integration [21], [22].

4. Results and discussion

Table 3 summarizes the results of the three case studies. The calculations lead to payback periods of 2.0, 3.7, and 3.3 years, which means that HTHP integration would be cost-effective under current assumptions. Overall, the case study examples show significant annual energy savings of 55%, 60%, and 66%, and CO\(_2\) emission reductions of 71%, 75%, and 98%, respectively. The COP varies between 2.0 and 2.7 according to the COP-fit function shown in Figure 8.

Table 3. Results of the case studies, with COP, energy savings, investment costs, reduction of CO\(_2\) emissions, and payback periods.

</table>
The case study ELSA has the highest temperature lift of 98 K and consequently the lowest COP as well as a cost multiplication factor for planning and integration of 3.0, but benefits from favorable electricity-to-gas price ratio and low specific investment costs due to the large HTHP (economies of scale).

In the Cremo case study, the electricity-to-gas price ratio is higher, and the integration factor is 2.0, but the discount rate is low, leading to a DPP of 3.9 years. The pinch analysis is a powerful tool to determine the optimal placement of a HTHP, its size, and adequate evaporation and condensation temperatures.

The case study of Gustav Spiess AG shows a high CO\textsubscript{2} emission reduction of 98% because the company benefits from low CO\textsubscript{2} emissions by purchasing nuclear power. Using waste heat from the NH\textsubscript{3} chillers as a heat source shows great multiplication potential in other case studies in the Swiss food industry, where refrigeration machines for cooling foods are state of the art.

In addition to the three case studies, Table 3 also shows the results of the payback period for a possible Reference Case 2023 (Ref) with a heat source of 50 °C, a heat sink of 120 °C (COP of 2.5), and 1 MW heating capacity, and specific investment costs of 341 EUR/kW\textsubscript{th}. This scenario uses a discount rate of 10%, an average Swiss consumer electricity mix with a CO\textsubscript{2} emission factor of 0.128 kgCO\textsubscript{2}/kWh\textsubscript{el} [29], and a possible carbon tax refund of EUR 92.5/tCO\textsubscript{2} due to the reduction of CO\textsubscript{2} emissions. Electricity and gas prices are based on market data for 2023 [33] (0.15 EUR/kWh PEGAS NCG Year Future and 0.35 EUR/kWh Phelix Year Future, price ratio 2.33, as of December 11, 2022).

Figure 9 shows a sensitivity analysis of the payback period for the Reference Case 2023 (abbreviated as Ref). All input factors of the model were individually varied from -25% to +25% (factor 0.75 to 1.25), while the other parameters were kept constant. The sensitivity analysis reveals that the payback period is strongly sensitive to a change in electricity and fuel prices as well as the temperature lift of the heat pump.
Favorable conditions for HTHPs are higher values of fuel prices, operating time, fuel CO\textsubscript{2} emission factor, CO\textsubscript{2} tax, heating capacity, and lower electricity prices. In addition, an increasing CO\textsubscript{2} tax, along with subsidies and possible CO\textsubscript{2} compensation through the European emission trading system increase the financial incentives for HTHPs.

![Sensitivity Analysis](image)

Fig. 9. Sensitivity analysis of the payback period for a Reference Case 2023 (Ref) at 50 °C/120 °C heat source/sink, 1’000 kW heating capacity, and an electricity-to-gas price ratio of 2.33. The graphs below show the impact of electricity price, temperature lift, and cost factor for planning & integration on the payback period as a function of the electricity-to-gas price ratio.

On the other hand, low gas and high electricity prices lead to unfavorable conditions and are significant barriers to the investment of industrial HTHPs. As seen in the lower diagrams of Figure 9, the payback period is strongly determined by the electricity-to-gas price ratio. Above a price ratio of 2.7, the payback period is more than 10 years. In addition, the payback period is strongly influenced by the temperature lift, which determines the COP and, thus, the operating cost of the HTHP and the avoided fuel consumption.

For given energy prices and temperature lift, the cost multiplication factor for planning & implementation leads to significant uncertainty in quantifying the payback period. The cost multiplication factor depends on the complexity of the HTHP integration and can only be properly determined after a thorough analysis of the project and indicative price quotations for the entire heating system implementation.

5. Conclusions

A simple cost model was developed to pre-assess the economic feasibility of integrating HTHPs into actual industrial processes based on investment costs and annual cost savings. The analyzed HTHP integrations at ELSA, Cremo, and Gustav Spiess show significant annual energy savings of 55%, 60%, and 66%, and CO\textsubscript{2} emission reductions of 71%, 75%, and 98%, respectively. The calculations lead to payback periods of 2.0, 3.7, and 3.3 years, which means that the integration of HTHP would be cost-effective under the current assumptions. However, it should be noted that the financial evaluation strongly depends on the individual case. A sensitivity analysis has shown that higher fuel prices mainly shorten the payback period. An electricity-to-gas price ratio below 2.7 leads to payback periods below 10 years. Temperature lifts below 70 K appear to be profitable. Economic challenges arise with high temperature lifts, low gas prices, and high discount rates. Overall, the availability of closed-cycle HTHP products and steam compressors shows that the case studies are technically feasible with the integration concepts presented. A wide range of HTHP products is available up to 120 to 160 °C supply temperature. Individual HTHP products achieve temperature lifts of up to 125 K. HTHPs are also available in the large heating capacity range >10 MW. More detailed discussions with HTHP manufacturers are required in the next step to clarify the end-user-specific integration conditions. In addition,
the cost model can be applied to other Swiss case studies for initial cost estimation. Future work could include integrating an advanced heat pump model that considers the effects of refrigerant, compressor efficiency, and cycle design.

Field Experience with Residential Heat Pumps in Switzerland: Potential for Improvement and Future Developments

Cordin Arpagaus*, Matthias Berthold, Michael Uhlmann, Ralph Kuster, Mick Eschmann, Stefan Bertsch

Eastern Switzerland University of Applied Sciences, Institute for Energy Systems (IES), Werdenbergstrasse 4, CH-9471 Buchs

Abstract

This study summarizes the main findings from field measurements with 14 air-to-water heat pumps (AWHP) and 12 brine-to-water heat pumps (BWHP) in Switzerland. The focus is on heat pump control optimization and possible future performance developments until 2050. The following statements can be derived so far:

- AWHPs with variable-speed compressors are particularly suitable for new buildings with low supply temperatures (e.g., floor heating).
- At a temperature lift of 25 K, AWHPs with inverter technology are 22% more efficient on average than those with fixed speed. At 40 K, both compressor types operate equally efficiently.
- For retrofits and higher supply temperatures, BWHPs are preferable due to their higher efficiency and more stable source temperature. However, proper sizing, integration, and parameterization are key to the efficient and durable operation.
- AWHPs currently achieve a measured Seasonal Performance Factor (SPF) of 3.5 in new single-family houses (combined heating and hot water mode), while BWHPs achieve an SPF of 4.9.
- In an average-case scenario (new house, 30 °C to 35 °C floor heating, 60% Carnot efficiency), SPFs of 6.3 and 7.9 are reachable by 2050.

Keywords: field measurements; domestic heat pumps; air-to-water heat pumps; brine-to-water heat pumps; efficiency; optimization

1. Introduction

Heat pumps (HP) for heating and hot water production are on the rise in Swiss households. In 2021, 33,704 units were sold, corresponding to a growth rate of 20% compared to 2020 (28,064 units) [1]. About 56% of the HPs fall in the heating capacity range between 5 and 13 kW and over 86% below 20 kW. Furthermore, 73% are air-to-water heat pumps (AWHP), 25.6% are brine-to-water heat pumps (BWHP), and 1.4% are groundwater-to-water heat pumps (GWHP).

At the same time, estimating the field performance of such HP systems is becoming increasingly important, as the efficiency responds to their integration into the heating system and the settings of the HP control. Therefore, the Heat Pump Test Center (WPZ) and the Institute for Energy Systems (IES) at the Eastern Switzerland University of Applied Sciences in Buchs (SG) have been conducting field measurements of HPs on behalf of EnergieSchweiz since 2015.

The main objectives of the field measurements are to investigate the real performance of HP systems and identify the systems’ optimization potential, which can then be implemented. Typically, five new HPs are included in the measurement series every year.

Until 2020, the field measurement campaign included mainly new HP systems installed in single-family houses (new buildings or renovations). However, from 2021 on, HP systems in multi-family homes with a heating capacity of approximately 20 to 30 kW have been included. Before on-site installation, the HPs are...
evaluated in the laboratory at the Heat Pump Test Center (WPZ), and the measuring equipment (e.g., PT-100 sensors with four-wire technology and flow sensors) are calibrated [2], [3].

Compared to former field studies in the 1990s and early 2000s like FAWA (Field Analysis of Heat Pump Installations) [4], the measurement methodology and data acquisition technology have changed considerably. Thanks to digitalization, much more data is available and can be monitored. In addition, precise and automated measuring equipment and high sampling rates of 10 Hz enable meaningful measurement data. Between 30 and 40 sensors are installed in each HP system, and mean values are stored every 10 s. The goal is an overall uncertainty of the target values (e.g., COP, SPF, etc.) of <10 % [3], [5].

The most important results of the field measurements are published in the annual reports of EnergieSchweiz. In addition, many of the results are also presented in Swiss technical journals for planners and installers so that new findings can be implemented directly. The reports and publications are publicly available for download on the website [6] of the University of Applied Sciences Eastern Switzerland.

Moreover, the results from the field monitoring study from 2015 to 2019 have already been presented at the 13th IEA Heat Pump Conference 2020 [3] and the Purdue Conferences 2021 [5], [7], and 2022 [8]. The results clearly show the expected dependence of the seasonal performance factor (SPF) on the supply temperature \( T_{\text{supply}} \) and the selected heat source (e.g., air and brine) [8].

AWHPs in new buildings achieved an average SPF of 3.7 with floor heating (35 °C), while BWHPs had an average SPF of 5.7 [7]. At higher supply temperatures, such as about 50 °C in old buildings with radiator heating, average SPF values of about 2.9 for AWHPs and 4.4 for BWHPs were measured (see Table 1). Combined heating and hot water production systems showed 3 % to 9 % lower SPF due to increased supply temperatures. Typical optimization measures identified were adjusting the heating curve and the heating limit, legionella routines, increasing the charging time at midday for AWHPs and preheating the hot water with the compressor before starting the legionella program with an auxiliary heater. BWHPs were recommended for refurbished buildings.

As of August 2022, 26 HP systems are included in the field measurements campaign. This comprises 14 AWHPs, 9 of which are speed-controlled, and 12 BWHPs with 7 speed-controlled models. In 4 installations, hot water is heated with a separate domestic hot water heat pump (DHWHP). Cooling mode is activated at 6 objects. Meanwhile, up to 6 heating periods, i.e., 2016/17, 2017/18, 2018/19, 2019/20, 2020/21, and 2021/22, can be evaluated per system [9].

So far, the monitoring results have shown that most HP systems are efficient and run robustly. Severe deficiencies were found only rarely. However, the greatest optimization potential was identified in the HP control systems. Therefore, this paper summarizes important findings concerning the optimization of the controller settings.

2. System boundaries and key performance indicators

For the characterization of HP systems in the field monitoring study, EnergieSchweiz has defined different system boundaries and key performance indicators [2], [10]. Figure 1 shows an example of a BWHP with direct heating and domestic hot water storage.

The system boundaries are drawn not only in terms of sensor position but also in terms of time. In addition, a distinction is made between the operating modes “heating,” “hot water charging,” and “cooling.” The electrical standby power consumption (standby here means compressor standstill and no cooling operation) is assigned to the “space heating (SH)” or “domestic hot water charging (DHW)” operation, depending on the position of the three-way valve.

The seasonal performance factor \( (SPF^+) \) (Eq. 1) is the key indicator for the efficiency of the HP unit. Only the electrical energy of the compressor, fan (for AWHPs), source pump (for BWHPs), and control electronics of the HP are considered in this indicator. In contrast to the \( COP^+ \), the \( SPF^+ \) value also includes the energy demand of the source circulation pump \( (E_{\text{CP,source}}) \) for BWHPs.

The heat utilization ratio \( (HUR) \) (Eq. 2) also includes the electrical energies of the sink circulating pump \( (E_{\text{CP,sink}}) \) and all electrical auxiliary heaters \( (E_{\text{ext,HP}}) \). In this way, the efficiency of the entire heat generation, including the electricity consumption for the distribution system, is considered and thus made comparable to other heating systems.

Finally, the system utilization ratio of domestic hot water \( (SUR_{\text{DHW}}) \) (Eq. 3) defines the efficiency of the overall hot water generation concerning the used domestic hot water from the storage tank outlet. It includes all storage and distribution losses. A smaller DHW demand generally leads to lower energy demand and efficiency since the losses are more significant. In addition, the \( SUR_{\text{DHW}} \) can also be determined for DHWHPs, allowing comparison with DHW charging of combined HPs.
Fig 1. System boundaries and key performance indicators (SUR, HUR, SPF, COP) of a brine-to-water heat pump with a direct heating circuit and domestic hot water heating with a storage tank (Definitions based on EnergieSchweiz [2], [10]).

The total electrical energy requirements for the entire HP system, commonly referred to as electricity consumption, are summarized in the value $E_{tot}$. Notably, only the performance indicators SPF, SPF$_{SH}$, SPF$_{DHW}$, and SUR$_{DHW}$ do not include standby losses since the electrical energies are only considered during active compressor operation. On average, the share of electrical standby losses is 2% to 3% of the total annual electrical energy demand [9].

The specific DHW heat requirement ($H_R_{DHW}$) (Eq. 4) and the total heat requirement ($T_HR$) (Eq. 5) refer to the energy reference area of the building (ERA) for better comparability of different building sizes. For the evaluation of the specific heating and electrical energy demand ($Q_{HD}$ and $E_{HD}$) (Eq. 6 and Eq. 7), the required charging energy ($Q_{SH}$ and $E_{SH}$) is related to the ERA.

The heating degree days ($HGT$) reflect the weather influence of a period (month or heating season) and/or location. A heating limit temperature of 12 °C and an indoor target temperature of 20 °C are used for new buildings ($HGT_{20,12}$). For renovated buildings, the heating limit is usually set at 16 °C ($HGT_{20,16}$). Heating degree days are only counted if the average daily temperature is lower than the heating limit [9]. Finally, the HGT results from the difference between the average daily temperature and 20 °C.

To sum up, the following formulas and parameters are used for data evaluation of the field measurements:

$$SPF^+ = \frac{Q_{SH}+Q_{DHW}}{E_{tot}-E_{CP,\text{Sink}}-E_{ext,HE}}$$  \hspace{1cm} (1)  
$$HUR = \frac{Q_{SH}+Q_{DHW}}{E_{tot}}$$  \hspace{1cm} (2)  
$$SUR_{DHW} = \frac{Q_{DHW}}{E_{DHW}+E_{ext,HE}}$$  \hspace{1cm} (3)  
$$HR_{DHW} = \frac{Q_{DHW}}{ERA}$$  \hspace{1cm} (4)  
$$THR = \frac{Q_{SH}+Q_{DHW}}{ERA}$$  \hspace{1cm} (5)  
$$Q_{HD} = \frac{Q_{SH}}{ERA}$$  \hspace{1cm} (6)  
$$E_{HD} = \frac{E_{SH}}{ERA}$$  \hspace{1cm} (7)  
$$ER_{DHW} = \frac{E_{DHW}}{ERA}$$  \hspace{1cm} (8)

3. Results

3.1. Effects of control optimization measures of a HP in a renovated building

This section presents some control optimization measures in a renovated single-family house from 1975 with inverter-regulated AWHP (Object No. 24 in the field study) [9]. Based on the evaluation of the heating season HS 2020/21 in the field monitoring study, some optimization measures could be implemented for the 2021/22 heating season. Data evaluation enables a direct performance comparison of the two heating seasons. The effects of control optimization on the HP system performance were as follows:

- **Speed reduction of the heat sink circulation pump**: The speed was reduced by approx. 10 % resulting in a decrease in the average pump power from 30.4 to 17.3 W. The running time decreased by 4 %, and the annual energy consumption of the pump reduced by 45 % (from 78.1 to 42.7 kWh/a).

- **Speed reduction of the compressor**: The compressor's minimum speed was reduced, lowering the minimum compressor power consumption from 4 to 2 kW. This increased the compressor's control range, and the compressor's annual operating hours increased by 2.5 % to 2,374 hours, although the total specific heat requirement (THR) decreased by 9 % to 66.3 MWh.

- **Reduction of the maximum heating capacity in the DHW mode**: The maximum thermal load in the DHW mode has been reduced from 8 to 6 kW to allow lower supply temperatures during storage tank charging and thus improve efficiency. Figure 2 (A) shows that the average supply temperature in DHW mode (TSupply,DHW) decreased from 51.4 °C in the heating season HS 2020/21 to 49.0 °C in HS 2021/22. At the same time, the specific DHW heat requirement (HRDHW) decreased to 87 %, while the demand for electrical energy for DHW heating (ERDHW) decreased to 61 % compared to the previous year (Figure 2, B).

- **Reduction of the heating curve and temperature rise in the buffer tank**: The temperature rise in the buffer tank was reduced in HS 2021/22. The temperature rise in the heating mode was decreased by 7 %, and the specific heating demand (QHD) by 8 %. However, the specific electrical energy demand in heating mode (ERD) decreased by 31 %, which is attributed to higher efficiency (Figure 2, D) resulting from the mentioned improvements. The efficiencies increased in the heating and DHW operating modes. The SPF*, HUR, and SPF*SH parameters increased by about 37 % (e.g., from 2.2 to 3.1), while the SPF*DHW and HURDHW increased by 42 %, and SURSDHW even doubled (from 0.6 to 1.2). In DHW operation, the thermal energy demand (HRDHW) decreased by 13 %, and electrical energy demand (ERDHW) by 39 %.

Overall, the example of Object No. 24 shows that relatively simple control optimization measures can significantly impact the performance of an AWHP system.

Fig. 2. Comparison of two heating seasons, HS 2020/21 and HS 2021/22, in a renovated single-family house from 1975 (Object No. 24 equipped with an inverter-regulated AWHP [9]) after control optimization on the HP. (A) Change of the supply and source temperatures in heating and DHW mode, (B) Comparison of the heating degree days and the specific thermal and electrical demands in heating and DHW mode (thermal demand decreased by 8%, electrical demand decreased by 31%), (C) Adjusted heating curve in HS 2021/22 (approx. 7 K lower supply temperature) compared to HS 2020/21 after a reduction of the temperature rise in the buffer tank, (D) Comparison of the efficiencies in heating, DHW, and combined operating modes for the heating seasons HS 2020/21 and HS 2021/22 (Data source: [9]).

3.2. Shifting the DHW charging operation to time windows with high outdoor air temperatures for AWHPs

As a next example, Figure 3 (A and B) compares the DHW charging characteristics of two renovated single-family houses (Objects No. 11 and No. 15) equipped with AWHPs. The graphs show hourly averaged data from 365 days (9/1/2021 to 9/1/2022) for several parameters over the daytime (00:00 to 24:00).

In Object No. 11 (Figure 3, A), the DHW operation often occurs in the morning between 7:00 to 8:00, accounting for about 48% of the thermal energy. This time window corresponded to an annual average outdoor air temperature of 10.0 °C, thus the time with the lowest outdoor air temperature. Conversely, the highest outdoor air temperature was 16.6 °C and occurred between 15:00 and 16:00. Therefore, shifting the DHW mode operation to times with higher outdoor air temperatures would significantly increase the overall efficiency of the AWHP system if it does not result in a loss of comfort due to too low tapping temperatures.

As can be seen, in the time window from 11:00 to 12:00, the electrical consumption of the compressor was almost zero due to active power blocking by the local grid operator. Such blocking times are based on the load.
profiles of grid utilization and prevent controllable devices like HPs from consuming electricity at peak loads. Thus, blocking time detection can help optimize PV self-consumption or source temperature maximization.

Figure 3 (B) shows an equal representation for Object No. 15 (renovated single-family house with inverter-driven AWHP). Here, the DHW charging operation by the AWHP was concentrated at midday. 88% of the DHW was generated between 12:00 and 15:00. This means that most of the DHW charging occurred when the outdoor air temperature (or the heat source temperature of the AWHP) was close to its daily maximum. In the selected time frame from 12:00 to 15:00, the average outdoor temperature was 15.7 °C. Ideally, the DHW charging operation would have to occur even two hours later (i.e., from 14:00 to 17:00) to reach the highest possible heat source temperature of 17.2 °C. In this context, the summertime changeover must also be considered. A one-hour shift results from the change of the clock to summertime. Another time shift results from later daily maximum temperatures in summer.

To sum up, the analysis of the HP operation over the day of Objects No. 11 and No. 15 showed that the DHW heating demand is virtually identical (273 W thermal power on average). However, Object No. 11 required more than twice the electrical compressor power (693 W vs. 299 W on average) and heating power (1'997 W vs. 999 W) due to operation in the early morning at the lowest outdoor air temperatures. Therefore, the timing of DHW charging after noon, between 13:00 and 15:00, is crucial for the high efficiency of the AWHP system and can be set in the HP controller settings. As a rule of thumb, a 10 °C higher source temperature results in 25% higher HP efficiency.
3.3. Comparison of fixed speed (on/off) and variable speed (inverter-driven) HPs

Inverter-driven HPs can modulate the compressor speed and thus dynamically adapt the HP performance to the required heating or DHW demand within certain limits. In contrast, the compressor speed is constant in conventional on/off HPs. In the following, some results of inverter-driven and on/off HPs are compared, and topics such as performance, sizing, running time (e.g., the compressor starts, cycling), and standby losses are discussed [8], [9].

Figure 4 shows the seasonal performance factor of 8 variable-speed and 4 fixed-speed AWHPs in heating mode ($SPF_{SH}$) as a function of the temperature lift between source and supply temperature (outdoor air temperature range between 0 and 10 °C accounts for >70 % of the annual heat demand). Each point represents a daily average. The Carnot efficiency of 30 % and 50 % is also plotted for orientation. Likewise, power function trendlines are added for each compressor group.

![Figure 4. Comparison of the seasonal performance factor of variable speed and fixed speed (on/off) AWHPs in heating mode as a function of the temperature lift between supply temperature and ambient air temperature as the heat source (ranging from 0 to 10 °C). Each point is a daily average (Data source: [8], [9]).](image)

The evaluation shows that the Carnot efficiency of the variable-speed AWHPs was about 40 % over the entire temperature range. At a temperature lift of 25 K, the examined AWHPs with inverter ($SPF_{SH}$ 4.67, variable speed) were on average 22 % more efficient than those with fixed speed ($SPF_{SH}$ 3.85) [8]. Both compressor types achieved similar Carnot efficiencies for larger temperature lifts of about 40 K. However, the smaller the temperature lift, the lower the efficiency of the on/off HPs. At small temperature lifts, the Carnot efficiency also decreased below 30 %. A major reason is that fixed-speed HPs switch on and off much more frequently than variable-speed AWHPs. In addition, the temperature differences inside the heat exchangers of the HP are smaller with a variable speed compressor in part-load operation. Furthermore, the type of compressor used can also influence efficiency. For example, variable-speed rotary piston compressors usually work more efficiently at small temperature lifts than scroll compressors with fixed speeds [11]. In conclusion, variable speed AWHPs are especially suited for new residential buildings with low supply temperatures, e.g., 30 °C to 35 °C for floor heating.

However, the measured data for the heating season HS 2021/22 also revealed that the potential of inverter-driven HPs is not always fully exploited. Figure 5 shows that not all variable speed HPs have a significantly longer running time per start (red dots on the secondary axis). On average, the evaluated AWHPs with inverters had about 4 times more running time per start than on/off units (2 hours per start vs. 0.5 hours per start). For BWHPs, the average running time per start of inverter HPs was even 9 times higher than for on/off units (6.5 hours per start vs. 0.7 hours per start).
The annual operating times differed considerably in some cases. For example, on average, speed-controlled inverter AWHPs had 1.7 times the operating times of on/off units. The difference was even greater for BWHPs. Here, the inverter machines had, on average, even 2.2 times longer operating hours.

For both AWHPs and BWHPs studied, one inverter system (Objects No. 23 and 14) ran for over 5,000 operating hours in the HS 2021/22. The average running time of the corresponding AWHP was 7.7 hours per start, and that of the BWHP was 11.9 hours per start. Even with optimal design, inverter-driven BWHPs achieved a higher average running time as the power control range depends essentially on the heat source temperature, which varied considerably more for AWHPs than for BWHPs.

In conclusion, the following general recommendations can be made for inverter-driven HPs:

- **Design:** Inverter-driven HPs should be well-matched to the heat demand of the building. Oversizing leads to a limitation of the control range due to the minimum HP capacity. Then, continuous operation of AWHPs is only possible at relatively low outdoor temperatures to deliver the minimum capacity to the building. If the heating demand is lower, an inverter-driven HP must also switch to cycle operation. Therefore, the advantages over an on/off HP are no longer given in these time ranges.

- **Start-up:** Good and solid commissioning is especially important for inverter-driven HPs. Software parameters such as the heating curve, heating limit, legionella activation, etc., must be determined and correctly set.

- **HP manufacturer:** There is potential to increase the efficiency of inverter-driven HPs. Some inverter-driven HPs have high standby losses in combination with long downtimes. In DHW operating mode, attention should be paid to low compressor speeds, as these lead to lower temperature differences in the hot water heat exchanger and thus increase the COP. In many cases, DHW generation is performed at a constant high speed because the main focus is likely to be on a short charging time and less on efficiency.

In addition to significant differences in operating behavior and efficiency, there were also revealing differences in standby losses between fixed-speed and variable-speed HPs. In general, standby losses are the energy that occurs during a HP standstill, i.e., when the compressor, including the auxiliary heater, is not in operation. The main causes of standby losses are the control system, an oil sump heater, and, in the case of inverter-driven HPs, the inverter. In the field monitoring study, these standby losses vary considerably depending on the object.

Figure 6 shows the average standby powers and the resulting annual standby losses grouped by 8 on/off and 16 speed-controlled HPs examined in the field monitoring study. The highest standby losses were found in some inverter-driven HPs. However, others with low standby losses indicate that high standby losses in...
Inverter-driven HPs were not system related. The average standby power for the measured on/off HPs was 12 W, while the mean value of the inverter-driven HPs was 27 W and, thus, 2.3 times higher. On average, the five HPs with the highest standby losses (all with speed-controlled compressors) consumed 49 W.

Depending on the object, the electrical standby losses ranged between 0.5 % and 10 % of the total annual electrical demand. Across all HPs, the standby losses accounted for 2 % of the total annual electrical energy demand. For some inverter-driven HPs, there is still a relatively high potential for optimization, as a comparison with the "best" systems shows.

Qualitatively, the annual standby losses (secondary axis of Figure 6) showed a similar picture as the average standby power. However, the standby energy depends on the respective running or standby time, which is influenced by many factors, including the HP design (e.g., dimensioning of the heating capacity), the hydraulic integration, parametrization, and the actual user behavior (e.g., selected room temperature or DHW demand). For example, this effect can be seen in the comparison of Objects No. 2 and No. 24, whose average standby power was almost identical. However, the annual standby losses of No. 24 were about 29 % higher than those of No. 2. Thus, lower standby power does not necessarily mean lower standby losses [8], [9].

![Fig. 6. Average standby power and annual standby losses of 8 fixed-speed on/off HPs and 16 speed-controlled inverter-driven HPs examined in the field study, sorted by decreasing standby power (Data source: [8], [9]).](image)

In summary, comparing variable speed HPs with conventional on/off HPs shows a clear difference in efficiency and control strategies. Furthermore, standstill losses were much higher with an inverter because the HP control and frequency converter were always running. On the other hand, fixed-speed systems started up more frequently than variable-speed systems. The average running time of variable-speed compressors was more than twice that of fixed-speed systems. This indicates that many variable-speed compressors run at a more optimal operating point than units without capacity control, even though they tend to be oversized and often not optimally parameterized.

### 3.4. Seasonal performance factor for AWHPs and BWHPs by 2050

Table 1 summarizes the average SPF s of AWHPs and BWHPs in heating (SH), DHW, and combined (SH+DHW) mode based on 2018 field measurement data and provides an outlook for future development until 2050 for an average scenario with 60 % Carnot efficiency [12]. For the forecast, the considered efficiency strongly depends on the supply temperature of the building category (30 to 35 °C assumed for a new building, 40 to 45 °C for renovation, and 50 to 55 °C for old buildings). AWHPs currently achieve a measured SPF<sub>SH+DHW</sub> of 3.5 in new single-family houses, while BWHPs achieve an SPF<sub>SH+DHW</sub> of 4.9. Assuming the average-case scenario, SPF<sub>SH+DHW</sub> values of 6.3 and 7.9 appear reachable by 2050, corresponding to a significant efficiency increase compared to today [12]. However, a prerequisite is that the economic and political framework conditions are set in such a way that further development of HP technology by the manufacturers takes place.
The difference in efficiency between AWHPs and BWHPs is most evident in the low supply temperature range, where the higher heat source temperatures have relatively more influence. In contrast, the difference in efficiency is smaller for old buildings because much running time of the AWHPs is at high outdoor temperatures. Nevertheless, field measurements show that BWHPs with higher supply temperatures perform better than those in the low-temperature range. Furthermore, BWHPs benefit from a stable geothermal heat source and have an average source temperature (7.9 °C) that is about 4 K higher than AWHPs (3.8 °C) [9].

Table 1. Seasonal performance factor (SPF) of AWHPs and BWHPs in heating (SH), hot water (DHW), and combined mode (SH+DHW) in 2018 and for an average future scenario in 2050 with 60 % Carnot efficiency (Data source: [12]).

4. Conclusions

AWHPs with variable speed compressors are well suited as a heating system for the conditions in Switzerland, especially for new residential buildings with low supply temperatures (e.g., floor heating). Due to the low heat demand in new buildings, AWHPs are usually the most economical and frequently chosen HP type. On the other hand, BWHPs are preferred in renovations due to the higher supply temperatures and heating capacities. However, correct dimensioning, integration, and parameterization are key to the efficient and long-lasting operation of all heat pump types.

Regarding efficiency, the analyzed AWHPs with variable speed compressors perform better on average than fixed speed models at a temperature lift below 40 K. At around 25 K temperature lift, the advantage of inverter-driven AWHPs is approximately 22 % in the SPF. However, in standby mode, inverter-driven HPs revealed considerable standby losses, which, combined with the low compressor running time, can significantly decrease system efficiency. The annual standby losses can vary between 25 kWh/a and 350 kWh/a depending on the system (factor of 14!).

Although good HP efficiencies are already achieved in the field, these can be increased by simple tricks in the controller settings. The greatest potential for optimization was identified on the HP control side. Recommendations are:

- Optimization of the supply temperature (i.e., settings of the heating curve and heating limit, 1 °C lower supply temperature corresponds roughly to 2.5 % efficiency gain)
- Optimizations in the control of the heat sink pump and the compressor speed
- Timing of DHW operation for AWHPs in the early afternoon (e.g., 13:00 to 15:00), as outdoor temperatures are higher than in the early morning hours (activation of summer function if available).

Assuming an average scenario with 60 % Carnot efficiency, SPF values (heating and DHW) of 6.3 for AWHPs and 7.9 for BWHPs seem achievable by 2050 if the economic and political framework conditions are set in a direction favorable for highly efficient HPs. What is needed in the medium term are better control systems for HPs that simplify installation and HPs that optimize themselves according to the heat demands of the building and the customer needs.

Multiparametric Analysis of Novel Multilevel Temperature Heat Pumps (LEAP) for Multi-Sink Heating

E.B. Badran¹, M. Yebiyo, C.H. Stignor, M. Axell, O. Gustafsson, M. Willis

RISE, Division of Built Environment, Department of Energy & Resources, Stockholm 114 28, Sweden

Abstract

Industrial sectors are currently seeking ways to decarbonize their processes which rely primarily on fossil fuel boilers. Heat pumps offer high-quality heating that could substitute boilers due to their high coefficient of performance (COP) for moderate temperature lifts. It is proven that the heat pump efficiency deteriorates with increased temperature levels. This paper examines multilevel heat pumps (LEAP) as an efficient way to produce high and/or variable-level sink temperatures. The LEAP concept operates between 0°C and 160°C with three heating levels at 60°C, 110°C, and 160°C. With a two and three-stage independent layered heat pump system, the sink heat exchanger is divided into two heat exchangers at each stage. One is used to supply the external load requirements, and the other is to cover the source or internal load on the higher consecutive stage cycle. The external load heat exchangers can be connected in series or parallel to control the desired load output temperature. A multi-parameter selection analysis was conducted using EES software to evaluate several natural and synthetic refrigerants with low values of the Global Warming Potential (GWP) index. For different scenarios, selected low GWP refrigerants were investigated based on their thermophysical properties. The multiparametric analysis shows that for each stage a COP of 3.5 was achieved and a total COP of 2.5 can be obtained for the LEAP concept. This is equivalent to an increase of about 40 % more than a single heat pump can provide. The best synthetic refrigerants were R-1234ze (Z), R-1224yd (Z), R-1233zd (E), and R1366mzZ (Z). On the other hand, the best natural refrigerants were R-600 (n-Butane), R-600a (Isobutane), R-601 (n-Pentane), and R-601a (Isopentane).

1. Introduction

Decarbonization of commercial and industrial processes is a requirement for a sustainable future. There is a great interest in increasing the use of waste heat, making efficient use of thermal energy and replacing fossil fuel boilers with other cleaner technologies. Heat pump systems are considered a greener alternative to fossil fuel boilers because electricity with a high share of renewable sources can power the system. Moreover, in the absence of waste heat sink sources, the heat must be extracted from near ambient temperatures. This would lead to higher temperature difference between both heat source and heat sink reservoirs, therefore; penalizes the system's energy performance and decreasing its environmental benefits.

Multilevel heat pump applications are scarce [1]. The most common solution for increasing energy performance in high-temperature lift applications is using multilevel vapor compression configurations. The LEAP concept, with the multi-layered configuration, offers flexibility in the operation and adaptation to the application. The potential of two-stage heat pump cycles compared to single-stage has been evaluated in terms of energy performance and heating capacity [2]. A two-stage cascade system has been investigated with appropriate configurations for 60 K and 80 K temperature lifts compared to other technologies, such as ejector or parallel compression. In each stage, efforts are mainly devoted to its optimization in terms of intermediate

¹ Corresponding author. Email address: bassam.badran@ri.se
temperature and refrigerants [3]. The use of natural refrigerants Butane (R-600) and Isobutane (R-600a), respectively, in a cascade system appeared to be the most viable working fluids in terms of COP for the low-temperature circuit, while R-601a (n-Pentane) and R-1336mzz (Z) were the most promising for the high-temperature stage [4]. Uusitalo et al. studied combinations of refrigerants and concluded that the temperature level in the cascade heat exchanger has a significant effect on the COP [5]. Wang et al. explored the applicability of an auto-cascade heat pump for heating in cold climates. The research found that R-134a / R-600 with a mass ratio of 0.8/0.2 could get a COP of 2.15 [6]. Yu et al. presented a novel auto-cascade heat pump for electric vehicles. Theoretical analysis indicated that the proposed system with CO2/R-290 improved the COP by 12.3 % compared to a single-stage compression system using CO2 [7]. Chen et al. proposed a novel vapor injection auto-cascade heat pump for high-temperature water heating, which introduced the liquid branch after the partial condensation into the injection port through a cascade internal heat exchanger based on the conventional auto-cascade cycle [8]. A most recent study investigated a three-stage cascade for very low-temperature refrigeration [9]. They studied different operating, energetic, and exergetic parameters and obtained the most suitable refrigerant combination. They found that this system has an optimum condensation temperature for each intermediate temperature.

R-134a and R-245fa refrigerants will be used as a base reference to select an appropriate refrigerant for each stage since they will be replaced in the upcoming years to prevent the usage of hydrofluorocarbons with high GWP. Dawo et al. investigated and showed that three low GWP refrigerants could replace R-245fa at a constant heat source temperature of 120°C with small variations in efficiency and heating output [10]. Several literature studies show that most multi-layered heat pumps only consider a two-stage system. They do not use the intermediate levels to satisfy other heating consumptions. This paper presents a multiparametric analysis of multilevel temperature heat pumps (LEAP) to obtain multilevel sink temperatures for variable heating applications.

2. LEAP configuration with multilevel sink temperatures.

The multi-layered heat pump concept is used to overcome the problems of decreasing compressor efficiencies and power consumption due to high-temperature lifts and give the user the freedom to choose the required sink temperature for different applications. To reach high-temperature outputs from a low-temperature heat source, moderate steps of temperature lifts can be utilized. This gradual increase is enough to cover greater temperature lifts. If no waste heat source is available, then the heat sink can be the same as ambient or even below ambient temperature. Therefore, additional stages should be considered for operating between ambient and industrial high temperatures. Usually, cascades are designed in two stages with the same working fluid, and this solution is enough to cover greater temperature lifts, for example, commercial refrigeration or air source heat pumps.

However, high-temperature industrial applications can reach 150°C, so additional stages should be carefully considered when operating between ambient and industrial high temperatures. When selecting the refrigerant, it is necessary to consider the thermodynamic and thermophysical properties, the environmental issues, and safety characteristics. Fig. 1 shows the temperature-entropy diagram of an ideal three-stage multi-layered heat pump, in which the different temperature levels in this system are visible.

![Fig. 1: T-s Diagram for LEAP Concept.](image-url)
Fig. 2 illustrate the conceptual structure of the LEAP idea where the condenser in the internal cycles is divided into two or several heat exchangers with equal loads. The first heat exchanger will cover the load of the evaporator in the successive cycle, whereas the remaining heat exchangers will supply the external users with the required loads at specific temperature. The external load heat exchangers can be connected in series or parallel to control the desired output temperature. Therefore, this system possesses excellent flexibility in covering different heating consumptions in buildings or industrial applications such as HVAC or domestic hot water systems.

The main assumptions for each LEAP concept start with an initial source load of 200 kW as the base load for the whole system, an isentropic efficiency of 70% for each compressor within the system, isenthalpic expansion within the expansion valve, constant and equal temperature lifts for each stage, no internal heat exchanger, and pressure drops and heat transfer to the ambient are neglected.

2.1. Low-GWP refrigerants for LEAP concept.

This section provides the various criteria considered to identify the refrigerant with the best thermophysical and thermodynamic properties, which maximizes the system's performance and minimizes the environmental impact. A variety of refrigerant types have been considered in order to choose the best refrigerant for the LEAP concept.

Fig. 3 shows the families of synthetic refrigerants obtained from natural ones and how the chemical processes would be done to obtain the required synthetic refrigerant.

Fig. 4 represents the triangle of elements, Hydrogen on the top, Carbon on the bottom left, and Fluorine on the bottom right. From the triangle, we can locate flammable, toxic, and long atmospheric lifetime (fully halogenated) areas. We can also find areas where refrigerants have high GWP values and high ozone depletion potential (ODP) rates.
All refrigerants will be investigated for a single-stage heat pump with different temperature lifts to eliminate and choose the right media for different stages in the LEAP concept. Table 1 illustrates the refrigerants under investigation in this paper. It shows the trend of increasing the critical temperature of the refrigerants and states the molar mass of the refrigerants’ molecules. It is clear from the table that some refrigerants are limited in substituting R-134a and R-245fa, and some are superior thermodynamically. All refrigerants in the table have a GWP around unity and almost zero ODP rates; therefore, their direct impact on climate change can be considered ultra-low.

### 2.2. Refrigerants’ selection for each stage.

Simulating a single-stage heat pump with different temperature lifts of 30, 40, 50, 60, 70, and 80K for the same conditions mentioned above, we notice that the heating loads for all “drop-in” refrigerants vary between -8% and 6% for R-134a as base refrigerant and between -14% and 2% for R-245fa as base refrigerant. Similarly, the COP ranges between -17% and 14% for R-134a and between -5% and 24% for R-245fa. Fig. 5 illustrates the COP trend for all refrigerants with a constant temperature lift of 60 K. The evaporator temperature starts with the boiling point temperature of the selected refrigerant with a gradual increase of 2K. The COP values decline as we go higher in the evaporator temperature as we go closer to the critical temperature. It also shows the available refrigerants that can substitute R-134a and R-245fa with respect to COP values.

![COP trend for all refrigerants.](image)

Table 2 indicates the variation of COP and heating load (HL) for all investigated refrigerants in a single-stage heat pump with a temperature lift of 60 K as a sample parameter. These values are given in equations (1) and (2) for R-134a and R-245fa as the base refrigerants. We notice from the table that the base refrigerants can be replaced with several refrigerants with an increased COP values and some variation in the heating load on the sink side. The trend is more stable in R-245fa with increasing temperature lifts where the COP values increased while the heating load capacity decreased for all refrigerants. This trend is not clear for R-134a.

Table 2 indicates the variation of COP and heating load (HL) for all investigated refrigerants in a single-stage heat pump with a temperature lift of 60 K as a sample parameter. These values are given in equations (1) and (2) for R-134a and R-245fa as the base refrigerants. We notice from the table that the base refrigerants can be replaced with several refrigerants with an increased COP values and some variation in the heating load on the sink side. The trend is more stable in R-245fa with increasing temperature lifts where the COP values increased while the heating load capacity decreased for all refrigerants. This trend is not clear for R-134a.

\]

The first stage in the LEAP concept work between 0°C and 60°C for the heat source, the second stage operate between 50°C and 110°C, and between 100°C and 160°C for the third stage. This means that the maximum temperature for the heat sink is 150°C. If we take the critical temperature of the refrigerant as a base for comparison with positive COP values and a temperature lift of 60K, several candidates for the first stage, as per Table 2, can be selected. If we, however, open the selection for all COP values, the option to select a suitable refrigerant can widen, and the choice will vary for each LEAP stage.

Table 3 shows the selected refrigerants for each stage with boiling temperature below 0°C and critical temperature above 60°C for the first stage, below 50°C and above 110°C for the second stage, and below 100°C and above 160°C for the third stage.

3. Results & Discussions

3.1. LEAP results with 2-layered heat pump.

Running the simulation software EES for variable combinations of refrigerants between the first and the second stage starting from the boiling point of the refrigerant, we notice that no matter what the selection
would be for the first stage, the second stage will output increasing COP values, as seen in Table 4, and fluctuating heating load values.

</tbody>
</table>

The structured array of increasing COP values in the second stage is composed of the following refrigerants: R-600a, R-600, R-1224yd (Z), R-1336mzz (Z), R-1234ze (Z), R-601a, R-1233zd (E), and R-601. The best combination for the 2-layered heat pump is R-600 with a COP of 3.448 for the first stage and R-601 with a COP of 3.722 for the second stage. If the choice is to use only synthetic refrigerants, then that R-1234ze (E) with a COP of 3.252 for the first stage and R-1233zd (E) with a COP of 3.675 for the second stage. In the 2-layer heat pump, we obtain two levels of temperatures, 50°C and 100°C, or we can increase the sink source temperature from 10°C to 100°C in one step.

If a single-stage heat pump is supposed to deliver the same sink temperature of 100°C from a 10°C source temperature, then the temperature lift is 110 K. By looking at the refrigerants' thermophysical properties, we can see that only R-600 and R-600a will comply, and the COP values will be 1.6 and 1.4 respectively compared to a total COP value of 2.56 for the LEAP two stages. Using a 2-layered heat pump will therefore lead to energy savings of almost 40%.

### 3.2. LEAP results with 3-layered heat pumps.

In the third stage layer, the compressor enthalpy discharge values will land in the vapor-liquid mixture zone instead of the superheated zone due to the positive slope of the vapor line in the P-h chart. To overcome these discrepancies, the superheat and subcooling temperatures will be increased to overcome the false values.

Using the same analogy from the 2-layered heat pump, Table 5 summarizes the refrigerants that can be selected for each stage. For the first and the second stage, the array of refrigerants is the same. Considering the third stage, fewer options are available. The best option is R-600 for the first and the third stages, with COP values of 4.143 and 5.877 respectively, and R-601 for the second stage with a COP value of 4.527. If a single-stage heat pump is supposed to deliver the same sink temperature of 150°C from a 10°C source temperature, then the temperature lift will be 160K. In this case, only R-601 and R-601a will comply, and the COP values will be 1.336 and 1.264 respectively with high-power compressors. The total COP value for the LEAP three stages is 2.539. The increase in using a 3-layered heat pump is an energy saving of almost 48%.

### 4. Conclusions

This paper analyzes the performance of a three-stage heat pump with multilevel heating based on different working fluids for taking advantage of the flexibility of heat pumps in comparison with other heating technologies. The most suitable low GWP refrigerants for condensing temperatures of 60°C, 110°C and 160 °C (at the evaporation temperature of 0°C, 50°C, and 100 °C respectively) have been studied in terms of
operational and thermodynamic potential. The highest heating production is set at 150 °C, and the nominal heating capacity is 200 kW. The heat transfer to the external flow in the intermediate and low condensing temperature depends on the cycle selection.

Refrigerants have been classified according to the critical temperatures, pressures, and working pressure-temperature relationship. R-1224yd (Z), R-1234ze (Z), R-1234ze (E), R-1225ye (Z), R-1234yf, R-1243zf, R-290, R1270, R600, R600a with positive COP values have been proposed at the first stage to replace R134a; R-1336mzz (Z), R-1233zd (E), R-1224yd (Z), R-1234ze(Z), R-600, R-600a, R-601, and R-601a at the second stage; R-601, R-601a, R-1336mzz (Z) and R-1233zd (E) at the third stage. From that list, carbon dioxide, water, and ammonia have not been considered for this study because of the significant difference in critical temperatures and safety requirements to HFCs traditionally used (R-134a and R-245fa).

Refrigerants with a higher coefficient of performance capacity have been selected for each cycle. R-1234ze (E) and R-1233zd (E) as synthetic refrigerants, and R-600 and R-601 as natural refrigerants for a 2-layered heat pump with a total COP of 40% more than using the single-stage heat pump. R-1234ze (E), R-1233zd, R1336mzz (Z) as synthetic refrigerants, and R-600, R-601, and R-600 as natural refrigerants for 3-layered heat pump with a total COP of 48% more than using the single-stage heat pump. These values of COP are promising since it makes the heat pump a valuable alternative to natural gas boilers in most European countries.

Abstract

High-temperature heat pumps (HTHP) with supply temperatures above 100 °C are becoming increasingly important for the electrification and decarbonization of industry. However, their adoption is slow because there is still a lack of knowledge about their capabilities, design, control, and optimal integration, resulting in few practical implementation examples. This study investigates the technical and economic feasibility of HTHP integration based on case studies from the Swiss industry. ELSA (Estavayer Lait SA), Cremo SA, and Gustav Spiess AG support the research and provide access to industrial process data. ELSA, Switzerland’s largest industrial dairy on a single site, is interested in a HTHP supplying steam for cleaning-in-place processes. Cremo SA manufactures dairy products and sees opportunities to integrate a HTHP in a milk permeate drying plant that consumes a large amount of 3 bar steam. Gustav Spiess AG produces meat products and sees potential for integrating a HTHP into sausage cooking processes for steam generation at about 115 °C. In addition, other Swiss industrial companies in the food, biotech, and chemical sectors also show interest in HTHPs for applications such as distillation, sterilization, drying, and steam generation. This study presents suitable HTHP integration concepts based on case studies with quantified efficiency gains, energy savings, CO₂ reduction, and cost-efficiency results. It also includes an up-to-date review of HTHP suppliers derived from participation in the IEA HPT Annex 58 that shares results and knowledge with international experts on HTHPs.

1. Introduction

1.1. Application potential of industrial HTHPs in Switzerland

Switzerland has been pioneering in developing and commercializing heat pumps (HP). The first European HPs were realized in Switzerland (e.g., in 1877 at the salt works at Bex) [1]. In 2021, HP sales increased to an all-time high of 33,704 units (20% growth compared to 2020) [2]. Especially in the small-capacity range for single- and multi-family houses, HPs are an established technology for space heating and domestic hot water, with a market share of over 90% in new buildings. Above 100 kW heating capacity, 169 HPs were sold (around 0.5% of all units) since, in larger heating capacity ranges, oil and gas boilers still dominate process heat generation [3]–[5]. Therefore, replacing fossil heating systems with electrically-driven industrial HPs is...
a possible scenario to reduce CO₂ emissions from industry. High-temperature heat pumps (HTHP) with supply temperatures above 100 °C are increasingly important to replace fossil fuels in industries [6]–[8]. The most relevant application areas for HTHPs are the food/beverage, chemicals, and pulp/paper industries for processes like drying, evaporation, sterilization, or similar thermal processes with available waste heat from about 30 °C to 70 °C and process heat demand from 80 °C to 150 °C [9]. Based on annual energy consumption of around 43 TWh in Switzerland [10], a 30% share of process heat and steam below 150 °C [11], and a moderate conversion rate of 40% to HPs and HTHPs [12], the addressable energy savings potential from the use of HTHPs in the Swiss industry can be roughly estimated at 2'893 GW/a which is approximately 6.7% of the total process heat demand [13] (Table 1).

</tbody>
</table>

Compared to natural gas, which has an emission factor of 0.201 kg CO₂ per kWhₙ of useful heat [14], the consumer electricity mix available in Switzerland is 0.128 kg CO₂/kWhₘ [15]. On this basis and with an average COP of 3.0 to 4.0 for an industrial HTHP at about 40 K to 60 K temperature lift from heat source inlet to sink outlet (assuming 45% Carnot efficiency [6], [7], [16]), the generated CO₂ emissions per useful heat are about 0.032 to 0.043 kg CO₂/kWh, which is 5 to 7 times lower than for a gas boiler (assuming 90% boiler efficiency). Assuming that integrated HTHPs would run with 5'000 operating hours per year on average, this results in a total heating capacity of 579 MW and, with specific investment costs (incl. installation, without integration, valid for 500 kWₙₙ HP size) of approx. 450 to 700 EUR per kW heating capacity [17], a potential market of 260 to 405 million EUR for Switzerland. Assuming an average heating capacity per HTHP unit of 1 MWₙₙ is equivalent to installing around 579 HTHP units.

Thus, integrating industrial HTHPs will contribute to energy savings, CO₂ reduction, and a substantial new market. Furthermore, expanding renewable energy and increasing energy efficiency in industrial processes align with the federal government’s Energy Strategy 2050 [18]. Consequently, HTHP technology supports the efforts of Switzerland’s net carbon emissions to net zero by 2050 [19].

1.2. Existing challenges for the wider spread of HTHPs

However, HTHPs are just beginning to enter the market of industrial heat production. There is still a lack of knowledge about available HTHP technologies and products (>100 °C supply temperature), methods for optimal integration, proper sizing, control, dynamic behavior, and techno-economic feasibility, resulting in few realized references with operational experience. As highlighted in a white paper [20], demonstration projects with increased knowledge sharing at the international level are needed to drive further HTHP technology dissemination and achieve greater visibility, particularly in process electrification. In this context, the authors of this study participate as Swiss representatives in the IEA HPT Annex 58 on HTHPs to exchange results and knowledge with international experts. In recent studies, the techno-economic feasibility of integrating HTHPs for steam generation in distillation applications was investigated [21], [22], and an up-to-date overview of the latest HTHP developments and products for supply temperatures above 100 °C was presented at the China Heat Pump Conference 2022 [16]. The analysis of the integration of HTHPs into ammonia and pulp production was also presented at CPOTE 2022 [23] and ECOS 2022 [24].

1.3. Objectives of this study

This study investigates the technical and economic feasibility of HTHP integration based on case studies in Swiss industrial companies with heat source temperatures from 40 to 80 °C to provide process heat (e.g., steam) at 115 to 150 °C and about 0.5 to 3.5 MW heating capacity. First, a review of current HTHP products and the corresponding working domains (e.g., heating capacity, temperatures) is given. Next, a simple economic model is used at an early planning stage to assess whether a HTHP integration could be economically viable. Then, the investment and operating costs of HTHPs are analyzed for the case studies using a cost model with different
input parameters. Finally, the payback period, the avoided CO₂ emissions, and the energy savings are calculated, and the main influencing factors are discussed in a sensitivity analysis.

2. Market review of industrial HTHPs and operating ranges

The range of industrial HTHP products on the market has grown steadily in recent years (especially since 2018 [6]). Table 2 presents an overview of 33 HTHP products with heat supply temperatures above 100 °C based on information collected in the IEA HPT Annex 58 project [25]. The list includes closed-cycle and open-cycle HPs for mechanical vapor recompression (MVR). It is structured by maximum supply temperature, HTHP supplier, country, compressor type, the working fluid (refrigerant), maximum heating capacity, and technology readiness level (TRL) [16]. The specific investment costs are also given in EUR/kW. It should be noted that the HTHP suppliers provided the information without third-party validation. Therefore, the data is indicative and may vary in the final installations depending on the application-specific parameters.

Table 2. Overview of HTHP technologies and suppliers structured by maximum supply temperature above 100 °C [16] (Note: The HTHP suppliers provided all information without third-party validation. Therefore, the data is indicative and may vary in final installations depending on application-specific parameters).

Figure 1 shows the industrial HTHP products sorted by their maximum heat supply temperature and heating capacity. The heating capacities range from laboratory demonstrators of about 10 kW to larger 70 MW units. Illustrated in color are the compressor technologies, including screw, piston, turbo, and others like the rotary vane compressor from ToCircle, the heat transformer from QPinch, or the Rotational HP from Ecop using a noble gas in a Joule cycle. These last examples show various technologies emerging alongside more classical Carnot cycles.

In most cases, turbo compressors are used for large heating capacities. For HTHP applications and high temperature lifts, compressors must be able to handle high pressure ratios. Therefore, the compressor manufacturers offer optimized designs for special applications.

For HTHP application, the steam compressors must preferably offer high flow rates at low suction pressure, high pressure ratios to reduce the number of compression stages, temperature resistance (e.g., need for liquid injection), and long-term corrosion resistance. In particular, a development perspective is small steam compressors for integrating HTHPs in industrial processes with an open cycle or combined in a two-stage cycle with MVR [26].

For example, Spilling’s piston steam compressors operate at suction pressures above 1.4 bar(a) (110 °C) and achieve temperature lifts of up to 100 K with a 3-stage compression design in one unit. Piller’s VapoFans are used in multi-stage MVR applications with suction pressures down to about 100 mbar(a) (45 °C). Enerin and Olvondo provide HTHPs with helium (R704) as working fluid and double-acting piston compressors in a Stirling cycle, which allow flexible operation conditions, high limits, and supply temperatures above 200 °C.
Some HTHP suppliers provide closed-cycle HTHPs with up to 165 °C supply temperature using HFO refrigerants, e.g., the HeatBooster from Heaten or the ThermBooster from SPH. Other suppliers realize steam-generating HP using natural refrigerants, e.g., Ohmia Industry with ammonia (R717) in a bottom cycle and water (R718) in an open top cycle with MVR, Mayekawa with n-butane (R600), or Johnson Controls (Sabroe) with an R717/R600 cascade system using piston compressors.

Hybrid Energy uses ammonia/water (R717/R718) as the working medium in an absorption/compression cycle. As a result, temperatures up to 120 °C are achieved with high efficiency, and potentially high temperature glides on the heat source and sink. Recently, Fenagy commercialized CO₂ HPs for hot water heating from 30 to 120 °C with heating capacities up to about 1,800 kW.

Other manufacturers of HTHP products not listed in Table 2 and Figure 1 are Ago Calora (absorption-compression cycle, R717/R718, up to 150 °C), Ochsner (HFO refrigerants, up to 130 °C), Oilon (R1233zd(E), up to 120 °C), PureThermal (R717/R600, up to 120 °C), or Combitherm (HFO refrigerants, up to 120 °C). Finally, several large-scale HTHPs with > 10 MW heating capacity for industrial applications are supplied, for example, by Friotherm, MAN Energy Solutions, Turboden, Mitsubishi MHPS, or Siemens Energy.

Figure 2 shows the operating maps of some industrial HTHPs as a function of the heat source and sink temperature. In particular, there is a higher share around 50 °C heat source and 120 °C sink temperature. The operating limits are determined by the permissible condensation pressure, evaporation pressure, compression ratios, differential pressure across pistons, compressor speed, discharge gas temperatures, lubrication (e.g., oil temperature issues), and lowest allowable suction pressure.
Overall, Table 1 and Figures 2 and 3 demonstrate the availability of HTHP products and steam compressors and can be used as decision-support data for selecting appropriate HTHP suppliers. A preliminary technical feasibility check for HTHP integration consists of verifying the availability of a HTHP compatible with the temperature levels of the heat source and sink and heating capacity for a given project. In addition, industrial site constraints may further limit the HTHP integration options, such as the choice of refrigerant used (e.g., natural or synthetic), cycle concept (e.g., open, closed, or combinations), and space limitations.

Finally, a Pinch analysis can determine the optimal HTHP integration in an industrial context, which also identifies heat recovery options to increase efficiency and reduce energy consumption. Depending on the application, tailor-made HTHP designs are required (i.e., concepts for large temperature glides in the heat sink versus steam generation with no temperature glide).

3. Case studies and economic model

The following section describes case studies of potential HTHP integrations from the industrial companies ELSA, Cremo SA, and Gustav Spiess AG that support the Swiss project Annex 58 HTHP-CH by giving access to industrial process data. Furthermore, various other Swiss industrial companies (e.g., food, biotech, chemical) and HP suppliers are in contact with the project team showing interest in HTHP integration.

3.1. Case Study at ELSA (Estavayer Lait SA)

ELSA (Estavayer Lait SA) is Switzerland's largest dairy on a single site, processing around 260,000 t/a of milk into a wide range of fresh dairy products, such as UHT milk, yogurt, quark, and cream. The main heat treatments are pasteurization and sterilization in the temperature range of 65 to 155 °C. In addition to the production processes, CIP processes (Cleaning in Place) require large amounts of water and are an important steam consumer (e.g., 4.5 bar(a), 148 °C) (Figure 3). Today, process steam is generated by a wood chip steam boiler and several natural gas boilers (71.6 GWh/a or 275 kWh/t milk processed).

The process requirement for CIP is keeping the circulating basic and acidic solutions at 75 °C and 60 °C respectively, while the “sterilization” step of processing equipment, taking place after cleaning and, if needed, before the next operation, requires circulating hot water at 90 °C. These requirements could, in principle, be fulfilled with a hot utility below 100 °C; however, retrofitting the CIP stations (comprising 65 heat exchangers in total) for a hot water utility at 95 to 100 °C instead of steam at 4.5 bar(a) would be both expensive and difficult to implement because of the lack of space.

Therefore, to save energy and water, ELSA is interested in integrating steam-generating HTHPs that use waste heat from the NH₃ chillers (about 23.7 GWh/a at 40 °C, currently discharged through cooling towers) or drain water (about 490,000 m³/a at 50 °C) as a heat source to replace some of the steam required for the CIP processes (about 22.7 GWh/a at 7,200 h of operation corresponding to 3.15 MW). Although the heat sources and sinks have yet to be confirmed, Figure 3 shows potential HTHP integration points for the CIP plants. Measurements are ongoing to determine the mass and heat balance of CIP operations and to check whether a significant share of the consumed 4.5 bar(a) steam could, in practice, be supplied at a significantly lower temperature and affordable costs.
The electricity price for 2023 is around 0.18 CHF/kWh [27] in Estavayer for a large industrial company (Category C7), and the gas price (Type X) is about 0.13 CHF/kWh, including CO₂ tax of 0.02 CHF/kWh [28]. These conditions result in a favorable electricity-to-gas price ratio of around 1.4. Compared with natural gas, which has a CO₂ emission factor of 0.201 kg CO₂ per kWh [14], an average Swiss consumer electricity mix of 0.128 kg CO₂/kWhel is considered [29]. The cost multiplication factor for planning and integration is assumed to be 3.0 because the installation environment is quite complex, and space is tight.

3.2. Case Study at Cremo SA

Cremo SA in Villars-sur-Glâne processes around 240,000 t/a of milk into various dairy products, including cheese (Gruyère, Vacherin fribourgeois, Raclette), butter, skim milk, milk proteins, and milk permeate powder. Today, the heat is supplied by two 5 MW gas-fired steam boilers (12 t/h steam, baseline consumption). In addition, a district heating network (105 °C/80 °C supply/return) from the nearby waste incineration plant provides heat to an internal hot water loop at 105 °C/60 °C that is connected to spray dryers (for preheating air), a TIXOTHERM™ drying process [30], evaporators, pasteurizers, CIP stations, building HVAC, and tap hot water. In case of a future reduction of the district heating temperature to 80 °C / 60 °C, the possibility of a large-scale HTHP is considered (around 5 to 10 MWth) to adapt to the changing heat transfer rate (Figure 4).

Fig. 4. Potential HTHP integration point at Cremo using district heat as a source and upgrading the heat to the internal hot water loop.

Another potential integration point for a HTHP has been identified in the TIXOTHERM™ drying plant (Figure 5), which produces milk permeate powder (containing milk sugars) and currently consumes about 10% to 15% of the total steam demand for heating a Rosinaire™ paddle dryer [30]. Presently, there is only limited heat recovery on the humid exhaust air. Therefore, this case study is a priori suitable for a HTHP integration to supply low-pressure steam at around 1.4 bar(a) (110 °C) to the paddle dryer using humid exhaust air as a heat source (65 °C) and substitute steam generation from the steam boilers.

Fig. 5. Potential HTHP integration point at Cremo in the TIXOTHERM™ drying process with a Rosinaire™ paddle dryer, where humid exhaust air could be used as a heat source to generate steam.
Figure 6 (left) shows the calculated Composite Curves (CCs) as the initial situation before the integration of a HTHP, indicating a Heat Recovery (HR) potential through direct heat transfer of about 600 kW between air flows and a Pinch temperature at around 70 °C. Furthermore, Figure 6 (middle) shows the corresponding Grand Composite Curve (GCC) with an integrated HTHP, providing a 940 kW condensation capacity at 120 °C and 570 kW evaporation capacity at 38 °C, from which a COP of 2.3 can be derived (see COP-fit formula in Figure 8). Finally, Figure 6 (right) shows the CCs after integrating the HTHP. The example demonstrates a potential reduction of the Hot Utility (HU) by 100% (from 940 to 0 kW) and the unused waste heat by 47% (from 1,204 to 634 kW), and an increase of the HR potential by 249% (from 605 to 2,113 kW).

![Composite curves (CC, left) and grand composite curve (GCC, right) of the TIXOTHERM process with paddle dryer at Cremo showing the potential HTHP integration providing low-pressure steam at 110 °C and using humid exhaust air as a heat source (Pinch at 70 °C, evaporation temperature at 38 °C, condensation temperature at 120 °C, COP of 2.3).](image)

A challenge is the low evaporation temperature (and thus the large temperature lift of 80 K) and the probably insufficient evaporation capacity if the waste heat is to be recovered exclusively from the drying process. Therefore, additional waste heat sources must be identified at about 35 to 40 °C. The estimated annual operating time of the potential HTHP is about 6,400 hours, which is within the range of various techno-economic studies presented in a literature review [21], [22]. The electricity price for a customer of the size of Cremo is 0.2 CHF/kWh, and the gas price is 0.11 CHF/kWh, corresponding to an electricity-to-gas price ratio of about 1.8. The CO₂ emission factor of electricity at Cremo is around the average Swiss consumer electricity mix of 0.128 kg CO₂/kWh [29], as the mix contains renewables, just not purely renewables. Furthermore, a discount rate of 2% is used to estimate the discounted payback period of the HTHP investment. The cost multiplication factor for calculating planning and integration costs is assumed to be 2.0.

3.3. Case Study at Gustav Spiess AG

Gustav Spiess AG in Berneck (SG) produces meat products such as sausage, ham, and bacon. Today, a gas boiler provides steam (6 to 8 bar(a)) to heat the pasteurization and cooking/smoking cabinets (Figure 7). The steam pressure is reduced to 1.5 bar(a) (115 °C) to achieve cabinet temperatures of 85 to 90 °C and a sausage core temperature of about 72 °C. Here, integrating a 550 kWth steam-generating HTHP is under consideration, using the waste heat from the NH₃ chillers as a possible heat source at 40 to 50 °C. Typical operation is 12 hours per day, 250 days per year, resulting in an annual operating time of about 3,000 hours. The expected payback period for new energy-related infrastructure investments is about 8 to 10 years. The electricity price for medium-sized customers in the given area is 0.25 CHF/kWh, and the gas price is 0.17 CHF/kWh resulting in an electricity-to-gas price ratio of 1.5, which appears favorable for electricity-powered heating and cooling technologies. The purchased electricity mix is nuclear energy with a low CO₂ emission factor of about 0.012 kg CO₂/kWh. The cost multiplication factor accounting for planning and integration is assumed to be 2.0.
3.4. Economic evaluation and COP estimation

The economic evaluation of the case studies is based on a calculation tool developed in MS Excel, illustrated in Figure 8 [21], [22]. It assumes that the investment of the gas boilers is depreciated and that the gas boilers remain for production safety, redundancy, start-up operation, and peak load coverage. Input parameters to the evaluation tool are electricity price ($c_{el}$), gas price ($c_{fuel}$), operating hours ($t$), heating capacity ($Q_h$), temperature lift between the heat source and sink ($\Delta T_{lift}$), specific investment costs ($c_{inv,HP}$), maintenance cost factor ($f_{maintain}$), interest rate ($i$), the emissions factors of electricity and fuel ($f_{CO2}$), and CO$_2$ tax refund (subsidies). The output results are the $\text{COP}$, CO$_2$ emissions reduction ($\dot{m}_{CO2, reduction}$), annual cost savings ($C_{savings}$), and the payback period ($PP$). The calculation tool helps to quickly evaluate the economic feasibility as a “go/no-go” decision.

1. First, the efficiency of the HTHP is estimated using the temperature lift ($\Delta T_{lift}$) and a COP fit-curve ($\text{COP} = 52.94 \cdot \Delta T_{lift}^{-0.716}$) derived from quotes from various heat pump suppliers [21], [22].

2. Next, the investment costs ($C_{inv,HP}$) of the industrial HTHPs are evaluated based on the specific investment costs ($c_{inv,HP} = 3'157 \cdot Q_h^{-0.322}$) according to price information from heat pump suppliers, the heating capacity ($Q_h$), and a cost multiplication factor ($f_{inv,HP}$) accounting for planning and integration (typically between 1.5 to 4.0 depending on the complexity of integration, e.g., including heat storage, site’s electrical installation, piping, hydraulics, etc.) [21], [22].

3. Then, the annual cost savings are calculated considering the following:
   - electricity cost ($C_{el}$) to operate the HTHP.
   - maintenance costs ($C_{maintain}$) of the HTHP using a multiplication factor ($f_{maintain}$) on capital cost (typically between 1.5% to 6%, in the case studies, 4% is used) [21], [22],
   - saved fuel costs ($C_{fuel}$) (assuming 90% boiler efficiency $\eta_{fuel}$), and
   - possible refunds of CO$_2$ reduction ($C_{CO2}$) (e.g., carbon taxes or subsidies).

4. After that, the payback period of the HTHP investment is evaluated as a trade-off between the investment costs versus the expected annual cost savings resulting from the heat pump investment.
5. Finally, the discount rates \( i \) are considered to calculate the discounted payback periods \( (DPP) \) \([31]\), depending on the investor’s risk tolerance (e.g., sector, company size, energy intensity, funding source, new technology, etc.) \([32]\). Typical discount rates for HP investments range from 5% to 15%, according to reviewed literature \([21]\), \([22]\). The \( DPP \) (discounted payback period) is the period after which the cumulative discounted cash inflows cover the initial investment \([31]\). The \( DPP \) can therefore be interpreted as a period beyond which a project generates economic profit. In contrast, the static \( PP \) gives a period beyond which a project generates accounting profit.

\[
\text{DPP} = \frac{\ln (1 - \frac{C_{\text{total}}}{C_{\text{savings}}})}{\ln (1 + i)}
\]

\[
C_{\text{savings}} = C_{\text{CO2}} + C_{\text{fuel}} - C_{\text{el}} - C_{\text{equipment}}
\]

\[
C_{\text{CO2}} = \frac{m_{\text{CO2, reduction}} \cdot C_{\text{CO2, fuel}}}{\eta_{\text{fuel}} \cdot \text{COP}}
\]

\[
C_{\text{fuel}} = \frac{(Q_h \cdot t \cdot c_{\text{fuel}})}{\text{COP}}
\]

\[
C_{\text{el}} = \frac{(Q_h \cdot t \cdot c_{\text{fuel}})}{\eta_{\text{fuel}} \cdot \text{COP}}
\]

\[
C_{\text{CO2, fuel}} = \frac{m_{\text{CO2, reduction}} \cdot C_{\text{CO2, fuel}}}{\eta_{\text{fuel}} \cdot \text{COP}}
\]

\[
C_{\text{total}} = C_{\text{CO2, fuel}} + C_{\text{fuel}} + C_{\text{el}} - C_{\text{equipment}}
\]

\[
DPP = \frac{\ln (1 - \frac{C_{\text{total}}}{C_{\text{savings}}})}{\ln (1 + i)}
\]

\[
\eta_{\text{fuel}} = \eta_{\text{fuel}}(\Delta T_{\text{in}}) = 3'157'Q_h^{-0.322}
\]

\[
\text{COP} = 52.94'\Delta T_{\text{in}}^{-0.716}
\]

\[
PP = \frac{C_{\text{fuel}}}{C_{\text{savings}}}
\]

\[
\eta_{\text{fuel}} = \eta_{\text{fuel}}(\Delta T_{\text{in}}) = 3'157'Q_h^{-0.322}
\]

\[
\text{COP} = 52.94'\Delta T_{\text{in}}^{-0.716}
\]

Fig. 8. Economic calculation, COP, and specific investment costs to derive the payback period for HTHP integration \([21]\), \([22]\).

4. Results and discussion

Table 3 summarizes the results of the three case studies. The calculations lead to payback periods of 2.0, 3.7, and 3.3 years, which means that HTHP integration would be cost-effective under current assumptions. Overall, the case study examples show significant annual energy savings of 55%, 60%, and 66%, and CO2 emission reductions of 71%, 75%, and 98%, respectively. The COP varies between 2.0 and 2.7 according to the COP-fit function shown in Figure 8.

The case study ELSA has the highest temperature lift of 98 K and consequently the lowest COP as well as a cost multiplication factor for planning and integration of 3.0, but benefits from favorable electricity-to-gas price ratio and low specific investment costs due to the large HTHP (economies of scale).

In the Cremo case study, the electricity-to-gas price ratio is higher, and the integration factor is 2.0, but the discount rate is low, leading to a DPP of 3.9 years. The pinch analysis is a powerful tool to determine the optimal placement of a HTHP, its size, and adequate evaporation and condensation temperatures.

The case study of Gustav Spiess AG shows a high CO₂ emission reduction of 98% because the company benefits from low CO₂ emissions by purchasing nuclear power. Using waste heat from the NH₃ chillers as a heat source shows great multiplication potential in other case studies in the Swiss food industry, where refrigeration machines for cooling foods are state of the art.

In addition to the three case studies, Table 3 also shows the results of the payback period for a possible Reference Case 2023 (Ref) with a heat source of 50 °C, a heat sink of 120 °C (COP of 2.5), and 1 MW heating capacity, and specific investment costs of 341 EUR/kWₘ. This scenario uses a discount rate of 10%, an average Swiss consumer electricity mix with a CO₂ emission factor of 0.128 kgCO₂/kWhₘ [29], and a possible carbon tax refund of EUR 92.5/tCO₂ due to the reduction of CO₂ emissions. Electricity and gas prices are based on market data for 2023 [33] (0.15 EUR/kWh PEGAS NCG Year Future and 0.35 EUR/kWh Phelix Year Future, price ratio 2.33, as of December 11, 2022).

Figure 9 shows a sensitivity analysis of the payback period for the Reference Case 2023 (abbreviated as Ref). All input factors of the model were individually varied from -25% to +25% (factor 0.75 to 1.25), while the other parameters were kept constant. The sensitivity analysis reveals that the payback period is strongly sensitive to a change in electricity and fuel prices as well as the temperature lift of the heat pump.
Favorable conditions for HTHPs are higher values of fuel prices, operating time, fuel CO₂ emission factor, CO₂ tax, heating capacity, and lower electricity prices. In addition, an increasing CO₂ tax, along with subsidies and possible CO₂ compensation through the European emission trading system increase the financial incentives for HTHPs.

Fig. 9. Sensitivity analysis of the payback period for a Reference Case 2023 (Ref) at 50 °C/120 °C heat source/sink, 1’000 kW heating capacity, and an electricity-to-gas price ratio of 2.33. The graphs below show the impact of electricity price, temperature lift, and cost factor for planning & integration on the payback period as a function of the electricity-to-gas price ratio.

On the other hand, low gas and high electricity prices lead to unfavorable conditions and are significant barriers to the investment of industrial HTHPs. As seen in the lower diagrams of Figure 9, the payback period is strongly determined by the electricity-to-gas price ratio. Above a price ratio of 2.7, the payback period is more than 10 years. In addition, the payback period is strongly influenced by the temperature lift, which determines the COP and, thus, the operating cost of the HTHP and the avoided fuel consumption.

For given energy prices and temperature lift, the cost multiplication factor for planning & implementation leads to significant uncertainty in quantifying the payback period. The cost multiplication factor depends on the complexity of the HTHP integration and can only be properly determined after a thorough analysis of the project and indicative price quotations for the entire heating system implementation.

5. Conclusions

A simple cost model was developed to pre-assess the economic feasibility of integrating HTHPs into actual industrial processes based on investment costs and annual cost savings. The analyzed HTHP integrations at ELSA, Cremo, and Gustav Spiess show significant annual energy savings of 55%, 60%, and 66%, and CO₂ emission reductions of 71%, 75%, and 98%, respectively. The calculations lead to payback periods of 2.0, 3.7, and 3.3 years, which means that the integration of HTHP would be cost-effective under the current assumptions. However, it should be noted that the financial evaluation strongly depends on the individual case. A sensitivity analysis has shown that higher fuel prices mainly shorten the payback period. An electricity-to-gas price ratio below 2.7 leads to payback periods below 10 years. Temperature lifts below 70 K appear to be profitable. Economic challenges arise with high temperature lifts, low gas prices, and high discount rates. Overall, the availability of closed-cycle HTHP products and steam compressors shows that the case studies are technically feasible with the integration concepts presented. A wide range of HTHP products is available up to 120 to 160 °C supply temperature. Individual HTHP products achieve temperature lifts of up to 125 K. HTHPs are also available in the large heating capacity range >10 MW. More detailed discussions with HTHP manufacturers are required in the next step to clarify the end-user-specific integration conditions. In addition,
the cost model can be applied to other Swiss case studies for initial cost estimation. Future work could include integrating an advanced heat pump model that considers the effects of refrigerant, compressor efficiency, and cycle design.

Analysis of the performance of a heat pump with subcooling control as a function of the refrigerant charge

Belén Llopis-Mengualª, Emilio Navarro-Perisª*

ªInstituto Universitario de Investigación de Ingeniería Energética (IUIIE), Universitat Politècnica de València (UPV), Camino de Vera s/n, 46022, Valencia, Spain

Abstract

When using hydrocarbons like propane (R290) as a refrigerant in heat pumps, it is critical to detect if the system is undercharged to find potential leaks, as they are flammable. This is specially challenging in reversible air-to-water heat pumps where a liquid receiver to compensate for the charge fluctuations is commonly installed. This liquid receiver introduces some tolerance of the system to charge fluctuations which are desirable from the system performance point of view but also makes especially difficult the pre-diagnosis of a possible leak. This study has experimentally characterized the performance with different refrigerant charge levels of a reversible air-to-water propane heat pump with a liquid receiver at the compressor inlet and a variable-speed compressor. It has different control strategies: superheat control for cooling and subcooling for heating mode. The work shows the evolution of the most important system variables like discharge, condensation, and evaporation temperature, as well as subcooling and superheat, and which could be the impact on the system performance. Finally, the use of compressor speed as a tool to diagnose potential system undercharge faults have been pointed out as a promising strategy.

1. Introduction

Nowadays, attempts are being made to reduce the energy consumption in heating, cooling, and domestic hot water, since it accounts for the 80% of the energy that citizens consume [1]. Heat pumps that use outdoor air to heat water for heating and domestic hot water can undoubtedly contribute to this. In addition, if they are reversible, they can also provide cold water for air-conditioning. According to [2], heat pump sales grew by 34% in Europe in 2022, and within a short period of time, heat pump installations are expected to increase.

Concerning the refrigerants used in these systems, the European Union currently restricts a large number of hydrofluorocarbons (HFCs), which are the ones that have been used the most. The main alternatives, harmless to the ozone layer and without influence upon the greenhouse effect, are natural refrigerants such as carbon dioxide, ammonia, and hydrocarbons. However, the latter has a safety problem, given the refrigerant's flammability. Thus, it is critical to detect if refrigerant charge leakage occurs. Sensors that detect this are currently expensive or require much maintenance and must be replaced regularly. Besides, understanding how the system will behave if this fault occurs is also essential for early detection and proper maintenance.

Many experimental tests have been conducted to evaluate the system performance with refrigerant charge variation. For example, [3] analyzes the performance with the charge level of several split and rooftop air-source heat pumps with refrigerants R410A and R407C and with different compressors and expansion devices. Another is [4], which also imposes different refrigerant charge levels, among other faults, to a split residential heat pump in cooling mode with a Thermal Expansion Valve, measuring the effect on variables with these faults. In this work [5], they use experimental tests with different refrigerant charge levels to generate a virtual...
refrigerant charge sensor. They use several types of systems, both air-to-air and water-to-water, with variable speed compressors and some of them reversible for cooling and heating, with accumulators at the condenser outlet to compensate for different charge requirements between modes. In the latter case, they conclude that their virtual sensor does not work well with higher refrigerant levels in the accumulator because charge variations did not significantly change the vapor compression cycle variables. A similar conclusion is reached in this study [6], in which they simulate undercharge faults in a refrigeration system with a liquid line receiver but obtain significant differences in the prediction of system variables under low charge conditions due to the presence of the accumulator.

Nevertheless, there are few studies on reversible air-to-water heat pumps on their performance depending on the refrigerant charge. In this type of system, the analysis is essential because when changing between cooling or heating modes, the refrigerant charge requirements and the difference in internal volume between heat exchangers generate particular behaviors. In this study [7], they experimentally analyze the refrigerant mass distribution of each component of the cycle in an invertible air-to-water heat pump with R32, showing significant differences in the refrigerant charge distribution depending on the conditions.

To address this issue, some studies like [8] have shown that it is beneficial for such reversible systems to use an accumulator in the compressor suction to compensate for charge variations depending on the mode of operation. With this, the subcooling is regulated by the expansion valve instead of the superheat. Besides, some works as [9] study different subcooling control strategies with this system to optimize the performance of a heat pump.

In the present work, it is experimentally investigated the influence of the charge in a reversible air-to-water propane heat pump with different operating modes: cooling mode with superheat control and heating mode with subcooling control. The system has an accumulator at the compressor suction and uses a variable-speed compressor. The study analyzes the variables that would allow the detection of refrigerant leaks in this system in heating mode, given its particularity of subcooling control with an accumulator in the compressor suction which acts as a charge reservoir.

2. Methodology

2.1. Experimental setup

In this study, it is conducted an experimental campaign with a reversible air-to-water heat pump with 7 kW of nominal capacity that uses R290 (propane) as a refrigerant. Figure 1 shows the schematic of the system, whose main components are: a rotary variable speed compressor, a brazed plate heat exchanger (BPHX), a finned-tube heat exchanger, an electronic expansion valve (EEV), and a liquid accumulator at the compressor suction. In addition, the system has a reversible valve or 4-way valve for switching between modes.

The main differences between modes are the following. In cooling mode, the BPHX is the evaporator used to cool water, and the EEV maintains a constant superheat (SH) at the compressor suction (the superheat is taken as the difference between the compressor inlet temperature and the evaporation temperature). However, in heating mode, the BPHX is used as a condenser to heat water, and the EEV maintains a constant subcooling (SC) at the condenser outlet (the subcooling is taken as the difference between the condensing temperature and the condenser outlet temperature). The manufacturer designs this heat pump with the target of optimizing the heating mode. This mode is the one in which the system is going to work more hours during the year.
Fig. 1. Experimental setup of the reversible air-to-water heat pump

The unit is tested in a psychrometric chamber capable of recreating the needed working conditions of the heat pump. Figure 1 shows the location of the sensors in the system. These are compressor suction and discharge pressure, refrigerant temperature before and after each component, and water and air temperature. In addition, the refrigerant mass flow rate in heating mode was measured with a Coriolis flowmeter installed at the outlet of the BPHX (condenser in heating). To obtain the refrigerant flow rate in cooling mode, it was measured the water flow rate with a Coriolis flowmeter. From this, it is obtained the refrigerant flow rate with the corresponding balance in the BPHX. In addition, an averaging pitot tube flowmeter is used to obtain the fan’s airflow. The refrigerant charge used in each test is measured with a Gram LHK-150 scale, with a resolution of 10g. Table 1 lists the instruments used and their range and total error from the uncertainty analysis.

2.2. Test campaign

Table 2 shows the conditions at which the unit is tested. These correspond to both modes of operation, different air and water inlet conditions, and compressor speeds. Each of these conditions is tested for a range of refrigerant charges, which are defined as:
Where $m_{\text{ref-test}}$ is the refrigerant charge at a given test and $m_{\text{ref-nominal}}$ the unit’s nominal (standard) charge, indicated by the manufacturer. Thus, a refrigerant charge percentage of 85% means that the unit is charged with a 15% less refrigerant charge than the nominal that should have.

2.3. Heat pump model

In this study, a model of the air-source heat pump using the dedicated software IMST-ART has been built, see [10] for a detailed description. This software allows modeling and simulating vapor compression cycles with their real components in detail. Particularly, it is able to perform a detailed simulation of the heat exchangers based on the most relevant heat transfer, void fraction, and pressure drop correlations of the literature considering variables like refrigerant charge or oil in the system.

In order to build the model, detailed geometrical information about heat exchangers and the variable speed compressor must be supplied. In addition, the catalogue data's cooling capacity and compressor power input are introduced for different compressor speeds. When a compressor speed is set as an input, the model calculates interpolating between the various compressor speeds entered. Then, this is converted into volumetric and compressor efficiencies to calculate the whole cycle.

3. Results and discussion

3.1. Cooling mode

In cooling mode, the heat pump has 2 control strategies:

a) Control a target SH to be maintained.

b) Control a subcooling of 3 K. This second condition is activated when the water inlet temperature is 7°C or lower in order to avoid having evaporating temperatures lower than 0°C.

To analyze the results obtained after the experimental campaign, the inputs measured in each case have been introduced in the model with the nominal charge. Thus, the refrigerant charge needed by the system in those conditions has been calculated. Table 3 shows the inputs used and the necessary refrigerant charge calculated for each of them. Thus, A23W18-80rps and A35W18-60rps need a higher charge (0.34 and 0.35 kg, respectively) and A35W7-30rps a lower one (0.28 kg). In addition, the target SH of the system in the cases with higher charge is 5-6 K, while the one with the lower charge is around 0 K. This can be achieved by having a liquid accumulator at the outlet of the evaporator that allows having saturation conditions at its outlet.

Figure 2 shows the refrigerant charge accumulation in the A23W18-80rps condition, which needs 0.34 kg. Since in this condition, the target SH to be controlled is 5K, the accumulator at the outlet of the evaporator will be almost empty, and the refrigerant in the liquid state will be concentrated at the outlet of the condenser, which in cooling mode is the finned-tube. The SC measured with these conditions is 18K, a significant value since the refrigerant is located there. If the system is undercharged or refrigerant leakage occurs, the charge will be reduced from the condenser outlet, and therefore the main effect of observing is the SC, which decreases (Figure 4a). For the same reason, the condensation temperature (Figure 4b) will also be reduced. Figure 4c shows that the SH can be controlled even if the refrigerant charge increases or decreases to around 5K. Concerning the discharge temperature (Figure 4d), no significant changes are observed either since its variation with the charge will depend mainly on the state of the accumulator at the compressor's suction.

The A35W7-30rps condition requires less refrigerant charge than the previous one, and considering the low water temperature which introduces subcooling control instead of a superheat control, more charge will accumulate in the liquid state in the system (Figure 3). Thus, if refrigerant leakage occurs, it will reduce the amount of refrigerant in the accumulator, but SC (Figure 4a) or condensation temperature (Figure 4b) will be maintained at the same values. However, following Figure 4c, if the refrigerant charge is reduced to 90% of the nominal, it is observed that the measured SH, which controls the EEV, is 2K, and with 85% charge, 5K. It means that the refrigerant charge has been reduced from the accumulator. The system can no longer have saturation conditions at the outlet and maintain 0K of SH, changing the SH target. Furthermore, in Figure 4d, it is seen how the discharge temperature increases as the refrigerant charge is reduced since, by decreasing the level of liquid refrigerant in the accumulator, it enters with a higher vapor quality to the compressor, leading to a higher discharge temperature.
3.2. Heating mode

In this mode, the EEV controls the SC at the condenser output instead of the SH. In this case, the SC target will be determined by a value that maximizes the COP in each condition, like the SH in cooling mode. Concerning the SH, the refrigerant in the liquid state will accumulate in the receiver at the evaporator outlet, ensuring saturation conditions and, therefore, SH of 0K. Table 4 shows the inputs to the model from the
measurements of each condition with 100% refrigerant charge. Thus, this table shows that the SH of each condition is 0K, being the evaporator outlet saturated and the target SC to be controlled by the EEV between 6 and 8 K, depending on the case. In addition, it is calculated with the model the refrigerant charge needed for each condition. Two conditions need more charge, A2W35-35rps, and A12W24-40rps, with required refrigerant charges of 0.53 and 0.47 kg, respectively. The A7W70-80rps and A10W45-80rps conditions need less refrigerant charge, both of them 0.35 kg.

To analyze how the system performance develops with the refrigerant charge, it is studied the evolution with the charge of some variables from the condition that needs more charge, which is A2W35-35rps with 0.53 kg, and one that needs less, which is A7W70-80rps. Thus, in the case of A2W35-35rps and following Figure 5, as this condition requires more refrigerant charge to operate, it accumulates less liquid refrigerant charge in the receiver at the evaporator outlet. When a situation of undercharge or refrigerant leakage occurs, it will be reduced from the accumulator, as the liquid refrigerant at the outlet of the condenser (in this mode, the BPHX) will be fixed, and the EEV controls that the same amount is maintained to have the same SC value (Figure 7a). However, as this condition needs a lot of refrigerant charge to operate, it is already observed in Figure 7c that for a charge reduction of 5%, saturation conditions cannot be maintained at the outlet of the evaporator (i.e., the accumulator is with a low liquid level) and the SH increases to 2K. At 85% refrigerant charge, a SH of 12K is reached. Furthermore, for this test point, it is seen in Figure 7b how the evaporation pressure and, thus, the evaporating temperature decrease accordingly. Figure 7d shows the evolution of the discharge temperature with the refrigerant charge. It is observed that as the charge decreases, the discharge temperature increases by reducing the level of the accumulator, and the refrigerant enters the compressor with a lower vapor quality.

Fig. 5. Description of the accumulation of liquid refrigerant charge with the heating mode condition of Tair=2ºC/Two=35ºC (fc=35rps).

However, in the case of test condition A7W70-80rps, less refrigerant charge is needed than in the previously described condition. Therefore, it will accumulate more liquid refrigerant than in the previous case. This
refrigerant is collected in the accumulator at the evaporator outlet since, as in the previous case, the amount of refrigerant accumulated at the condenser outlet depends on the value controlled by the EEV, which will remain constant regardless of variations in the refrigerant charge (Figure 7a). Likewise, the refrigerant charge required to operate is lower, and the level of liquid refrigerant in the accumulator is higher, reducing the charge to 85% makes the level still enough to maintain saturation conditions at the outlet of the evaporator. Figure 7c shows how the SH is kept at 0K. Similarly, Figures 7b and 7d show how the evaporation and discharge temperature also do not vary when reducing the refrigerant charge, showing that the accumulator has a high refrigerant charge level.

Fig. 6. Description of the accumulation of liquid refrigerant charge with the heating mode condition of $T_{air}=7^\circ C/T_{out}=70^\circ C$ ($f_c=80$ rps).

Fig. 7. Experimental measurements in heating mode of a) subcooling, b) evaporation temperature, c) superheat, and d) compressor discharge temperature.
With the experimental tests varying the refrigerant charge and the model it is possible to simulate the required charge in each condition, and it has been done a study varying some parameters. As it has been seen previously, the heat pump's performance will vary with the refrigerant charge depending on the condition. An analysis in heating mode has been done. Using the model, two usual application conditions in this mode have been selected (Twi=30ºC/Two=35ºC and Twi=65ºC/Two=70ºC) changing the compressor speed and the air inlet conditions (evaporator inlet). The SC has been maintained constant with a value of 7 K and a SH=0K, since it is assumed that, there will be enough liquid refrigerant in the accumulator to have saturation conditions at the evaporator outlet.

The refrigerant charge required by the system for each case has been obtained. The results are shown in Figure 8. It is observed that for low compressor speeds and low air temperature, the system needs more charge to operate. This is mainly because of the variation in the compressor speed which changes the suction conditions. By decreasing the compressor speed, evaporating pressure and the density increase, requiring more refrigerant charge. The required charge will be slightly higher for the case of Twi=30ºC/Two=35ºC than for Twi=65ºC/Two=70ºC. The zone denominated as "A" will have the performance previously described for A2W35-35rps (Figure 5). Since it needs more refrigerant charge to operate, the accumulator will have a lower liquid level. A 5% decrease in refrigerant charge will already cause changes in SH and discharge temperature, being much more pronounced with a 15% less charge. In the zone referred to as "B", the system needs a lower refrigerant charge to operate than in "A". It would be a refrigerant charge requirement similar to the tested conditions A12W24-40rps (0.47 kg). In this case, changes in discharge temperature and SH would be seen, but from a higher refrigerant reduction (15% in the case of the performed tests).

The rest of the contour plot that is not zone "A" or "B" in both Twi/Two conditions will follow the performance described for the A7W70-70rps condition (Figure 6). In them, despite reducing the refrigerant charge by 15%, the charge requirements for that operating point can be satisfied because the accumulator still has a high liquid level. Considering this, if a refrigerant leak happens, no change in the operating variables could be observed for conditions outside of zones A and B.

Therefore, an undercharge fault diagnostic method to be explored in heating mode for this air-to-water heat pump with subcooling control can be to change the compressor speed to low values and, to a lower degree, reduce the water outlet temperature, bringing the system to zone A or B. With this, it can be seen if there are deviations from the typical values in the system variables that the heat pump would have in a given operating condition with a 100% refrigerant charge, such as the SH, the discharge temperature, or the evaporation temperature.

![Fig. 8. Required system refrigerant charge with different compressor velocities and air inlet dry bulb temperature in heating mode. a) Twi=30ºC/Two=35ºC, b) Twi=65ºC/Two=70ºC.](image-url)
4. Conclusions

This study presents an experimental campaign in which the dependence on the charge of a heat pump with a liquid receiver is analyzed, and it can be seen as a first step in order to determine future fault detection strategies in these systems. In cooling mode, the SH is controlled with an EEV, and in heating, the SC is controlled, having an accumulator that ensures SH=0K at the evaporator outlet. The study presents how the system variables change with the refrigerant charge and illustrates how the liquid refrigerant charge varies in the system in different conditions. Finally, the refrigerant charge required depending on the outdoor air conditions and compressor speed in heating mode is presented.

Some conclusions drawn are:

- In cooling mode, this system works by controlling the SH and therefore accumulating the refrigerant in a liquid state, mainly at the outlet of the condenser. Therefore, a refrigerant charge variation controlling SH>0K will cause the SC at the condenser outlet to increase or decrease as the charge increases or decreases respectively. The condensation temperature will also increase or decrease to a lower extent.
- In the case that the system controls the subcooling in cooling mode, a refrigerant charge higher than nominal will not cause changes. However, reducing it will cause changes in the discharge temperature and SH, as the liquid level in the accumulator will drop. The behaviour in these conditions is similar to the heating mode.
- In heating mode, the system controls the SC at the condenser outlet with the EEV, and the accumulator at the suction has a high refrigerant level, with SH=0. In conditions requiring a higher amount of charge, the accumulator will have a lower liquid level. Thus, reducing the refrigerant charge will increase the real SH and discharge temperature. Besides, to a lower degree, the evaporation temperature will drop.
- At these conditions, increasing the charge level will cause the discharge temperature to decrease and the evaporating temperature to increase slightly.
- At points that require a low refrigerant charge in heating mode, the accumulator level will be high, so by reducing the refrigerant charge by up to 15% in the tests, no changes in system variables are observed.
- In heating mode, at low compressor speeds, the heat pump needs more refrigerant charge to operate, being the more critical conditions from the charge point of view. The reduction of compressor speed in conditions that require a low refrigerant charge to diagnose an undercharge condition allows the observation of the deviation from the expected values in the discharge temperature and SH, so it results in an alternative to be explored in fault diagnosis of this kind of systems.

Abstract

Energy communities play a key role to move towards a low-carbon and decentralized energy system with higher penetration of renewable energies, offering new opportunities for citizens to actively participate in the energy transition. However, the term energy community is widely addressed in literature as photovoltaic systems shared by several users to cover their electricity needs. The present work describes the georeferenced modelling and assessment of potential domestic hot water energy communities based on heat pumps thermal energy communities in 150 residential buildings in a representative Mediterranean city. With the objective of contributing to the development of this concept in the literature and provide insights on the potential at a district level for its energy transition. The aggregated economic and emission savings of domestic hot water in the district can reach up to 85% and 73% respectively for heat pumps. The analysis shows that the implementation of domestic hot water energy communities could represent a significant reduction in the CO2 emissions of the residential sector using the air as a heat source with a reduced cost compared with individual air source heat pump systems.

1. Introduction

Tackling climate change is one of the biggest challenges of the humanity. Nowadays, cities are one of the biggest problems, being responsible for 72 % of Global Warming Emissions (GWE) despite occupying only 3 % of the land [1]. Still, cities are the solution at the point where they face a huge transition towards energy efficiency and renewable energy inclusion. European Union (EU) settles the objective of decarbonizing the economy for 2050, with a reduction of 90 % GWE regarding residential sector among others [2].

Residential sector in Europe is responsible for 40 % of total energy consumption and 36 % of GWE. The majority of its energy use is due to HVAC purposes, with a 65 %, followed by 13.9 % due to Domestic Hot Water (DHW) [3]. The HVAC consumption will require energy efficiency actions directed to reduce the energy demand of buildings mainly through energy refurbishment. However, DHW demand cannot be reduced without affecting comfort. Considering that it represents on average 18.9% of the final energy consumption in the residential sector [10], energy efficiency measures will be necessary to reduce the energy consumption of the equipment to satisfy this demand.

1. Introduction

Tackling climate change is one of the biggest challenges of the humanity. Nowadays, cities are one of the biggest problems, being responsible for 72 % of Global Warming Emissions (GWE) despite occupying only 3 % of the land [1]. Still, cities are the solution at the point where they face a huge transition towards energy efficiency and renewable energy inclusion. European Union (EU) settles the objective of decarbonizing the economy for 2050, with a reduction of 90 % GWE regarding residential sector among others [2].

Residential sector in Europe is responsible for 40 % of total energy consumption and 36 % of GWE. The majority of its energy use is due to HVAC purposes, with a 65 %, followed by 13.9 % due to Domestic Hot Water (DHW) [3]. The HVAC consumption will require energy efficiency actions directed to reduce the energy demand of buildings mainly through energy refurbishment. However, DHW demand cannot be reduced without affecting comfort. Considering that it represents on average 18.9% of the final energy consumption in the residential sector [10], energy efficiency measures will be necessary to reduce the energy consumption of the equipment to satisfy this demand.
Many possibilities exist for improving the energy efficiency of current DHW production systems. Not only do there exist different technologies (solar thermal, biomass or heat pump (HP)), but also different options regarding the system production level (individual, building or full district). In the decision-making process on the energy planning of future cities, these decisions could change cities as we know them, as well as citizens and how they relate to the energy topic.

Among these alternatives, HP appears as a very promising solution for urban environments where a high population density living in multifamily houses are quite common. This kind of dwellings have the characteristics of limited amount of space and limited amount of solar surface irradiated, which postulates the HPs as one very reliable alternative overall if the climate conditions are soft like in the Mediterranean European area.

Energy Communities (ECs) are an initiative recently emerged that seeks the active participation of citizens in the energy transition. According to EU, this initiative definition corresponds with collective actions participated by citizens, public and private entities around a renewable energy project [4]. Energy Communities constitute a radical change towards distributed energy systems, promoting people empowerment and contributing to the formation of awareness among citizens regards a sustainable energy use.

In this way, this research work aims to give some hints on the best decision for this transformation and determine up to which level the HP could place an important role in that transformation. The paper focuses on DHW production, analyzing one full-district current state and different alternatives regarding system production level considering only the HP technology. The technologies studied and compared are gas boiler, immersion electric heater, individual Air Source Heat Pump (ASHP) and collective operated ASHP. The paper studies a representative Mediterranean city of the Europe warmer climate.

2. Method

For the study, the city of València with its neighborhood of Illa Perduda has been selected to perform the analysis. València city can be a city representative of Warmer EU climate and the conclusions here exposed can be of applicability to other Mediterranean cities. The district consists of an area with 164 total number of buildings, of which 150 are residential ones, mainly built during 60s-70s. The average building contains 17 dwellings, with a maximum of 210 dwellings in one building and a minimum of 6.

Concerning that the study considers different system level production, the DHW demand has been obtained for an individual dwelling and at a building level, considering each residential building of the district. Figure

![Figure 1. Analysis area selected for the study. District of Illa Perduda in Valencia, Spain.](image1)

![Figure 2. Histogram of the number of dwellings per building of the district.](image2)
2 illustrates the number of dwellings per building for the full district. An average value of 2.3 inhabitants per dwelling has been assumed, matching EU average [5].

To model the energy demand, DHWcalc software has been used [6]. DHW 1-minute draw-off profiles have been obtained, including cleaning, shower, bath and cooking consumptions based on published indications in [7]. As an example, Figure 3 includes 2 draw-off profiles for a random day, for 1 dwelling and 20 dwellings.

Concerning the dynamic energy simulations, TRNSYS software has been used [8]. The 4 different DHW production technologies studied and compared have been modelled and simulated in TRNSYS. All the models have been created and validated against commercially available systems. The net water temperature of València has been used, considering an average value for each month. The user demand has been considered at 45 °C, whereas the set-point temperature for collective cases has been set at 60 °C considering legionella normative. The models that include storage tank, consider a 0.8 W/m² K value for the heat losses.

- **Immersion Electric Heater (IEH):** it consists of an 80 L storage tank with an aspect ratio of 2 and a nominal capacity of 1.5 kW. The temperature sensor has been placed in the 1st node. 55 °C set-point temperature has been considered to minimize energy consumption but also guaranteeing user comfort, matching energy-label of the commercial product.

- **Gas Boiler (GB):** it consists of an instant-heating system of 28 kW and 92 % efficiency. As an instantaneous system, the annual energy consumption is not affected by the set-point temperature considering a fixed demand.

- **Individual ASHP:** an individual ASHP commercially available has been modelled at HP unit level using IMSTart software. A HP performance map has been created and included in a new TRNSYS type. The map was created varying the external conditions for the operation of the HP, concerning more than 3,500 operating conditions. The HP works with propane as natural refrigerant and has 1 kW heating capacity and 180 l storage capacity. It consists of a plate heat exchanger condenser, a finned tube evaporator, an expansion valve, and a scroll compressor. The condenser is directly connected to the DHW stratified-storage tank, and it operates with a variable water inlet temperature (Tci) and a water outlet temperature (Tco) fixed at 64ºC. The HP is designed to heat up water from 10 to 64ºC. The HP unit as been optimized, according to its operation on the system, by the subcooling. In such a way that the high temperature lift on the water side match in an optimum way with the temperature profile in the heat pump.

- **Collective ASHP:** the individual HP unit of the ASHP model has been optimized using IMSTart to work under collective conditions, specifically adjusting the subcooling of the model. The HP unit model developed has been included in a new TRNSYS type. This type is connected to a stratified storage tank. In order to take into account the re-circulation losses, a 10 % annual energy consumption reduction has been considered. The HP size and tank volume have been properly analyzed for each building in the district through a parametric study varying the range of each of them and following comfort criteria explained in the following. For each of the buildings of the district, a performance map of the full system was created concerning different HP and tank sizes and taking into account the comfort restrictions of each simulation. Based on this map, the optimal sizing of HP and tank has been found for the minimum consumption point of the map. Thus, the
proper sized cases have been selected among those that comply with the comfort restrictions and achieve the minimum annual energy consumption.

Constraints settled have to do with comfort restrictions and HP starts. To guarantee user comfort, two restrictions have been defined: (i) the annual percentage of discomfort has to be lower than 0.5 %; (ii) the maximum available time out of comfort for each hour of the day has been settled to 5 seconds. To guarantee system reliability, a maximum number of starts of 9 per hour has been set. In the collective installation case, the simulations that do not comply with the restrictions would not be considered. Whereas, in the individual DHW production level these restrictions will be considered as outputs, since the sizing is defined by the manufacturer.

In order to analyze each case and compare them, the following system performance indicators have been used:

- SPFuser: as the quotient between the useful heat received by the user and the total system energy consumption (including compressor, fan, and circulation pumps).
- COP: as the quotient between HP heat delivered and energy used by the compressor.
- Annual energy consumption: considering the consumption of the system, including compressor, fan, and circulation pumps.
- Annual emissions: considering an emission factor of 0.201 tCO₂/MWh for gas [9] and 0.112 tCO₂/MWh (ref) for electricity.
- Annual energy cost: considering an energy price of 0.067 €/kWh for gas and 0.2 €/kWh for electricity.

3. Results

In this section, the main results are presented and discussed. First of all, an analysis of the current situation regarding the DHW production of the neighborhood under study is performed. Secondly, the results of the different alternatives to the current DHW production systems are described in terms of performance, energy consumption, emissions and energy costs. Finally, the alternatives technologies are compared, and the outcomes discussed.

Figure 4 depicts the DHW demand of each of the buildings of the neighborhood in liters per day. The demand is directly related with the number of dwellings in each building.

**Current scenario**

The current state in the neighborhood, regarding the production of DHW, is governed by low energy efficient and high polluting systems, considering the year of construction and the social vulnerability situation.
of it. According to recent literature, DHW is produced by 28.6% of the dwellings using IEH, by 70.4% using GBs [10].

Table 1 summarizes the current situation regarding the use of GB and IEH. The table shows the annual emissions and energy cost related to the DHW production in the district. On average, one dwelling is responsible for 532 kgCO2/y and has an energy cost of 464 €/y.

**Individual ASHP renovation scenario**

Concerning the results of individual ASHP, Table 2 includes the main results for 1 dwelling. In order to obtain global results, it was assumed that each dwelling in the district did the renovation. The results show an average COP of 4, with a reduced annual discomfort, with 200 hours per year (2.3% in front of the 0.5% of the collective scenario). The total energy consumption accounted for 414 kWh/y, with an energy cost of 82.64 € and GWE of 46.28 kgCO2/y.

**Collective ASHP renovation scenario**

Figure 3. Annual emissions building to building.
Figure 5 and Figure 6 show the emissions and economic costs resulting from the use of the collective ASHP in each building of the district. Assuming every building in the district does the renovation, the total savings are shown in Table 3. The results show a total equivalent annual emissions of 150 tCO2 and 270 k€. The average dwelling was responsible for 36 kgCO2/y and had an energy cost of 65 €/y.

Comparison
Table 3 includes the results for the current scenario and each alternative regarding emissions and energy cost. The results show:

- Emission savings for both the alternatives over 90 % with respect to the current scenario, and energy costs savings above 80 %.
- Absolute annual savings over 2 ktCO2 and 1.6 M€ regarding the current scenario.
- The ASHP collective alternative shows 20 % higher savings than the individual ASHP. In details, the collective ASHP saves 42 tCO2 and 75 k€ more compared to the individual ASHP.
- The individual ASHP shows annual savings of 400 € per dwelling, whereas the collective one shows savings of 2310 € for the average building block.
- The installation of collective ASHPs in the district only requires 150 HP units and tanks, against the 4194 units needed with the installation of individual ASHPs.
- On average, the collective alternative needs 3 % less HP capacity and 85 % less storage volume than the individual one.
- Although this research works does not analyze in detail sustainability and investment efficiency matters, some opinions can be extracted:
  - Regarding sustainability matter, much less equipment is needed, and the HP size and tank volume are more reduced in the case of collective installations. This positions the collective alternative ahead of the individual.
  - Regarding investment efficiency matter, in 10 years the individual option achieves 4,000 € in savings whereas the collective reaches 23,100 € for the average building block.

{Bibliography} Considering also that the collective installation needs of HP size and storage are more reduced, this option could be much more cost-effective than the individual installation case.
4. Conclusions

This work has shown the high potential of ASHP to reduce the emissions associated to the DHW demand in buildings without the necessity of implementing complicated infrastructures like geothermal wells or having a centralized district heating network. It has been proved that for template climates like the one present in the Mediterranean coast a ASHP installed in each house without the necessity of neighborhood coordination could be the most easy solution to reach remarkable emission reduction objectives.

Nevertheless, the initial investment of this type of installation is far from being suitable and environmental responsibility of the users or some kind of public fundings must be promoted to install that kind of systems. On the other side, the collective installations and the development of thermal energy communities present the advantages of having a slightly higher potential of CO2 emissions reduction, having a significantly lower initial price of the HP components, and having a significantly less space requirements in the building which in some cases could be a critical argument for them. However, this kind of system requires the agreement between all the members of the community and some points regarding the legal implications of it are still under development.

Abstract

Heat pumps are a critical element of a decarbonized built environment, but their widespread adoption can increase house level electrical demand. This paper uses a simulation-based approach to examine the peak demand implications of replacing natural gas furnaces with air-source heat pumps in four Canadian cities. Results show that the peak demand impacts of heat pumps are closely tied to climate. In colder regions (Ottawa, Winnipeg), peaks occur when outdoor temperatures are lowest and auxiliary heating is needed to supplement or replace heat pump operations. Peak demand increases vs. gas heating may approach up to 8 kW in Ottawa and 9 kW in Winnipeg. In milder regions (Halifax, Vancouver), peak events are linked to heat pump use coincident with higher non-HVAC electrical loads. Peak demand increases may reach up to 3 kW in Halifax and Vancouver. Simulations show these increases may be mitigated by using energy stored in the building thermal mass to reduce heat pump operation during peak hours. Results can be used to understand the implications of greater heat pump adoption in Canada and identify approaches to address potential challenges.

Keywords: air-source heat pumps; heat pump peak electrical demand; cold climate heat pumps; peak electrical demand mitigation

1. Introduction

The Canadian Net Zero Accountability Act outlines Canada’s commitment to achieving carbon neutrality by 2050 \cite{1}. Heat pumps have strong potential to drive the decarbonization of Canadian buildings via their ability to efficiently electrify space heating and cooling. However, transitioning from fossil fuel to heat pump systems can increase demand on electrical grids, affecting their ability to provide reliable decarbonized energy. Demand increases can be particularly significant for air-source heat pumps (the most common form of heat pump integration in Canada \cite{2}), which often require supplemental electrical heating to maintain space temperatures during colder winter days typical in Canada. Understanding the peak demand implications of heat pumps, and any potential mitigation strategies, is essential in supporting an increased adoption of these systems in Canada.

Quantifying the peak demand of heat pumps via building simulation can be a challenge. Peak demand analysis requires the use of smaller time steps, where the impact of controls, heat pump transients (e.g., defrost and start-up), and the interaction with any auxiliary systems can be represented. Yet, many typical building simulation programs average performance across an hourly time step and are unable to adequately capture shorter term heat pump transients. Several simulation-based studies have examined the peak demand impacts of heat pump adoption in Europe \cite{3,4}, and two locations in Canada \cite{5}. However, further work is needed to better understand how the peak electrical demand implications of heat pumps vary across additional Canadian regions, and what measures can be taken to mitigate added demand.

This paper uses a simulation-based approach to (I) examine the electrical demand implications of transitioning from natural gas furnaces to air-source heat pumps, and (II) explore how increased demand may be mitigated during peak periods via improved controls. First, detailed models of new construction housing are developed in four Canadian cities (Halifax, Ottawa, Winnipeg, Vancouver), and combined with a series of non-HVAC load profiles to quantify baseline thermal and electrical performance. An enhanced data-driven heat pump model is then used to examine the peak demand implications of air-source heat pump integration, and how this added electrical demand may be minimized via the application of a preheat/setback strategy. Results provide an overview of the potential challenges faced in the widespread deployment of air-source heat pumps, and how they may be addressed using improved controls and other approaches.

2. Base Case Housing Models

Climate and the type of heating system being replaced have an important impact on the magnitude of peak electrical demand increase associated with heat pump systems. This study examines four Canadian regions, each representing a unique set of boundary conditions. Key parameters are summarized in Table 1 [6,7]. The percentage of homes currently heated using fossil fuels is derived from available data at the provincial level [7], in the absence of reliable information for each specific city examined. While this percentage varies greatly between areas, these systems represent at least 50% of single detached homes in all selected regions.

All analysis is performed for a typical Canadian single family detached home. Housing geometry is based on the Canadian Centre for Housing Technology (CCHT) test homes located in Ottawa, Canada [8], and consists of two above ground floors and a finished basement with a total heated floor area of 284 m². The building envelope is modified to represent new construction in each selected region, based on the requirements specified in the National Building Code of Canada [6]. All base cases use natural gas furnaces for space heating, to examine the impact of transitioning from gas to heat pump systems. Key housing characteristics are summarized in Table 2.

Non-HVAC Load Profiles: Non-HVAC (i.e., lighting, appliances and plug loads) electrical load profiles have an important impact on house-level electrical demand. Analyzing the peak demand of heat pumps in homes with different electrical load profiles can provide an idea of how the added electrical demand associated with heat pumps may vary under different internal gains and space use types. This work uses a detailed load profile generator model (LPGM) developed using the bottom-up stochastic approach outlined by Wills [9], with additional refinements to better represent the homes and cases used in this study. Further details can be found in Mollier et al. [5].

Seven distinct active occupancy profiles are examined to better represent the range of peak demand increases possible when replacing a natural gas furnace with an electrically driven heat pump. For each occupancy profile type, occupancy levels between 2 and 5 people are considered, generating a total of 28 non-HVAC load profiles for each city. Table 3 summarizes the different occupancy profiles examined.

A daily average of each selected load profile is provided in Fig. 1 for a three-person household in Vancouver. While each daily profile is unique, they tend towards the averages shown below.

**Fig. 1.** Average daily occupancy profiles for a three-person household in Vancouver.

### 3. Heat Pump System Integrations

The added electrical demand associated with heat pump systems in Canada is closely linked to the operating range and cold climate performance of the selected system. Two heat pump performance curves are examined in this paper to better understand the influence of these characteristics.

**Variable Capacity Heat Pump (VCHP):** This unit is a typical market-available variable capacity heat pump. These systems have achieved a growing market share in Canada, driven by their ability to better modulate to space heating or cooling loads vs. more traditional single or two-stage units. However, these systems are not necessarily well adapted to cold climates, and may experience significant capacity degradations at the colder outdoor temperatures common in Canadian winters.

**Cold Climate Variable Capacity Heat Pump (CCHP):** As an alternative to the VCHP, a second heat pump system is modelled. This heat pump has an extended operating range, and is able to maintain a more substantial portion of its heating capacity at the colder outdoor temperatures common in Canada. As an illustration, the performance of the VCHP and CCHP are summarized below in Fig. 2.
Table 4 summarizes additional heat pump characteristics for both systems examined.

Heat pump integration and sizing approaches can also have an important influence on performance. All heat pump systems are examined in a centrally ducted configuration, supplying space heating and cooling to all three levels of the home. Each heat pump integration is sized to cover a majority of the space heating load in each region, as per Option C of NRCan’s Air-Source Heat Pump Sizing and Selection Guide [14]. CCHP sizing in Vancouver is limited by the lack of available units under 2 tons for the model line used in the analysis [13].

Electric resistance elements in the ductwork are used to supplement heat pump operations as needed to maintain comfort. Details on heat pump and auxiliary sizing are provided in Table 5. All auxiliaries are sized to either meet the difference between heat pump capacity and building load at design conditions (in regions where the design temperature is above the heat pump minimum operating temperature), or the full design load (in regions where the design temperature is below the heat pump minimum operating temperature). Auxiliaries activate in 2.5 kW stages to provide a more realistic representation of their impact on electrical demand.

4. Heat Pump Modelling

Accurately representing the performance characteristics of each heat pump system is critical to properly estimate peak electrical demand. All system models are developed in TRNSYS v. 18 [15] using the appropriate Canadian Weather for Energy Calculation (CWEC) weather file. TRNSYS offers a vast library of components for modelling of space conditioning systems, as well as the ability to easily add custom component models (as was done in this paper with the heat pump component described below). Unlike many building simulation programs which typically use an hourly time step, TRNSYS also allows the user to select a fixed time step for simulation. In this study, all simulations use a 2.5-minute timestep to better represent the control logic of the heat pump and auxiliary heating systems.

Heat Pump Performance Modelling

A custom component is used in TRNSYS to model each heat pump system. This enhanced model (TRNSYS Type 3255) is developed based on extensive test experience at the CanmetENERGY in Varennes facility and integrates a series of new capabilities including performance variations with compressor speed, and short-term transients including start-up, defrost, and cycling. Further details are provided in Breton et al. [16].

Type 3255 follows a data-driven approach to heat pump performance, using a performance map to represent variations in heat pump capacity and power with outdoor temperature and compressor speed. Performance data in this study has been derived via available manufacturer literature. Data sources are summarized in Table 6.

Heat Pump Control

A PID controller is used to vary the speed of the compressor to maintain the first floor of the home at 21°C in heating and 23°C in cooling. The controller also contains a minimum operating frequency, below which the heat pump remains off. This feature enables the model to capture on/off cycling at warmer conditions when building loads fall below the minimum capacity of the heat pump. Additional controls prevent the heat pump from operating beyond its manufacturer specific range of outdoor temperatures.

Capturing the interaction of the heat pump with any electric auxiliary heating is critical to accurately estimate electrical demand. Auxiliary systems have three modes, depending on heat pump operations:

I. **Heat pump is defrosting**: The auxiliary duct heater turns on at a constant, fixed, limited capacity to minimize occupant discomfort during defrost. This capacity is calculated based on the estimated indoor cooling effect in defrost, to ensure a minimum supply air temperature of 12°C to the home, as per building code minimum requirements [6]. Defrost length is fixed at 5 minutes (future work will add varying defrost lengths). As will be discussed later, the sizing of the auxiliary system for defrost has important electrical demand implications. Future work will examine the use of different sizing methods (e.g., different minimum temperatures) to more fully quantify and illustrate these impacts.

II. **Heat pump is operating**: The first stage of auxiliary heating operates with a lower setpoint (20°C vs. 21°C for the heat pump) to ensure space temperatures are maintained within an acceptable range while prioritizing heat pump operations. Subsequent auxiliary stages follow a setpoint 0.5°C below the previous stage (e.g., second auxiliary stage activates at 19.5°C). The heat pump and auxiliaries may operate in parallel.

III. **Heat pump is unable to operate**: When ambient temperatures are too cold for the heat pump to operate, the first auxiliary stage activates when space temperatures fall below the desired setpoint of 21°C. Subsequent auxiliary stages follow a setpoint 0.5°C below the previous stage.
5. Results

This section compares the peak demand implications of the Base Case, VCHP, and CCHP for each city, under each of the 28 load profiles outlined in Section 2. Focus is placed on heating mode, given the importance that space heating electrification has for Canadian electricity grids, with the analysis period defined as Oct. 1st to May 1st.

Transitioning from Natural Gas to Air-Source Heat Pumps in Colder Climates ($T_{\text{Design}} < T_{\text{HP,min}}$)

This section examines results for two cities (Ottawa, Winnipeg) where outdoor temperatures fall below the minimum operating temperature for the selected heat pump systems. Fig. 3 shows the occurrence of peak electrical demand for each non-HVAC profile over the heating season in Ottawa. Each bar represents the number of simulation runs that experience their maximum house-level electrical demand during the defined time period (i.e., the number of simulation runs where a peak occurs during the time period, out of the 28 times each system is simulated using a different electrical load profile). Base Case peaks are far more dispersed vs. the two heat pump systems, as peak demand in these cases is driven by occupant behavior. Conversely, peaks for the VCHP and CCHP occur when outdoor temperatures fall below the minimum operating temperature of the heat pump and auxiliary heating must be used to maintain space temperatures.

![Fig. 3. Occurrence of peak demand by system type over the heating season in Ottawa](image)

Fig. 4 shows the occurrence of peak demand by system in Winnipeg. Results follow a similar trend to Ottawa: Base Case peaks are dispersed due to their occupancy driven nature, while heat pump peaks occur during periods when ambient temperatures fall below the operating range of the heat pump. The distribution of peaks is identical for both the VCHP and CCHP units, as both systems experience an extended period when the heat pump is not able to operate and heating must be met using electric auxiliary elements. In both cities, it is important to note that peaks may occur with a high degree of coincidence across multiple homes, given that all heat pumps in a region will experience similar outdoor temperatures.

![Fig. 4. Occurrence of peak demand by system type in Winnipeg](image)
Fig. 5 compares the magnitude of peak electrical demand increase associated with each heat pump vs. the Base Case in Ottawa and Winnipeg. Given that both the VCHP and CCHP must rely fully on auxiliary heating during the coldest winter days, both systems demonstrate similar peak demand increases. In Ottawa, peak electrical demand may increase between 2.9 kW and 7.7 kW with the VCHP, and between 2.5 kW and 7.6 kW with the CCHP. In Winnipeg, VCHPs may increase electrical demand between 5 kW to 8.8 kW, while CCHP systems may increase electrical demand from 3 kW to 9 kW. It should be noted that the lower minimum increase (3 kW) associated with the CCHP system in Winnipeg primarily results from the random nature of the load profiles, rather than a difference between VCHP and CCHP systems. In all cases (both Ottawa and Winnipeg), peak load increases are driven by a combination of auxiliary electric heating plus some degree of non-HVAC electrical loads. In the Winnipeg CCHP case, during one simulation run the non-HVAC loads that coincided with maximum auxiliary energy demand were lower, leading to this smaller minimum increase.

The duration of any peak event can also be of value to electrical utilities. Fig. 6 compares the load duration curves (all load profiles) for both the VCHP and CCHP units in Winnipeg. Unlike the previous graphs, a comparison of the two insets shows a clear difference between the VCHP and CCHP systems. The VCHP system experiences a plateau at higher load for approximately 180h over the year, primarily associated with an extended duration of auxiliary heating. CCHP units reduce the duration of this plateau by over 30 hours, minimizing the added load placed on the grid by the heat pump system. Similar results are seen in Ottawa, although the magnitude of the reduction (8 h CCHP vs. 18h VCHP) is smaller due to the milder climate.

Fig. 5. Peak electrical demand increase for each heat pump system in Ottawa and Winnipeg.

Fig. 6. Load duration curves for VCHP and CCHP systems in Winnipeg over heating season.
Transitioning from Natural Gas to Heat Pumps in Milder Canadian Climates (T_{Design}>T_{HP,min})

The drivers of peak demand differ significantly in climates where the outdoor temperature always remains within the operating range of the heat pumps selected. Fig. 7 shows the distribution of peak electrical demand for all three systems in Halifax. Heat pump peaks are more dispersed, as peak demand is now driven by a combination of heat pump operations and occupancy-based non-HVAC electricity use (rather than aux. heating). Some correlation to colder temperature remains, as the heat pump must operate at higher compressor speeds (and power) to meet building loads during these periods, while defrosting is also needed. Results can have important implications for utilities, as it suggests that peak demand associated with heat pumps in milder climates may occur with a lower degree of coincidence, mitigating grid level peak demand increases.

Fig. 7. Occurrence of peak demand for all three systems in Halifax during heating season.

Fig. 8 compares the occurrence of peak demand across all three systems in Vancouver. Results follow a similar trend to Halifax, with a dispersion of peak demand across the heating season. The milder climate in Vancouver allows both heat pump systems to operate consistently without the need for any auxiliary heating (except when the heat pump defrosts), with peak demand events instead driven mainly by heat pump use coincident with non-HVAC end uses.

Fig. 8. Occurrence of peak demand for all three systems in Vancouver during heating season.

Fig. 9 compares the range of peak demand increase vs. the Base Case for each heat pump system in Halifax and Vancouver. Peak demand increases are smaller vs. the previous cities examined, as the heat pump operates consistently throughout the year. In both cities the VCHP and CCHP systems exhibit a similar range of peak demand increase, primarily because (i) they are sized according to the same objectives, and (ii) the outdoor temperature is not cold enough to reach the minimum operating temperature of either unit. In Halifax, peak demand increases range from 0.1 kW to 3 kW with the VCHP, and between 0.1 kW to 2.9 kW with the CCHP. Larger peak demand increases are associated with heat pump defrost (which activates a portion of aux. heating, as noted in Section 4) coinciding with higher non-HVAC electrical demand. Smaller peak demand increases are associated with the heat pump operating at lower speeds in combination with higher occupant driven loads. Peak demand increases are similar in Vancouver, ranging from 0 kW to 1.7 kW with the VCHP, and 0 kW to 3.1 kW with the CCHP case. Cases with peak demand increases near 0 kW relate to peak events driven solely by non-HVAC electrical loads, with the heat pump remaining in standby mode.
While heat pump peaks are more dispersed in Halifax and Vancouver, it is interesting to note when these peaks may occur during the day. Fig. 10 compares the occurrence of peaks over a 24h period for the Base Case, VCHP and CCHP systems in Halifax. Typical peak periods for the grid in the morning (7 AM to 9 AM) and evening (5 PM to 7 PM) are also shown [17]. Given the closer link to occupancy driven loads, it is not surprising to see that peaks are more likely to occur during the core periods of the day when occupants are active. This information is important to grid operators and planners, as it suggests that heat pump peaks may occur during periods of the day when demand is already higher, necessitating some form of demand reduction strategy to ensure grid capacity and stability.
Mitigating Peak Demand Associated with Heat Pump Systems

Peak demand increases associated with heat pump systems can also be mitigated in a number of ways, including improved controls or the integration of energy storage. As a simple example, a preheat and setback strategy is examined to reduce heat pump peak demand during defined morning (7 AM – 9 AM) and evening (5 PM – 7 PM) periods. Heat pump indoor temperature setpoints used in the analysis are presented in Fig. 11, and aim to heat up the interior space prior to peak periods, and then utilize the thermal capacitance available in the building mass to coast until the end of the two-hour peak. During all preheat periods, auxiliary setpoints lag behind the heat pump setpoint to prioritize heat pump operations. The setpoint strategy is presented as an initial analysis and will be further examined and optimized in future work.

![Graph showing indoor temperature setpoints](image)

Fig. 11. Setpoint strategy used in initial peak demand mitigation strategy for Halifax.

Fig. 12 compares the peak demand increase during the defined peak periods only (7AM-9AM, 5 PM-7PM) in Halifax with and without the mitigation strategy. It is immediately clear that the applied strategy greatly reduces the electrical demand of the building during peak hours by avoiding the use of the heat pump and any auxiliary systems. However, it is important to note that this demand reduction occurs only during the peak periods: Higher system electrical demand occurs just before and after these periods to preheat and recover space temperatures. In fact, overall peak electrical demand increases vs. the base case are actually higher when the mitigation strategy is applied, reaching up to 6 kW (vs. only 3 kW when no preheating/setback strategy is used). Applied on a larger scale, the associated electrical demand before and after the two-hour peak window could pose a significant challenge for utilities. As such, some form of dispersed strategy, where not all systems follow the preheat and setback schedule, may be required to achieve sufficient results at the grid level.

![Box plot showing peak demand comparison](image)

Fig. 12. Comparison of peak demand distribution during peak hours in Halifax with and without mitigation strategy.

Application of this strategy relies on the willingness of the homeowner to accept lower space temperatures over a short duration, and the ability of the building mass to maintain space temperatures within the desired range over the two-hour period. The current analysis shows that this strategy is viable for newer construction buildings but may be more challenging in older housing vintages with poorer envelope construction and higher rates of infiltration. Alternative strategies, including integrating thermal or electrical storage with the heat pump system (e.g., in a Climate & Comfort Box configuration [18]), hold strong promise to extend the peak management and energy flexibility potential of heat pump systems.
Discussion

Results highlight that the peak demand implications of heat pump systems are highly dependent on local climate. In areas where outdoor air temperatures fall below the minimum operating temperature of the heat pump, the occurrence of peak events is tied closely to colder periods when the heat pump requires partial or full auxiliary heating to maintain space temperatures. Given the link to outdoor temperatures, it is also possible that these peaks may occur with a greater degree of coincidence in the same region, imposing a larger aggregated load on the electrical grid. In regions where outdoor temperatures remain within the operating range of the heat pump, peak demand events tend to be more dispersed and may occur with a lower degree of coincidence. However, given that peak demand behavior in these cases is linked to heat pump operations coinciding with non-HVAC electrical use, peaks are likely to occur during periods of higher grid demand.

A brief analysis of the results would appear to show little difference between the VCHP and CCHP technologies in terms of peak demand. However, CCHP systems hold strong promise in reducing auxiliary heating, which has been shown in this study to be a leading driver of peak electrical demand in colder regions. The extended operating range of these systems also minimizes the period of time the home must be heated solely via the auxiliary system, reducing the probability that auxiliary heating will coincide with a larger non-HVAC electrical draw. As climate change brings more extremes in outdoor temperature, CCHP systems may also provide a degree of added resilience for both homeowners and grids, particularly in regions like Halifax where the need for heating down to -25°C is not currently required.

Heat pump sizing can also have an important impact on peak demand. In this study, all systems were sized with a focus on heating, as per Option C of NRCan’s Air-Source Heat Pump Sizing and Selection Guide [14]. Heat pumps sized to meet a smaller portion of the heating load will likely require further supplemental electric heating, increasing the duration and magnitude of peak demand vs. the results presented in this paper. The application of similar sizing objectives for the VCHP and CCHP cases also explains why peak demand increases are similar for both systems. Should both cases use the same size of heat pump (e.g., both 2 ton) instead of targeting the same percentage of annual heating load, results would likely reflect a strong preference for the CCHP system due to a reduced reliance on auxiliary heating.

6. Conclusion

This study has examined the peak demand implications of transitioning from natural gas furnaces to air-source heat pumps in four Canadian regions. Results show a strong link between climate and heat pump peak demand. In colder climates (i.e., Ottawa and Winnipeg, where ambient temperatures fall below the minimum operating temperature of the heat pump), peak demand is closely associated with periods of low outdoor temperatures when the heat pump must be supplemented partially or fully via electric auxiliary heating. Peak demand increases may reach up to 7.7 kW in Ottawa, and 9 kW in Winnipeg vs. a natural gas heated home. Given the link to outdoor temperature, peaks may also occur with a higher degree of coincidence, creating a larger aggregated load on the grid. In milder regions (i.e., Halifax and Vancouver, where outdoor temperatures remain within the operating range of the heat pump) peak demand is more closely linked to heat pump operations coincident with higher non-HVAC electrical loads. These peaks were more dispersed throughout the heating season but often occurred during peak hours when occupant activity was higher. Peak demand increases may reach up to 3.1 kW in both Halifax and Vancouver. An initial analysis of demand mitigation via preheating and temperature setback showed a strong ability to reduce electrical demand in Halifax during two-hour peak events in the morning and evening. However, this strategy also increased electrical demand before and after defined peak periods vs. the non-mitigation case, and as such requires careful application. Further work is needed to examine the viability of this strategy in other regions, and in older vintages of construction where the thermal capacitance of the building is reduced.

Future work will examine the peak demand implications of heat pumps in additional regions, and in a greater variety of residential building archetypes. Planned analysis also includes an in-depth examination of heat pump plus storage systems (e.g., Climate & Comfort Box solutions) to better mitigate peak demand without affecting thermal comfort in the building. Larger scale assessments of mitigation strategies at the grid level should also be performed to ensure that these strategies appropriately address the needs of utilities and avoid any unintended consequences (e.g., large peaks directly after a demand reduction period has ended).

Experimental Investigation Into The Effect of Charge Optimization And Standard Test Conditions On The Seasonal Performance In An R410A Heat Pump With Dedicated Subcooler

Sugun Tej Inampudi, Stefan Elbel

Abstract

There is an increased focus on the amount of refrigerant charge used in the HVAC&R systems due to the new restrictions and ongoing phase down of high GWP refrigerants as part of the F-gas regulation. In the current study, seasonal performance for a variable speed compressor in an R410A water ethylene glycol (WEG) heat pump system having a nominal heating capacity of 9 kW is estimated according to EU 14825. This study experimentally studied the effect of charge and the fixed/variable outlet condition on the seasonal performance of the water heat pump equipped with a variable speed compressor. The results of a charge optimization done at part load conditions show an unexpected peak in \( \text{COP}_{\text{dec}} \) and results indicate that optimum charge has a higher impact on the efficiency at part load conditions than the nominal conditions. Based on the experimental results, the difference in the order of 5% in \( \text{SCOP} \) is found when comparing optimum charge and non-optimum charge in a variable speed compressor. \( \text{SCOP} \) can change by almost 22% depending on whether fixed/variable condenser temperature outlet operation is used.

Keywords: charge optimization; heat pump; seasonal performance; dedicated subcooler; EU 14825; SCOP

1. Introduction

Due to the new restrictions and ongoing phase down of high GWP refrigerants as part of the F-gas regulation, there is an increased focus on the amount of refrigerant used in the HVAC&R systems. This increases the focus on potential benefits of having the optimum charge in a HVAC&R system. There are experimental studies which show the impact of charge level on cooling/heating capacity and energy efficiency. A refrigerant charge reduction of 25% led to an average energy efficiency reduction of about 15% and capacity degradation of about 20%. When the refrigerant was charged to 75% of design, the SEER value decreased by 16% [1]. An experimental investigation was conducted to study the effect of low charge level of R-22 on the performance of a 3-ton residential air conditioning system. The experimental results show that if a system is undercharged to 90% there is only a 3.5% reduction in cooling capacity however, the system performance suffers serious degradation if the level of charge drops below 80% [2].

Though there are many studies which predict that not operating at the optimum refrigerant charge can impact the cooling capacity and the efficiency of the system. The charge optimization is done at the nominal operating conditions and this charge might not be the optimum for part load operations. Beginning 2023, there are new DOE requirements for the HVAC systems to have higher SEER in USA. This increases the focus on seasonal performance than a single point efficiency. One of the ways to increase the seasonal performance is to use compressor capacity modulation.

An experimental study by the same authors analysed the effect of charge on the COP of a single speed and variable speed compressor in a dedicated subcooler chiller system. A peak was observed in COP at charge before the receiver starts filling up and this peak was more pronounced at the part load conditions. When the variable speed compressor was tested at a lower charge, the IPLV.SI was higher by 5% than when tested with the higher charge. They concluded that the peak in COP occurs due to the relative sizing of the condenser and subcooler and the optimum charge corresponds to the scenario when some portion of the two-phase heat transfer is happening in the subcooler [3]. Additionally, cases with different high side configuration were discussed and the peak COP was only observed for the case with a dedicated subcooler [4].

In the current study, the seasonal performance of an R410A heat pump for water heating application with a variable speed compressor is estimated according to EU 14825 standard [5]. The seasonal performance is estimated for the case with constant and variable $T_{\text{weg,co,out}}$. The initial tests are done using the nominal charge of 1.5 kg which was estimated for the same R410A system for cooling application [3,4]. The charge optimization for the heat pump is conducted at part load conditions to see if a peak in COP like the cooling application is observed [3,4]. This study also tries to explain a peak in COP observed in this dedicated subcooler with receiver system when the receiver is empty during the charge optimization test. The variable speed compressor is then tested at the optimum charge with constant and variable $T_{\text{weg,co,out}}$ to determine the effect of charge optimization on seasonal performance estimation.

2. Experimental Facility Description

Figure 1 shows the schematic of the R410A Water Ethylene Glycol (WEG) heat pump. A mixture of 20% water and ethylene glycol is used as the secondary fluid. Two closed WEG loops are connected to the evaporator and condenser. Variable speed pumps and electric heaters are used to control the WEG flow rate and the outlet temperature of the condenser and the inlet temperature of the evaporator. An additional heat exchanger with chilled water flowing through is included in the condenser WEG loop to reject the heat from the condenser WEG loop. All the heat exchangers used in the facility are brazed plate heat exchangers (BPHX) and their dimensions are provided in Table 1. A 0.9 L receiver is connected between the condenser and the subcooler. Superheat is maintained at constant value by an electronic expansion valve (EXV) equipped with a superheat controller while the subcooling is a function of the charge.

Fig. 1. Schematic of the R410A experimental facility
This experimental facility was also used by the same authors to compare the seasonal performance of different compressor modulation strategies for cooling application and the results show that variable speed compressor has the best seasonal performance [6,7,8]. A variable speed compressor than can operate between 15 and 100 Hz is used for this study.

Type-T thermocouples, absolute and differential pressure transducers, and Coriolis-type mass flow meters are used to obtain the refrigerant side measurements while type-T thermocouples, differential pressure transducers, and Coriolis-type mass flow meters are used to obtain WEG measurements. The data is collected at steady-state conditions at 5s intervals for 15 consecutive minutes, and the data is averaged over the collection period. REFPROP 10.0 was used to calculate the WEG and R410A properties [9]. The uncertainty of the sensors used in the experimental facility is presented in Table 2. This estimation does not include the uncertainty in thermophysical properties. However, the uncertainty in enthalpy difference can be approximated as the uncertainty in specific heat which is around ±0.5% [9]. An uncertainty propagation analysis carried out revealed an experimental uncertainty of ±0.3% for $\dot{Q}_{\text{co}+\text{sc},\text{ref}}$ and ±5.7% for $\dot{Q}_{\text{co}+\text{sc},\text{WEG}}$.

The capacity is calculated on the refrigerant side and the WEG side. For the WEG side, mass flow rate, temperature, and specific heat are used to calculate capacity as shown in Equation (1). For the refrigerant side, temperature and pressure are used to calculate the enthalpy which is then used with the mass flow rate to calculate the capacity as shown in Equation (2). The capacity reported is the average of the refrigerant side and WEG side capacity given by Equation (3). The difference between the two capacities is indicated by the error given by Equation (4). This error is always less than 6% for the part load rating tests. Power consumed by the compressor is measured using a Wattmeter. The ratio of the average capacity and power consumed by the compressor is used to calculate the COP$_{\text{dec},\text{avg}}$ as shown in Equation (5). The heating capacity is always the combined heat rejected from the condenser and dedicated subcooler.

\[
\dot{Q}_{\text{co}+\text{sc},\text{weg}} = \dot{m}_{\text{WEG}}c_p\Delta T \tag{1}
\]

\[
\dot{Q}_{\text{co}+\text{sc},\text{ref}} = \dot{m}_{\text{ref}}\Delta h \tag{2}
\]

\[
\dot{Q}_{\text{co}+\text{sc},\text{avg}} = \frac{(\dot{Q}_{\text{co}+\text{sc},\text{weg}}+\dot{Q}_{\text{co}+\text{sc},\text{ref}})}{2} \tag{3}
\]

\[
\varepsilon_{\dot{Q}_{\text{co}+\text{sc}}} = \frac{(\dot{Q}_{\text{co}+\text{sc},\text{weg}}-\dot{Q}_{\text{co}+\text{sc},\text{avg}})^{100}}{\dot{Q}_{\text{co}+\text{sc},\text{avg}}} \tag{4}
\]

\[
\text{COP}_{\text{dec},\text{avg}} = \frac{\dot{Q}_{\text{co}+\text{sc},\text{avg}}}{W_{\text{cp}}} \tag{5}
\]

$\dot{Q}_{\text{co}+\text{sc},\text{avg}}$ as defined in Equation (3) and COP$_{\text{dec},\text{avg}}$ are used for the estimation of the seasonal performance of the compressor (Sections 4.1, 4.3 and 4.4), but $\dot{Q}_{\text{co}+\text{sc},\text{weg}}$ defined in Equation (1) and COP$_{\text{dec},\text{weg}}$ are used during the charge optimization sections (Section 4.2). When the system is undercharged, the refrigerant is a two phase substance at the subcooler outlet which affects the Coriolis mass flow meter measurement. Though this problem does not exist at higher refrigerant charges, $\dot{Q}_{\text{co}+\text{sc},\text{weg}}$ and COP$_{\text{dec},\text{weg}}$ are still used to be consistent across all the refrigerant charges tested.
3. EU 14825 Standard

EU 14825 standard is used for the determination of the seasonal performance of a water heat pump [5]. Though there is an USA standard AHRI 551/591 available for chiller application, there is no such standard for water heat pump [10]. This standard defines the seasonal performance using \( SCOP \), seasonal coefficient of performance. \( SCOP \) is a representative for the whole designated heating season calculated as the reference annual heating demand divided by the annual electricity consumption for heating. Only the compressor power consumption \( W_{cp} \) is included in the estimation of \( SCOP \). The current study estimates the seasonal performance using part load conditions for water/brine-to-water units for low temperature application for average heating season. These test conditions are given in Table 3. \( SCOP \) is calculated using \( COP_{PL} \), outside temperature, number of annual hours in which these temperatures are recorded. EU 14825 standard defines these characteristic reference temperatures and annual hours. The methodology to determine the \( SCOP \) according the European standard EN 14825 was explained for a domestic brine-to-water heat pump for low-temperature application in another study [11].

In this study, the bivalent temperature was selected equal to the design temperature causing the E and F conditions to become the same. As seen in Table 3, condenser and evaporator inlet and outlet conditions are mentioned for the full load condition (E&F) while for the remaining part load conditions, only the condenser outlet and evaporator inlet temperatures are given. The standard requires that the condenser and evaporator WEG flow rate used for the full load condition be used for the remaining part load conditions as well. The standard requires the evaporator outlet WEG temperature to be 7°C for the 100% load condition but the WEG flow required to achieve a 3°C temperature difference across the evaporator is beyond the maximum flow rate possible with the available pumps in the experimental facility. Hence, a 5°C temperature difference is used for the evaporator as well. A 5°C is used for the condenser in the EU 14825 standard as well as for the evaporator in cooling application in both the USA and EU standard [5,10].

If the compressor cannot be unloaded to the required part load ratio, then the compressor is run at the minimum step of unloading at the same condenser outlet and evaporator inlet condition shown in Table 3 and \( COP_{dec} \) is calculated. Then this \( COP_{dec} \) is degraded to \( COP_{PL} \) using the \( CR \), \( C_d = 0.9 \) as shown in Equations (6) and (7). \( CR \) is the ratio of the required heating demand to the supplied heating capacity by the system. The degradation coefficient \( C_d \) can be determined by performing a specific cycling loss test defined in EU 14825 or a value of 0.9 can be assumed according to the standard [5].

\[
CR = \frac{Q_{load}}{Q_{capacity}} \tag{6}
\]

\[
COP_{PL} = COP_{dec} \frac{CR}{C_d CR + (1-C_d)} \tag{7}
\]

4. Results And Discussion

4.1. Seasonal performance of a variable speed compressor with 1.5 kg of charge

4.1.1. Constant condenser WEG inlet conditions

Seasonal performance results of a variable speed compressor charged with 1.5 kg of refrigerant are shown in Figure 2. The selected compressor can operate between 15 and 100 Hz. The load is a linear function of the part load conditions. The maximum heating capacity is equal to the load at the E&F condition obtained with the variable speed compressor operating at 72.5 Hz. This operating frequency is equal to the one used for the
cooling performance tests conducted [8]. As the test condition changes from E&F to D, the condenser WEG inlet temperature remains constant at 35°C and the required load changes from 100% to 15%. The variable speed compressor can match the required heating load at E&F, A and B condition by changing the compressor operating frequency. Since this compressor can operate below 28.3 Hz, it should have been able to match the required heating load at C condition. Additionally, at the D condition, the compressor should have been able to operate at 15 Hz (lowest possible frequency) and provide a closer heating capacity. However, if the compressor operates at a frequency below 28.3 Hz, the required pressure ratio is outside the compressor operating envelop and thus it is limited to this 28.3 Hz. This high pressure ratio is caused by the constant condenser outlet test condition on WEG side. The compressor undergoes cycling losses at C and D condition and the magnitude of these losses are higher at the D condition. This can be by the difference between \( \text{COP}_{\text{dec,avg}} \) and \( \text{COP}_{\text{PL}} \) and the cycling losses in Figure 2. \( \text{SCOP}_{\text{avg}} \) calculated for this compressor is 4.33.

![Figure 2. Seasonal performance of variable speed compressor with constant \( T_{\text{weg,co,out}} \)](image)

4.1.2. Variable condenser WEG outlet temperature

Seasonal performance results of the same variable speed compressor when tested according to the variable condenser WEG outlet temperature requirements are shown in Figure 3.

![Figure 3. Seasonal performance of variable speed compressor with variable \( T_{\text{weg,co,out}} \)](image)
The operating frequency and the performance of the compressor are the same at E&F condition due to the similarities between both the standard requirements. However, at the part load test conditions, the required part load ratio remains the same as the case with constant WEG outlet temperature but the condenser outlet temperature changes. This temperature drops from 35°C at E&F condition to 24°C at D condition. This drop in the condenser temperature causes the pressure ratio to be within the compressor operating envelop. Thus, the compressor can match the required cooling load at C condition and operate at its lowest possible frequency of 15 Hz at D condition. This lowers the cycling losses experienced by the compressor and both $COP_{\text{avg}}$ and $COP_{\text{PL,avg}}$ are higher when using this test matrix. The $SCOP_{\text{avg}}$ calculated for this compressor is 5.26.

4.2. Charge optimization of variable speed compressor at B condition

Charge optimization results of the variable speed compressor at B condition are shown in Figures 4, 5 and Table 4. Figure 4 shows the variation of $COP_{\text{dec,weg}}$, $Q_{\text{co+sc,weg}}$ with charge while Figure 5 shows the variation of compressor work, superheat and subcooling with charge.

![Fig. 4. Variation of $COP_{\text{dec,weg}}$ and $Q_{\text{co+sc,weg}}$ of variable speed compressor with charge at B condition](image1)

![Fig. 5. Variation of $W_{cp}$, $\Delta T_{in}$ and $\Delta T_{ex}$ of variable speed compressor with charge at B condition](image2)
Table 4 presents the charge, $COP_{dec,weg}$, percentage change in the heating capacity, power consumption between two consecutive refrigerant charges. It also shows the difference between the subcooler outlet enthalpy of two consecutive charges. The evaporator superheat and UA are also available in Table 4. Though Figure 4 looks like a typical charge optimization curve for a system with TXV/EXV with a receiver, there is an unexpected peak in $COP_{dec,weg}$ that occurs when the receiver is empty. To explain the reason why there is a peak in $COP_{dec,weg}$ and why it occurs at that charge, the entire charge optimization curves are divided into four regions.

Region 1 (0.80 to 1.15 kg): In this region, the refrigerant charge added goes to the evaporator due to the EXV being completely open. Thus, as the charge increases in the evaporator, the superheat at the evaporator outlet reduces. This in turn increases the evaporator UA. A lower superheat, higher evaporator UA increases the heat transfer in the evaporator and thus also increases the condenser heat rejection. Additionally, the subcooler outlet enthalpy increases in this region. Thus, there is no positive impact of the subcooler in this region. At the end of this region, the evaporator superheat reaches a constant value and the EXV can maintain the required superheat.

Region 2 (1.20 to 1.25 kg): The maximum $COP_{dec,weg}$ occurs in this region. The increase in the heating capacity at this point compared to the previous charge is due to the decrease in subcooler outlet enthalpy. This is the first point where the subcooler outlet enthalpy reduces compared to the previous charge. The compressor power also increases; however, the percentage increase of the heating capacity is higher than the percentage increase of power consumption. Thus, this results in a peak in $COP_{dec,weg}$. This is the last point in region 2 and 3 where the relation in Equation (8) is valid.

$$\frac{\Delta Q_{cc}}{Q_{cc}} > \frac{\Delta W_{cp}}{W_{cp}} \tag{8}$$

</table>

Quality at the subcooler inlet, ratio of heat transfer happening in the subcooler to the total heat transfer happening in the condenser and subcooler and the single phase (subcooled liquid) heat transfer happening in the subcooler are plotted against the charge in Figure 6. In the region 1, the quality at the subcooler inlet...
increases because as the charge is added to the system, refrigerant mass flow rate increases while the heat transfer happening in the condenser does not change significantly. This causes an increase in the quality at the subcooler inlet (condenser outlet). The \( \text{COP}_{\text{dec,weg}} \) maximum occurs when the quality at the subcooler inlet is 34%. This means at the charge corresponding to the \( \text{COP}_{\text{dec,weg}} \) peak, some portion of the two phase heat transfer happens in the subcooler. This can also be seen that 30% of the total heat transfer is happening in the subcooler at the maximum \( \text{COP}_{\text{dec,weg}} \) charge and as the charge increases, more heat transfer occurs in the condenser. Additionally, the single phase heat transfer happening in the subcooler increases as the charge increases beyond the maximum \( \text{COP}_{\text{dec,weg}} \) charge but the ratio of heat transfer happening in subcooler decreases. This indicates that as additional charge is added though the single phase heat transfer increases in the subcooler, the total heat transfer happening in the subcooler decreases.

![Graph showing variation of refrigerant quality and subcooler heat transfer with charge](image)

Fig. 6. Variation of refrigerant quality at subcooler inlet, subcooler heat transfer with charge

The maximum \( \text{COP}_{\text{dec,weg}} \) approximately corresponds to a configuration shown in Figure 7 which indicates that the single phase subcooled refrigerant exists only at the outlet of the subcooler.

![Diagram showing approximate distribution of refrigerant at maximum \( \text{COP}_{\text{dec}} \) charge](image)

Fig. 7. Approximate distribution of the refrigerant at the maximum \( \text{COP}_{\text{dec}} \) charge

Region 3 (1.30 to 1.50 kg): In this region, the relative increase in compressor power consumption is higher than the relative increase in heating capacity and the relation shown in Equation (9) is valid. Though the amount of subcooling increases 5°C to 9.4°C as shown in Figure 5, the enthalpy at the subcooler outlet only drops by 2.9 kJ/kg in the entire region 3. This drop is lower than the drop of 4.3 kJ/kg observed from the 1.20 kg to the peak \( \text{COP}_{\text{dec,weg}} \) charge of 1.25 kg. As the charge increases in this region, the condensation pressure goes up and the subcooling at the subcooler outlet increase, the heating capacity is determined by the enthalpy at the subcooler outlet not the subcooling. Additionally, there is a limit on the heating capacity due to the minimum
possible subcooler outlet enthalpy determined the inlet temperature of WEG while there is no such limit on the compressor outlet enthalpy and compressor power consumption.

\[
\frac{\Delta Q_{\text{co}}}{Q_{\text{co}}} < \frac{\Delta W_{\text{cp}}}{W_{\text{cp}}}
\]  

(9)

At the maximum \(COP_{\text{dec,weg}}\) charge and in region 3, the subcooler inlet is two phase refrigerant. As the charge increases in region 3, the fraction of two phase heat transfer happening the subcooler reduces. This reduction is seen by the drop in the subcooler inlet refrigerant quality in Figure 6. This increases the amount of two phase heat transfer happening in the condenser. Therefore, to get a higher heat transfer rate in the same condenser area, the temperature difference across the refrigerant and WEG in the condenser must increase. This leads to a higher condensation pressure and subcooling at the subcooler outlet. The increase in power consumption due to this higher condensation pressure is more than the increase in heating capacity as shown in Equation (9), causing a drop in the \(COP_{\text{dec,weg}}\) in region 3.

Region 4 (1.60 to 2.00 kg) and beyond (2.15 to 2.25 kg): Region 4 starts when the receiver starts filling up with the liquid refrigerant. The additional refrigerant charge gets accumulated in the receiver and thus there is no change in the system performance. When the charge is increased beyond the region 4 and the receiver holding capacity, the additional charge gets accumulated in the condenser which increases the condensation pressure, power consumption and reduces the \(COP_{\text{dec,weg}}\).

4.3. Seasonal performance of a variable speed compressor with 1.25 kg of charge

The results of the charge optimization study reveal that a peak in \(COP_{\text{dec,avg}}\) is seen when the system operates at 1.25 kg. To understand the impact of the charge optimization on the seasonal performance (\(SCOP_{\text{weg}}\)), the variable speed compressor is now tested using constant and variable condenser WEG inlet with 1.25 kg of refrigerant charge.

4.3.1. Constant condenser WEG inlet conditions

Seasonal performance results of a variable speed compressor charged with 1.25 kg of refrigerant are shown in Figure 8. The operating frequencies of the compressor are the same as in Section 4.1.1. However, the heating capacities with the reduced refrigerant charge is lower at the full load conditions by 2.2% than the one available when operating with 1.5 kg of charge. This difference in heating capacity drops at the part load conditions. The \(COP_{\text{dec,avg}}\) is higher for the 1.25 kg compared to 1.5 kg charge. The \(COP_{\text{dec,avg}}\) is 2% higher at the full load condition while it 4.3% higher at C&D and 6.6% at B condition. This shows that the charge optimization has a higher impact at the part load conditions than the full load conditions.

Fig. 8. Seasonal performance of variable speed compressor with constant \(T_{\text{weg,co,avg}}\).
Though it can be seen from Figure 8 that the compressor undergoes cycling losses at B condition, no cycling losses were included and $COP_{PL,avg}$ is equal to $COP_{dec,avg}$. The compressor can match the required heating capacity at B condition by operating at a frequency lower than 36.0 Hz, it is still operated at 36.0 Hz to match the frequency used when operating with 1.5 kg. This frequency allows an estimation of the effect of only charge on $COP_{dec,avg}$ for both the cases. And to ensure the case with 1.25 kg is not penalized for this operation, cycling losses are not included. The compressor does undergo cycling losses at C and D conditions for this lower refrigerant charge as well. However, the $COP_{PL,avg}$ are still higher for the lower refrigerant case. The $SCOP_{avg}$ for this compressor at 1.25 kg refrigerant charge is 4.56.

4.3.2. Variable condenser outlet temperature

Seasonal performance is estimated for the variable speed compressor charged with 1.25 kg of refrigerant according to the variable $T_{weg,co,out}$ test matrix. The results of the seasonal performance test are shown in Figure 9. The heating capacity at the full load condition (E&F) is still lower by 2% than when operating with 1.5 kg of refrigerant charge. The operating frequency of the compressor is maintained the same as the test case with higher refrigerant charge to only include the effect of refrigerant charge on the seasonal performance. The $COP_{dec,avg}$ and $COP_{PL,avg}$ are higher with 1.25 kg for all the test conditions and the difference is higher at part load conditions. The compressor only undergoes cycling losses at D condition when the required operating frequency to match the heating load is below minimum possible compressor frequency of 15 Hz. The compressor can match the heating load at C condition because of the reduced $T_{weg,co,out}$ and pressure ratio. The $SCOP_{avg}$ for this compressor at these conditions is 5.47.

![Fig. 9. Seasonal performance of variable speed compressor with variable $T_{weg,co,out}$](image)

4.4. Comparison of $SCOP_{avg}$ for all the investigated cases

The $SCOP_{avg}$ values calculated using the $COP_{PL,avg}$ for all the different tested cases are shown in Table 5. The case 4 with 1.25 kg of refrigerant charge and variable $T_{weg,co,out}$ is 26.3% higher than the case 1 with 1.5 kg of refrigerant charge and fixed $T_{weg,co,out}$. The $SCOP_{avg}$ of the compressor when tested according to the variable $T_{weg,co,out}$ is 21.5% higher than when tested according to constant $T_{weg,co,out}$ with 1.50 kg of charge and it is 21.0% with 1.25 kg of charge. This higher $SCOP_{avg}$ is due to the lower $T_{weg,co,out}$ which causes a drop in the compressor operating pressure and power consumption. Additionally, the compressor can match the heating capacity during the variable $T_{weg,co,out}$ test cases at the C condition and operate at the minimum possible frequency at the D condition. This eliminates the cycling losses at the C condition and reduces the cycling losses at D condition. These lead to a higher $COP_{PL,avg}$ for the case with variable $T_{weg,co,out}$. The $SCOP_{avg}$ for case 2 with fixed $T_{weg,co,out}$ and lower charge is 5.3% than the equivalent case 1 with higher refrigerant charge. Similar improvement of 4.8% is observed when comparing cases 3 and 4 with the variable $T_{weg,co,out}$. These difference cases show that there is an effect of test standard as well as the refrigerant charge on the seasonal performance estimates and the impact of test standard is significantly higher.
The peak in $\Delta S_I$ corresponds to the scenario when some portion of the two-phase heat transfer is happening between the condenser and subcooler at the peak condition and 4.8% for the variable outlet condition. Thus, the speed compressor was operated at this optimum charge, the subcooler. The relative difference between these two factors causes a peak in $S_I$. Any refrigerant leak in the system can also move the operating charge to region 2.

However, the heating capacity at the full load drops by around 2% when operating at lower refrigerant charge. Any refrigerant leak in the system can also move the operating charge to region 1 which drops the COP dec significantly. So, it is recommended to operate the system in region 3 to get a higher COP dec but not a huge drop in heating capacity. Additionally, operating a dedicated subcooler system with a receiver installed in between the subcooler at the peak COP dec does not make use of the installed receiver and the maximum possible subcooling from the dedicated subcooler.

5. Conclusions

This study experimentally studied the effect of charge and the fixed/variable outlet condition on the seasonal performance of an R410A water heat pump with a variable speed compressor. The $S_COP_{avg}$ for the variable speed compressor with variable outlet condition was 21.5% higher than the fixed outlet condition. The variable speed compressor cannot match the required heating load at one of the part load conditions with fixed outlet condition due to the required pressure ratio being outside the compressor operating envelop. This problem does not occur for the variable outlet condition, and this leads to a lower cycling losses and higher $S_COP_{avg}$.

Charge optimization for the variable speed compressor was done at part load conditions and a peak in COP dec,weg was observed at a charge before the receiver starts filling up. This maximum COP dec,weg occurs due to the relative amounts of heat transfer happening in the condenser and subcooler and the optimum charge corresponds to the scenario when some portion of the two-phase heat transfer is happening in the subcooler. The peak in COP dec,weg is due to the interaction between the increase in power consumption due to reduced two-phase heat transfer area in the subcooler and the increased heating capacity due to higher subcooling in the subcooler. The relative difference between these two factors causes a peak in COP dec,weg. When the variable speed compressor was operated at this optimum charge, the $S_COP_{avg}$ improved by 5.3% for the fixed outlet condition and 4.8% for the variable outlet condition. Thus, the COP dec can improve if the system is operated in region 2.

However, the heating capacity at the full load drops by around 2% when operating at lower refrigerant charge. Any refrigerant leak in the system can also move the operating charge to region 1 which drops the COP dec significantly. So, it is recommended to operate the system in region 3 to get a higher COP dec but not a huge drop in heating capacity. Additionally, operating a dedicated subcooler system with a receiver installed in between the condenser and subcooler at the peak COP dec does not make use of the installed receiver and the maximum possible subcooling from the dedicated subcooler.

Abstract

Air-source (air-air) heat pumps can play a critical role in driving an efficient electrification of space heating in Canadian buildings. However, the deployment of these systems is often challenging in Canada, complicated by large variations in climate, utility rates and structures, and existing heating energy sources. This paper uses a simulation-based approach, driven by an enhanced data-driven model, to develop a more comprehensive overview of the technical and economic potential of heat pumps as replacements for current common heating systems (natural gas furnace, oil furnace, electric baseboards) in Canadian residential buildings. Results highlight the economic value in transitioning from electric baseboards or oil furnaces to heat pump systems in each of the four regions examined (Halifax, Toronto, Winnipeg, Vancouver), and note the growing potential of heat pumps as replacements for natural gas furnaces, with planned carbon pricing resulting in lifecycle cost savings vs. gas furnaces by 2030 in all regions. Findings can be used to better understand the current and future context for heat pumps to support R&D, policy, and market development.

1. Introduction

The Canadian Net Zero Emissions Accountability Act outlines Canada’s commitment to achieving carbon neutrality by 2050 [1]. The built environment must play a key role in this transition: Canadian buildings account for 17% of national greenhouse gas (GHG) emissions, with nearly 80% of this total directed towards space heating, cooling, and hot water preparation [2]. Heat pumps are critical in driving decarbonization of the built environment via their ability to efficiently electrify space conditioning. However, supporting greater adoption requires an appropriate understanding of system selection and economics.

The Canadian context represents a particularly challenging set of circumstances for heat pump integration. Wide variations in both climates (mild maritime, to extreme cold) and utility rates and structures (vast differences in prices of natural gas vs. electricity) mean that the impact of heat pumps (e.g., on energy savings, utility costs, greenhouse gas (GHG) emissions) can differ greatly in a given region. Quantifying these impacts is a critical step in driving the policy and R&D required to facilitate a greater uptake of heat pumps in Canada.

Air-source (air-air) heat pumps are a popular choice of heat pump integration in Canadian homes, driven by their relative lower cost and ease of installation. Previous efforts have examined the role and impacts of these systems in Canada [3,4], but often focus on assessing heat pumps in a single building archetype or as a replacement for a single type of existing heating technology (e.g., natural gas furnaces). Recent studies [5] have attempted to present a more complete outlook but employ simplified heat pump models to facilitate analysis, limiting the ability to compare different heat pump technologies or assess the impact of system sizing.
This paper uses a simulation-based approach, supported by extensive testing and measured data, to examine the energy, GHG, and economic impacts of electrifying building thermal loads via the implementation of air-source heat pumps. A detailed, data-driven heat pump model is used to represent two common air-source heat pump integrations: A conventional variable capacity unit, and a cold climate (variable capacity) unit aimed at maintaining heating performance in the cold Canadian climate. Each heat pump integration is used to examine the impact of replacing three common heating systems (natural gas furnace, electric baseboards, oil furnace) in three types of typical single family Canadian housing. Results are used to examine the short- and medium-term role of air-source heat pumps in driving an effective, economic decarbonization of Canadian homes.

2. Definition of Base Cases for Heat Pump Integration

Climate, utility rates, and electricity generation methods (and associated GHG emissions) can vary greatly across Canada. Four Canadian regions are selected for this analysis, each representing a unique context for system integration. Table 1 summarizes key parameters for each region [2,6].

Three separate building archetypes are developed to better understand the impact of building size, construction, and heat pump integration method on energy and economic performance. These archetypes have been developed to represent specific segments of the residential building stock, with geometry and floor area derived from available literature and databases [7,8,9]. Each archetype also uses a different base case heating system to examine the impact of heat pumps replacing different common heating technologies. The most common residential heating energy system is highly region-dependent: Natural gas heating is prevalent from Western through Central Canada (Vancouver, Winnipeg, Toronto), while electrical or oil-based heating is more common in the Atlantic provinces (Halifax) [2]. To develop a more comprehensive understanding of the transition to heat pumps, all three of these heating base cases (Natural gas, oil, electricity) are examined in each region, even in situations where particular systems have smaller uptake. This can provide policy makers with information to better tailor potential incentive programs and identify situations where transitioning to a heat pump offers immediate energy and economic benefits. A summary of relevant parameters for each building archetype is presented in Table 2. Where possible, archetype performance has been validated using data from test homes (for L2S [3]) or compared with available literature [2].

For each archetype, building envelope performance is modified to represent region specific construction for the four selected cities in Table 1. For the M2S and L2S archetypes, envelope performance was selected based on the National Building Code of Canada (NBC) minimum requirements for the selected climate zones [6]. For the SB archetype, envelope performance was derived from the Canadian Single-Detached & Double/Row Housing Database (CSDDRD) [8] for the appropriate regions and 1960s vintage, with this archetype and construction period selected to represent the smaller, older homes where oil systems are typically still seen. A summary of envelope parameters for the SB archetype is provided in Table 3.
Table 3: Summary of Envelope Construction for SB Archetype

3. Heat Pump System Integrations

The developed housing archetypes serve as a basis to examine three different heating system transitions:

I. Natural Gas Furnaces to Air-Source Heat Pumps
II. Oil Furnaces to Air-Source Heat Pumps
III. Electric Baseboards to Air-Source Heat Pumps

Each transition is selected due to the unique economic boundary conditions imposed, and its relevance and potential impacts in supporting a decarbonization of Canadian residential buildings. In cases that involve a transition from fossil fuels, it is assumed that homeowners will proceed with a complete electrification of space and water heating, including the introduction of an electric (non-heat pump) hot water tank.

Heat Pump Integration and Sizing Methods

The base case mechanical systems for each archetype play a critical role in defining the form of heat pump integration. In cases where central ducted is available (replacing oil or natural gas furnaces), a ducted heat pump configuration is proposed, with the indoor coil of the heat pump integrated into a central air handling unit. For homes without central ducting (replacing electric baseboards), a ductless configuration is used, with the indoor unit of the heat pump integrated into the stairwell linking the first and second floors of the home. In this integration, the basement of the home is heating only using electric baseboards, as per the base case.

Heat pump sizing also has an important impact on system performance and economics. Given the cold Canadian climate, all heat pump systems are sized with a focus on space heating using Option C of NRCan’s *Air-Source Heat Pumps Sizing and Selection Guide* [10].

Heat Pump Technologies

Two market available air-source heat pump technologies are assessed to examine their economic and energy savings potential in each of the defined transition cases:

**Conventional Variable Capacity Air-Source Heat Pump (VCHP):** Variable capacity units are an increasingly popular option in the Canadian residential heat pump market. Unlike single stage heat pumps, variable speed systems are able to efficiently modulate their capacity to better match heating or cooling demand. However, these systems are not necessarily well adapted to cold climates, with many market-available options suffering significant performance degradations at the colder ambient temperatures common in Canadian winters. This integration focuses on these more conventional variable capacity systems in each region and transition case.

The performance of variable capacity systems is closely linked both to their rated performance and their ability to modulate their capacity to meet lower heating or cooling loads. Key parameters used in the analysis are provided below in Table 4, and are the same for all sizes of heat pumps used in the simulations.

*At AHRI Rating Conditions
Cold Climate Variable Capacity Heat Pumps (CCHP): Cold climate heat pumps combine variable speed compressor technologies with other cycle upgrades (e.g., larger outdoor heat exchangers, vapour injection cycles) to maintain a higher portion of heating capacity at low outdoor temperatures. Although multiple definitions of cold climate heat pumps exist in the literature [13,14], they are classified in this paper as systems operating to an outdoor temperature of -25°C and maintaining at least 65% of their rated heating capacity.

Figure 1 compares the normalized capacity of the ducted CCHP and VCHP systems used in this study. The CCHP unit maintains a much larger portion of its heating capacity at low ambient temperatures, while also operating to a lower minimum outdoor temperature. These characteristics have important implications for system efficiency and peak electrical demand.

![Figure 1: Comparison of CCHP and VCHP Normalized Heating Capacity [12,15]](image)

Table 5 summarizes key parameters for the CCHP systems examined in this study. Variations in rated COP are due to the differences in manufacturer listed performance among units of the same model line.

4. Modelling Methodology

Appropriately modelling the performance of each heat pump system is critical to properly assess its energy and economic benefits. All system models were developed in TRNSYS v.18 using the appropriate Canadian Weather for Energy Calculations (CWEC) weather file (2020 version). Simulations were run using a time step of 2.5 minutes in order to properly represent the control logic of the heat pump and its interaction with any auxiliary heating systems.

Heat Pump Performance Modelling

Examining the potential of variable and cold climate heat pump systems requires a simulation model capable of capturing their unique performance characteristics. In this study, all heat pump systems are simulated using a new enhanced heat pump model (TRNSYS Type 3255). This model has been developed based on extensive test experience at the CanmetENERGY in Varennes facility and integrates a series of new capabilities including performance variations with compressor speed, and key short term transients including startup, defrost, and cycling. Further details on this model are provided in Breton et al. [17].
Type 3255 employs a data-driven approach, using performance maps supplied as inputs to the model to represent variations in heat pump capacity and power as a function of temperature and compressor speed. Where possible, this study uses performance maps derived from detailed testing to drive simulations. In cases where this data is not available, performance data has been derived from manufacturer data sheets and information available in the open literature. For the ductless VCHP system, performance curves are derived from a database of variable capacity heat pump performance [18]. Data sources are summarized in Table 6.

Table 6: Summary of data sources for heat pump modelling

**Heat Pump Control**

A PID controller is used to vary the heat pump compressor speed to maintain 21°C in heating mode, and 23°C in cooling. The simulated controller also contains a threshold minimum operating frequency, below which the heat pump turns off. This feature enables the model to capture on/off cycling when building loads fall below the minimum capacity of the heat pump. Additional controls ensure that the heat pump only operates within its intended range of outdoor temperatures.

While heat pump systems are sized to cover the majority of annual heating demands, they are not selected to meet the full heating demands of the home at design conditions. As such, electric auxiliary systems are included to supplement heat pump operations as needed. When ambient temperatures are above the minimum operating temperature for the heat pump, auxiliary heaters use a slightly lower setpoint (20°C vs. 21°C for the heat pump) to prioritize heat pump operations while ensuring thermal comfort in the space. When ambient temperatures fall below the minimum heat pump operating temperature, auxiliary heaters maintain 21°C.

**5. Economic Analysis**

System economics play an important role in defining the pace of heat pump adoption in Canada. In this study, each system integration is evaluated over a 20-year lifespan, with a focus on capital, maintenance and operating costs (replacement costs are neglected). Lifecycle calculations use an inflation rate of 1.8% and a discount rate of 3.3%, based on current Canadian financial markets. Given current economic volatility, these values represent a conservative approach over the defined 20-year analysis period.

System capital costs are based on a component level analysis, and include all required equipment, controls, and ducting (for centrally ducted systems). Included components are summarized in Table 7. Given the focus on decarbonization in this paper, all transitions from fossil fuel heating systems also include replacing the base case hot water tank with an electric resistance equivalent storage tank. Heat pump costs do not include modifications to the electrical service of the home, which can significantly increase overall system costs.

System costs are derived via RS Means [20] and available online suppliers [21], and include both material and labour. All costs were adjusted for the appropriate region using factors from RS Means. For clarity, system costs are summarized by integration case in the *Results* section of this paper.
Utility rates and structures also play a critical role in defining the operating costs of the systems. This study uses current rates and structures in each region [22-28]. Rates include both fixed and energy charges, tiered/time of use structures, rate riders, and provincial or federal carbon pricing for 2022. Energy escalation rates were estimated using information from the National Energy Board of Canada [29]. Given the volatility in current (2022) energy markets, escalation rates can be considered a conservative estimate over the system lifespan. A summary of utility rates used in the analysis is provided in Table 8.

6. Results and Discussion

The developed methodology provides a basis to explore the energy and economic implications of air-source heat pump adoption across Canada. Results are presented by heating system transition below.

Transitioning from Natural Gas Furnaces to Air-Source Heat Pumps in Large Two-Storey Homes

Table 9 summarizes the energy performance of both heat pump systems as gas furnace replacements in large two-storey homes in Halifax and Toronto. Each system demonstrates a clear reduction in annual energy use, with savings for space heating and cooling ranging from 53% to 60%. Despite the colder climate and higher number of heating degree days in Halifax, annual savings are greater vs. Toronto because of a reduced need for auxiliary heating (Halifax has a smaller number of operating hours below -20°C). It is also interesting to note that the predominance of coal-fired electricity in Atlantic Canada yields an increase in GHG emissions with each heat pump case, although this is expected to change as the grid undergoes further decarbonisation.

Table 10 summarizes the energy performance of each heat pump system in Winnipeg and Vancouver. The impact of the different climates is immediately clear: The colder climate in Winnipeg reduces energy savings due to a greater reliance on auxiliary energy use, while the milder Vancouver climate yields higher operating efficiencies and greater energy use reductions (aux. heating is only used in Vancouver when the heat pump is in defrost). It is important to note that the savings associated with the CCHP in Vancouver are related to the operating efficiency of this unit across the most common winter temperatures (-5°C to +5°C), rather than a strong need for cold climate performance – This result may change if other VCHP or CCHP units are examined in the analysis, and is not a definitive reflection of VCHP vs. CCHP systems in this area. Future work is needed to investigate the sensitivity of results to the heat pump performance curve used, especially in milder regions where the cold climate capacity of the CCHP may be used less.

Table 11 summarizes the economic performance of each system in all four regions. Except in Halifax, all heat pump integrations result in higher lifecycle costs, primarily due to the increased cost of the heat pump systems vs. base case (natural gas furnace + air conditioner) that they are replacing. Interestingly, some form of utility cost savings is achieved using the CCHP in two of the four regions examined (Halifax, Vancouver), suggesting that an economic incentive to cover a portion of the heat pump system costs could shift the economic balance in favor of these systems (This result assumes a complete shift to electricity for all end uses and a removal of the gas connection). In this context, choosing the appropriate systems to incentivize (i.e., those that achieve the greatest utility cost savings) is of critical importance given the current marginal utility cost savings vs. the base case system.

</table>
A major factor impacting natural gas rates in Canada is the implementation of carbon pricing. Carbon prices evolve according a schedule defined by the federal government, ranging from a current surcharge of $0.0979/m³ of natural gas, to a value of $0.1860/m³ in 2025 and a final price of $0.3389/m³ by 2030 [30]. Table 12 summarizes the impact of 2025 and 2030 carbon pricing on the above results. Increases in carbon pricing allow CCHP systems to achieve operating cost parity with natural gas furnaces by 2025 in nearly all locations except Winnipeg, where CCHP operating costs are slightly higher vs. the base case. Using the 2030 carbon pricing, operating cost savings are enough in all regions to outweigh the higher capital costs associated with the heat pump integrations, although economic incentives may be needed to achieve the shorter-term payback periods (<10 years) often desired by homeowners.

Transitioning from Oil Furnaces to Air-Source Heat Pumps in Small Bungalows

Table 13 summarizes the energy performance of both heat pump technologies as replacements for oil furnaces in 1960s vintage small bungalows located in Halifax and Toronto. Results also reflect a transition from oil-fired hot water tanks to electrically heated tanks in each heat pump case. Compared to the natural gas cases, energy use reductions are even larger due to the lower efficiency of the oil-fired heating equipment in the base cases. In Halifax, GHG emissions still increase with each heat pump integration due to the carbon intensive nature of electricity generation. As noted previously, emissions associated with electricity are expected to fall in future years as electricity grids undergo further decarbonization.

*Seasonal Heating COP for whole home, inc. HP & aux.
Energy performance results for heat pump system integrations in Winnipeg and Vancouver are provided in Table 14. Each heat pump system offers strong heating and cooling energy use reductions, ranging from 55% to 80% depending on the region and heat pump technology. Heat pump seasonal performance is lower in Winnipeg, due to the colder climate and extended period of time when outdoor temperatures are below the minimum operating limit for the heat pump. Users may also note the higher annual heating energy use for the base case in Vancouver vs. Winnipeg, which relates to higher infiltration and poor envelope performance associated with 1960s construction in this region. As with the natural gas cases, the improved performance of the CCHP vs. the VCHP in Vancouver relates to its higher operating COP over the most common winter temperatures. This result is not suggesting cold climate performance is needed in Vancouver and should not be considered a definitive statement on VCHP vs. CCHP technology in this region. Instead, it highlights the importance of selecting systems that optimize operating efficiency over the most common winter temperatures.

*Seasonal Heating COP for whole home, inc. HP & aux.

Table 15 summarizes the lifecycle economics of each heat pump system replacing the oil-fired base cases. The high cost of heating oil means that all heat pump integrations offer strong utility cost savings vs. the base case, demonstrating the value to homeowners in transitioning from heating oil to heat pump systems. In most regions, the CCHP is the preferred option despite its higher initial cost, primarily because of the larger magnitude of energy use reductions it achieves vs. the VCHP. In Vancouver, the CCHP is preferred only because of its improved performance vs. the VCHP over the most common winter temperatures. This result may change when examining a different VCHP unit, and is not a definitive statement on the suitability of the CCHP vs. the VCHP in Vancouver. One challenge for homeowners is the higher cost of heat pump systems, which can be significant vs. furnace systems. Although not examined in this study, the Government of Canada has recently launched an incentive program to support homeowners in the transition from oil-fired to heat pump systems by covering a portion of capital and installation costs [31]. This program further increases the value proposition for heat pumps and will drive uptake in coming years.

Transitioning from Electric Baseboards to Air-Source Heat Pumps in Medium Two-Storey Homes

The final system transition examined is the replacement of electric baseboards with heat pump systems. As mentioned earlier, this integration varies from the two previous cases in that ductless heat pumps are used, which serve only the first two floors of the home. Table 16 summarizes the energy performance for this system transition in medium two-storey housing in Halifax and Toronto. It is clear that heating and cooling energy use reductions appear to be less than for the previous cases, primarily because the heat pump is no longer serving the whole home. When comparing only the energy used to heat the two above ground floors, energy use reductions are significantly higher, approaching 54% in each heat pump integration. VCHP and CCHP performance is also very close in both cities: Both systems maintain a similar portion of capacity at colder ambient temperatures and are sized using the same objectives.

Table 17 summarizes the energy performance of each heat pump integration in Winnipeg and Vancouver. The value of the CCHP is immediately clear in Winnipeg, with the extended operating range of this unit providing a strong reduction in baseboard energy use on the first and second floors of the home. Results in Vancouver follow a similar trend to Halifax and Toronto, with both the VCHP and CCHP offering similar performance over the heating season. Given the relatively clean electricity grids in Winnipeg and Vancouver, some readers may question the importance of transitioning from baseboards to heat pumps in the overall context of decarbonization. While the magnitude of GHG emission reductions is quite small in these two regions, transitioning to more efficient heat pump systems also frees up additional generating capacity to meet increased demand driven by population growth and a greater electrification of other sectors (e.g., transport).

Table 18 summarizes the economic performance of the heat pump systems replacing electric baseboard heating. Smaller capital costs for most CCHPs vs. VCHPs relates to the unit sizes: Given their improved capacity, smaller CCHPs were integrated while meeting the same sizing objective. Heat pump systems offer utility cost reductions in all cities, as would be expected given they are replacing a less efficient base case system using the same energy source. All heat pump systems achieve lifecycle cost savings over the 20-year analysis period, with the VCHP and CCHP systems offering relatively similar total costs. These overall savings tend to be limited somewhat by the higher cost of the heat pump systems vs. inexpensive electric resistance heating. As with the previous transitions examined, it is likely that incentives covering first costs may be needed to drive greater uptake and ensure payback periods fall within the expected range for homeowners.

7. Conclusions and Future Work

This study has examined the techno-economic impacts of heat pump adoption in single family Canadian housing. Using an enhanced, data-driven heat pump model, both variable capacity and cold climate variable capacity systems were simulated over a full year as replacements for (i) natural gas furnaces, (ii) oil furnaces, and (iii) electric baseboards. While simulations show the strong energy savings benefits of heat pumps, the economics of these systems are highly dependent on the regional climate, local utility rates and heating energy source being displaced. Integrating heat pumps as replacements for natural gas furnaces represents the most challenging current context, with heat pumps currently offering utility cost savings in only two of the four regions assessed (Vancouver, Halifax), with lifecycle costs higher in all regions. Heat pumps as replacements for oil and electric baseboard systems present a stronger value proposition in the current economic climate, offering both utility and lifecycle cost savings in all cases. An additional analysis using planned carbon pricing shows that by 2030 heat pumps will offer both utility and lifecycle cost savings vs. all three systems examined in this paper (natural gas furnaces, oil furnaces, electric baseboards), representing a significant improvement in system economics vs. the current context. Even when lifecycle cost savings are achieved, the adoption of heat pumps may be challenged by the higher first cost of these systems vs. those they are replacing. Results from this study can be used as a starting point to support the future policy and incentive programs needed to drive decarbonization of Canadian residential buildings.

Heat pump adoption is likely to rise significantly in the coming years as efforts to decarbonize space heating gain momentum. Although not examined in this study, understanding the electrical demand implications associated with this increased uptake is critical to ensure that local electricity grids have the capacity and infrastructure to support a greater electrification of building systems. CanmetENERGY in Varennes has previously used its simulation capabilities to examine the peak demand implications of air-source heat pumps in residential buildings, and will continue this work to complement the energy and economic impacts presented in this article. These peak demand implications also necessitate a new generation of heat pump systems that combine efficient heating and cooling with energy storage to increase flexibility and demand response capabilities. Ongoing research at CanmetENERGY in Varennes has identified novel combinations of heat pumps and thermal storage for the Canadian context, with planned work furthering this research through additional development and a small-scale proof of concept. This work is intended to further compliment the information presented in this paper and support the efficient electrification of Canadian residential buildings.

Abstract

Thermally Driven Heat Pumps represent an option to reduce the energy consumption for space heating and domestic hot water in hard-to-decarbonize buildings without impacting the electrical grid and utilizing the current and future gaseous energy vectors with high efficiency. Ariston Group and Politecnico di Milano developed a gas absorption heat pump for the residential market, exploiting design and manufacturing solutions to enable large-scale production and introducing technical features to assure high performance over the entire working range.

In particular, the use of a variable restrictor setup coupled with a patented solution, called “booster”, can reduce the temperature of the generator at high load and high lift conditions, enabling the heat pump to provide the nominal capacity from -22 °C to +40 °C of outdoor air temperature, with supply temperature up to 70 °C. Moreover, coupled with a specifically designed combustion system, the heat pump can modulate at 1:6 ratio of its nominal capacity. This feature makes it possible to maintain high efficiency also at part load conditions, avoiding the on-off operation and making redundant the installation of inertial buffer.

Additionally, an innovative strategy to perform the defrosting of the air-sourced heat exchanger without the need of acting on the thermodynamic cycle has been developed. This allows defrosting operations extremely fast, while offering an almost negligible effect on the heat pump performance and substantially no interruption to the heating service and contributing to the elimination of the need to install an inertial buffer.

The thermodynamic core of the appliance was built targeting large scale production. It allows for high specific capacity (kg/kW) and a small footprint (m²/kW) with the ability to serve nominal capacities ranging from 8 to 15 kW based on the configurations. Laboratory test to assess the performances based on the European Standard EN 12309 returned a seasonal gas utilization efficiency on the net calorific of 1.50, a seasonal primary energy ratio of 1.27, and extremely low electrical consumption for the auxiliaries.

1. Introduction

Many authors have already highlighted the importance of the climatization of the building stock toward the reduction of the primary energy consumption and CO\textsubscript{2} emissions. The built environment, particularly in western world, is characterized by several aspects:

- limited presence of high efficiency buildings, i.e. buildings with heat demand lower than 25 kWh/(m\textsuperscript{2} year)
- large presence of existing buildings with energy consumption above 150 kWh/(m\textsuperscript{2} year)
- low replacement rate, with less than 1% of building stock replaced annually by new buildings [1]
- presence in existing buildings of high temperature emitters, in particular radiators in Europe and heat exchangers for air ducted systems in North America.

\textit{E-mail address:} tommaso.toppi@polimi.it
To achieve a substantial reduction in primary energy consumption and in CO$_2$ emissions, a solution that could deliver substantial savings in the retrofit of existing buildings is needed. Indeed, the distinction between the new buildings and the existing buildings is pivotal to ensure that the reduction of emissions is achieved in the shortest possible time. While new buildings enjoy access to state-of-the-art construction technology, and large degrees of freedom in terms of architectural decisions (surface-to-volume ratio, orientation, size and position of windows, etc.), the retrofit of existing buildings has to face a high number of constraints including a limited budget and often the presence of the landlord during the retrofit (existing buildings cannot be easily vacated). Nevertheless, the large number of existing buildings with large yearly energy needs for space heating and the extremely high heat demand of these building make this challenge the most relevant and crucially important to address the overall challenge of reducing emissions.

To facilitate the adoption in the existing buildings the optimal solution needs to minimize the installation hurdles, i.e. not requiring changes to the existing emission systems in the building (radiators and diameter of piping). This requirement implies working with high output temperatures (up to 70 °C) and the limited flow rates typically used in systems designed for boilers that often do not exceed 1000 l/hour. Moreover, limited requirements for auxiliary equipment (inertial buffer, etc.) and the possibility to leverage the skills and competence already available in the installer base by avoiding forcing them toward new certification are crucial. At the same time, the proposed technology would need to meet the following requirements:

- Lower operating costs than state of the art (usually a direct combustion system).
- Low noise level to minimize the possible impact on outdoor quietness, in compliance with local legislation, even in presence of limited distance from the neighborhood’s property.
- Ability to deliver heat with constant power output particularly in high thermal lift conditions, typical of the most demanding climates of the North European and North American regions.
- Ability to serve both the space heating and the domestic hot water function to maximize the benefits to the overall heat demand of the building.
- Environmental benefits in terms of reduced global warming emissions (CO$_2$, F-Gases), reduced ozone depletion emissions (F-Gas) and reduced human health hazardous emissions (PMs, NOx, OGCV).

In addition, a solution that could be rapidly adopted will need to be compatible with the energy system in place and the one prospected in the future. Therefore, the reduced electrical load (not to rely on an already overloaded grid) and the ability to work with green gases (bio-methane, bio-LPG, hydrogen blends) is required.

Gas driven heat pumps meet these requirements, since they can be designed to work at high temperature, matching the needs of high temperature heating systems, and relay on an already existing and high-capacity gas network. Compared with existing fuel driven heating systems, as boilers, gas heat pump provide a substantial reduction of the gas consumption with a minor increase of the electricity needs. In [2] two prototypes with a nominal capacity of 23.5 kW have been tested and a seasonal gas utilization efficiency of 1.36 (based on gross calorific value) has been achieved, considering the climate region IV of the American and Canadian Standard. A value of about 1.25 has been found in [3] from numerical simulations on the use of gas heat pumps in various residential buildings in the average European climate. Looking at the comparison from a life cycle assessment prospective [4], in renovated buildings and with the 2020 European energy mix, the weighted environmental impact of a gas absorption heat pump results about 25% lower than the one of a condensing boiler and about 50% lower than the one of electrical driven heat pumps.

In this work, the development of a gas driven absorption heat pump (GAHP) is presented, with a focus on the innovative solutions adopted to meet the goal of efficient and safe operation over the entire working range. Three technical solutions are presented, i.e., the so-called “booster” function, the use of a double restrictor in the solution branch and the use of an innovative approach to defrosting.

Gas fired absorption heat pumps experience an increase of the temperature of the generator when the thermal lift (difference between source and supply water temperatures) and the capacity increases. Thus, traditionally, the thermodynamic cycle is designed to have the maximum temperature at the generator at the lowest outdoor air temperature, higher supply temperature and design capacity. Consequently, when the working conditions become more favorable, i.e., at lower lift and lower capacity, the temperature of the generator decreases. This has two main consequences. The first is that at very low load conditions the temperature of the generator may become sub-optimal or even decrease below the cut-off limit [5]. The second is that at mild conditions the heat pump results strongly oversized, leading to a poor efficiency and unfavorable weight to power ratio. To overcome these issues the innovative solutions have been implemented. The booster is a patented [6] solution, which allows to reduce the generator temperature at high capacity and high thermal lift. This permits a design of the cycle with a more favorable weight to power ratio, keeping the capability to provide the nominal capacity at design conditions, while maximizing the efficiency at intermediate lift and capacity, i.e., in those conditions when most of the yearly energy is delivered.
The use of a double restrictor allows a better tuning of the generator temperature across the working range, with further benefits on the efficiency.

The third innovative solution introduced in the heat pump concerns the defrosting operation, required to remove the ice layer which builds up on the air-sourced evaporator of all heat pumps. While in vapor compression heat pumps this is usually done by inverting the thermodynamic cycle and operating the evaporator as a condenser, allowing the hot refrigerant to melt the ice, in absorption heat pump the most common solution relies on a bypass of hot refrigerant from the generator to the evaporator, skipping the condenser. The cycle inversion of Vapor Compression HPs has a significant impact on the thermodynamic cycle and on the continuity of the power delivered to the user. The bypass of refrigerant usually implemented in GAHPs is less impacting but affects for a certain period the operation of the cycle and require a fine design of the internal volumes. For the developed heat pump an alternative approach has been selected, taking advantage of the use of an indirect evaporator: a heat exchanger is used to heat up the secondary fluid which circulates in the air-sourced heat exchanger using the supply water. In this work this system is described and details about its operation are provided.

2. Concept description

The Ariston Group initiative on Thermally Driven Heat Pumps focused on a common thermodynamic design that could serve a range of products to accommodate the need of the different local market in which the Group is commercially active. The design of the technological solution was therefore targeted to support different capacity ranges and aeraulic design and installation configurations.

First of all, the thermodynamic design was conceived in order to incorporate products with different capacity range. Indeed, the destination markets include different heat loads due to the different size and different insulation characteristics of the buildings. Therefore, to cover the largest possible portion of the European residential market, the sealed circuit was designed to be able to accommodate an output power in the range from 8 kW to 15 kW measured at air temperature of -22 °C and supply water of 70 °C.

Similarly, the different local market features and the different requirements in terms of expectation for quietness (with the associated legislation) resulted in product design solutions to be customized for such markets. Indeed, in several countries the noise limits are differentiated between day and night, with expectations for extremely low noise performance at night and in proximity to the fence or window of the neighborhood. Therefore, two different aeraulic designs, depicted in Figure 1, have been developed to accommodate the most differentiated acoustic emission targets and the requirements of markets where the form factor and total volume were highly valued. This mass customization approach was implemented in a platform design of the thermodynamics and in two set of aeraulic configurations (horizontal and vertical air flow) with substantially differentiated fans and air heat exchangers.

![Fig. 1 – The two aeraulic configuration developed to meet the requirements of the different European markets.](image)

Finally, the specific requirements of the local European market were translated in several options for possible installation configurations. Indeed, the compactness, local regulation on exhaust flue gas, resilience to extreme weather conditions generated different evaporator designs. In details, Ariston developed a technology platform where several features could be incorporated to maximize the customization to the
different markets. Among others, this approach included several unique features for a thermally driven heat pump as described in the following.

- Air sourced design with indirect evaporator: the evaporation of the refrigerant happens in a heat exchanger with a water-glycol mixture. This fluid is then used to exchange with outdoor air by means of an air coil. This design allows lower ammonia content, and an almost transparent defrosting cycle actuation.
- Combustion system designed and tested to comply with both current gases and expected new green gases (Bio LPG, Bio-methane, H2 blend). This feature allows the end-user to perceive the investment in the TDHP technology as something already designed for the future gases that will be injected in the grid.
- Design solutions for industrialization of pumping system, heat exchangers and solution desorber to allow high quality and high-volume manufacturing.

Similarly, the control architecture was developed to include:

- a sophisticated on-board controller able to control the appliance safety and efficient heat generation function,
- a plant controller to control most possible installation schematics used in the destination markets,
- remote access, and connectivity functions to allow functionality and performance monitoring,
- access to the entire ecosystem of accessories that the Ariston Group offers.

In this section, the technological features which have been incorporated in the heat pump to meet the mentioned level of flexibility, efficiency and quietness will be presented.

2.1. Booster

Heat pumps usually experience a performance reduction at high thermal lift, i.e. when the outdoor air temperature is low and when the supply water temperature is high. Therefore, heat pumps result undersized when the heating demand of the building is higher and require a backup system (electrical resistance or gas boiler) which increases the system complexity and cost and reduces the overall efficiency. Alternatively, if the heat pump is sized to handle the full load at design condition, it results largely oversized when the load is lower, i.e. for most of the heating season, again with negative impact on the costs and on the efficiency.

To overcome this issue, the booster concept [6] is aimed at allowing a gas input above the nominal value, while keeping the generator temperature below the maximum value, usually set at 180-200 °C for corrosion control reasons. The booster concept relies on two splits on the solution and the refrigerant circuit aimed at modifying the magnitude of the internal heat recoveries, with the purpose of lowering the temperature and increasing the ammonia mass fraction of the rich solution entering the generator. This has the effect of reducing the temperature in the generator and increasing the maximum amount of gas input.

![Figure 2](image)

Fig. 2 – scheme of the heat pump cycle during normal operation (a) and with activated booster function (b).

With reference to Figure 2, where the cycle layout is presented both under normal operation (a) and in booster mode (b), the solution which normally flows through the Solution Cooled Absorber (SCA) is deviated and directly sent to the generator, disabling the heat recovery given by the GAX (Generator Absorber heat eXchange) effect. Moreover, making use of a venturi tube, part of the refrigerant leaving the condenser is injected in the rich solution, increasing its ammonia mass fraction. This increases the mass fraction in the generator and its capability to generate vapor, transferring the extra gas input into latent energy. The possibility...
to increase the gas input up to 50% more than the design value permits to reach the maximum heating capacity even when the thermal lift is high. Thus, the thermodynamic cycle can be sized to operate with the maximum efficiency in the most frequent conditions, i.e., intermediate thermal lift and load, while keeping the possibility to meet the maximum capacity without the need of auxiliary systems.

A further effect of the activation of the booster is the reduction of the high pressure of the cycle. In fact, when the rich solution is directly routed towards the generator, the rectifier is not cooled anymore. This results in a lower mass fraction of the refrigerant leaving the generator, which causes a reduction of the condensation temperature. This is often beneficial since the booster is usually activated at high supply temperatures, which are also associated to high pressures. Thus, the booster can be used not only to deliver the required capacity without exceeding the maximum temperature at the generator, but also to increase the supply water temperature while keeping the maximum pressure within the design limits.

2.2. Two-stage restrictor

To further extend the capability of the heat pump to operate efficiently in all the loads and thermal lifts, a double stage restrictor has been used on the poor solution branch. The control of the flow rate on the solution branch consent to deal with two well-known correlated issues related to part load operation of gas driven heat pumps, i.e., the reduction of the temperature in the generator and a sub-optimal ammonia mass fraction in the circuit. In fact, gas driven heat pumps deal with part load by reducing the gas input. This automatically translate in a reduction of the generator temperature and a consequent increase of the ammonia mass fraction of the solution contained in the generator volume. These changes have various effects: they reduce the concentration spread between the rich and poor solutions (which impacts on the GAX effect in the SCA) and reduce the amount of ammonia available for the other components. The first issue has a direct impact on the efficiency of the heat pump and can even lead to cut-off conditions when the generator temperature decreases too much, forcing the control system to run the machine in an inefficient on-off operation. The second issue has an impact on the low pressure, which tends to decrease when the amount of ammonia available in the circuit is not sufficient, with a negative impact on the efficiency of the heat pump, which operates in an unnecessary artificially high thermal lift.

The use of a variable solution flow rate to maintain the generator temperature in its optimal value and to maximize the heat pump efficiencies in all the thermal lift and load condition has been proved numerically [5]. In this work, the concept has been deployed in the developed heat pump, opting for a two-stage restrictor instead of a continuously adjustable one to keep the cost and control complexity low. However, through a proper selection of the characteristic of the two restriction stages and in combination with the booster, it has been possible to maintain a high efficiency in the entire range of operating conditions.

2.3. Defrosting

The choice of an indirect evaporation allowed the design of an innovative approach to defrosting operation.

![Fig. 3. Schematic representation of the defrosting system during normal operation (a) and defrosting operation (b).](image-url)
With this system, which schematic operation is reported in Figure 3, the defrosting process is done by heating up the brine in the secondary circuit by means of a heat exchanger, called defrosting heat exchanger, paced in series with the supply water outlet. During normal operation (Figure 3a) the three-way valve DV allows the brine to circulate between the evaporator and the outdoor air heat exchanger, skipping the defrosting heat exchanger through the brine bypass. During defrosting operation (Figure 3b) the valve switches, closing the brine bypass and circulating the brine through the defrosting heat exchanger. Here the brine is heated up by the supply water, reaching a temperature warm enough to defrost the air-sourced heat exchanger.

3. Performances

In this section the measured performances of an initial prototype of a heat pump are presented. A first defrosting operation is reported to prove the effectiveness of the developed solution. Then, the effects of the booster and of the double restrictor on the thermodynamic cycle are showed with reference to some specific tests. Finally, the seasonal performance according to the European Standard EN 12309 and the representation of the operating range of a prototype of a heat pump incorporating the described solutions are reported.

3.1. Defrosting

The relevant temperatures useful to analyze a defrosting operation are reported in Figure 4. In particular, the black line indicates when the defrosting valve DV is opened (at time 18:42) and closed (at about 18:45). In the first part of the chart, the temperatures of the brine entering (T_{B1}) and leaving (T_{B2}) the outdoor air sourced heat exchanger are about -10 °C and -13 °C, significantly lower than the air temperature (0 °C) due to the presence of frost, while the supply water temperature is stable at 55 °C. When the defrosting operation starts, the brine passes through the defrosting heat exchanger and meets the warm water leaving the heat pump. As a result, the temperature of the brine entering the outdoor air heat exchanger (T_{B1}) increases up to a level sufficient to melt the ice. The increase of the temperature of the brine leaving the outdoor heat exchanger (T_{B2}) is slower due to the intense heat transfer taking place during the melting process. When the process is concluded by the return of the defrosting valve to its initial position, the supply water temperature reaches immediately the original value of 55 °C. The brine temperatures decreases more slowly due to the capacity of the circuit and of the outdoor heat exchanger, meaning that part of the sensible energy used to heat up the system at the beginning of the defrosting process is recovered. After the transient, the brine temperature stabilize few degrees below the air temperature, at the typical value associated to a frost-free heat exchanger.

The entire process lasts about 3 minutes and does not have any impact on the thermodynamic cycle. This makes the operation very efficient and allows to restore the supply temperature to its set value immediately. The basic principle herein described is subject to further improvements and it is associated to control features covered by industrial intellectual property of Ariston Group that include additional function for the management of the indirect evaporation and the defrosting.

![Fig. 4. Trend of the relevant variables of the brine circuit during a defrosting operation](image-url)
3.2. Effects of the booster

As mentioned in the previous section, the booster can be used for two different purposes, i.e., limiting the generator temperature at high capacity and high thermal lift or limiting the high pressure at high supply temperature. In the chart in Figure 5 the effect of the booster on the cycle when it is used to limit the high pressure can be observed. The test was run at 20 °C of air temperature, while the water inlet/outlet temperature was 50/70 °C. Under this condition the high pressure was the limiting factor to the delivered capacity, which was about 3.6 kW (green line). To increase the heating power without a further increase of the high pressure, the booster was activated at 15:28. As a result, the generator temperature (red line) dropped from 143 °C to 133 °C and the high pressure (blue line) from 25 bar to 22 bar, creating some space for an increase of the gas input and of the delivered capacity. From the chart it is also possible to see that even if the activation of the booster introduces significant variations on the operation of the cycle, the transition is very smooth and does not impact the heat pump stability.

![Fig. 5. Effect of the activation of the booster on the generator temperature and](image)

3.3. Effects of the double restrictor

Providing a complete picture about the use of the double restrictor in combination with the booster is complex and would require the disclosure of control strategies that have been specifically developed to maximize the benefits of these solutions and are considered confidential. However, in this section the impact on the thermodynamic cycle of the switch between the two restrictors configurations is described showing the variation of some relevant quantities. In Table 1 the two pressure levels of the cycle, the temperature in the generator, the gas input, the delivered heating capacity and the resulting GUE are reported for the operation with slow and fast restrictor, for two operating conditions. Of the two reported conditions, the first, with air at 0 °C and water temperature of 40/55 °C, has been selected because it shows an efficiency independent on the type of restrictor used. On the other hand, for the second conditions, characterized by a lower thermal lift, a higher efficiency is found with the slow restrictor, which allows for a higher generator temperature.

The two reported conditions allow the use of both the restrictors because they are characterized by an intermediate heating capacity (about 63% of the nominal capacity) and intermediate thermal lift. As the capacity and the lift increase, the fast restrictor becomes the only option available since the slow restrictor would lead to excessively high temperatures in the generator. On the other hand, at lower capacities and lower thermal lift, the slow restrictor is the only available alternative because with the fast restrictor the temperature of the generator would drop and lead to very low efficiency or even to cut-off conditions.

3.4. SPER based on the EN 12309

The efficiency of a prototype of such a heat pump has been measured in a certified laboratory at Politecnico di Milano premises following the procedure proposed by the European Standard EN12309 [7]. The Standard gives the possibility to calculate the Seasonal Gas Utilization Efficiency (SGUE) for three different outdoor design temperatures (2 °C, -10 °C, and -22 °C) corresponding to the three reference European climates warmer, average, and colder respectively. Moreover, for each climate, four different climatic curves are available, corresponding to different requirements of the emission system. For the present work, a design supply temperature of 55 °C, corresponding to the high temperature application, has been selected and the results for the average climate conditions are presented.

To calculate the SGUE, the Standard approach considers the GUE, i.e., the ratio between the heating capacity of the heat pump and the gas input, at different load ratios. The Part Load Ratio (PLR), i.e. the ratio between the design and the actual building loads, is calculated as a function of the outdoor design temperature and the actual outdoor air temperature, under the assumption that the building load is proportional to the difference between the indoor and the outdoor temperature and becomes zero at 16 °C.

The SGUE is calculated using the bin method as in Equation 1. The Standard prescribes to measure the GUE under the working conditions reported in Table 2 and to derive the values of GUE for the remaining air temperatures by interpolation. Since the performances of the GAHP are also affected by the return water temperature, the Standard allows a maximum temperature difference between supply and return temperature ($\Delta T_{max}$ in Equation 2), function of the outlet water temperature ($T_{w\text{ out}}$).

Besides the GUE, Table 2 reports the Auxiliary Energy Factor (AEF) for each measured condition, i.e., the ratio between the heating capacity and the electrical power required for the auxiliaries of the heat pump, namely electronics, blower, fan, water pump and solution pump. These values are used to calculate the Seasonal Auxiliary Energy Factor when the appliance is running (SAEF_{ON}) in a similar way as the one described to calculate the SGUE from the GUE. Adding the electrical consumption in standby mode ($E_{SB}$) and thermostat off mode ($E_{TO}$), equal to 6 W and 0 W respectively, the SAEF is obtained. As last step, weighing the GUE and the SAEF with their corresponding primary energy factors ($F_{EL} = 2.5$ and $F_{GAS} = 1$), the Seasonal Primary Energy Ratio is calculated as in Eq. 3.

The following seasonal figures have been obtained for the developed heat pump:

- GUE\_NCV: 1.50
- SAEF: 55.9
- SPER: 1.27

\[
SGUE = \frac{\sum_{j=1}^{N} h_j \phi_a(T_j)}{\sum_{j=1}^{N} h_j GUE(T_j)}
\]

\[
\Delta T_{max} = 7 + \frac{T_{w\text{ out}} - 35}{3}
\]

\[
SPER = \frac{1}{GUE \cdot SAEF}
\]

It must be mentioned that the test conditions reported in Table 2 have been run without activating the booster. This is due to the design choices, which aimed at delivering the design power at the design condition without the need of activating the booster, with the scope of assuring high efficiency over the space heating conditions. However, the booster can be activated when the outdoor temperature drops below the design conditions or when high water temperatures are required (e.g., during the domestic hot water preparation). Additionally, the booster operation is also influenced by the gas input, which impacts on the generator temperature. In the following section a rough indication about the conditions when the booster is needed is presented.

3.5. Operating range

Gas absorption heat pump is a technology which could be asked to operate over a very wide range of operating conditions. In fact, being the existing building its more natural application, the type of emission system and capacity requirements can differ significantly from case to case. Additionally, existing buildings can present high load and the need for high supply temperature in all type of climate conditions. The innovations described in the previous sections, beside enabling high performances, were introduced also to extend the operating range of the heat pump, to maximize the possible application that can be addressed with the same design. As a result, the described heat pump prototype can provide 70 °C of supply water with air temperature from -22 °C, i.e., the design condition of the reference European colder climate conditions to above 30 °C, typical of the summer season when domestic hot water production is still required. As reported in Figure 6, when the design capacity is required, supply temperatures above 55 °C and air temperatures below -15 °C require the activation of the booster. This region becomes smaller at the minimum capacity, where only the upper part of the supply temperature range requires the activation of the booster. The limitation existing at the combination of high air temperature and high supply temperature is given by the high pressure, which would exceed the design values.

![Fig. 6. Graphical representation of the operating range of a 10-kW heat pump at maximum and minimum capacity](image-url)
1. Conclusions

In this work the development of a prototype of a new product platform of gas absorption heat pumps for residential application has been presented. The main innovations introduced, their motivation and their impact on the heat pump operation have been described.

An innovative defrosting system has been developed, taking advantage of the use of an indirect evaporation configuration, with a brine auxiliary circuit. This system resulted very effective and able to complete the defrosting operation in about three minutes, with minimal impact on the user and no influence on the thermodynamic cycle.

The combined use of the patented concept of the booster and of a double stage restrictor allows the heat pump to operate from -22 °C to more than 30 °C of air temperature, with maximum supply temperature of 70 °C. It also made it possible to design the thermodynamic cycle to reach the maximum efficiency in the most frequent operating conditions in the heating season and to avoid the oversizing of the heat pump, keeping the dimensions and the weight low. Moreover, these solutions enabled efficient operation over the entire operating range, which resulted in a Seasonal Primary Energy Ratio measured according to the European Standard EN 12309 of 1.27 and a Seasonal Auxiliary Energy Factor of 55.9.

From this initial development work, Ariston completed the design of a new platform of TDHP products further enhancing these results.

Acknowledgements

The development of the gas absorption heat pump presented in this work has been done within the i-GAP research project, supported under the Call “Agreements for Research and Innovation of the Lombardy Region” co-financed by the ERDF ROP 2014-2020 of the European Commission. Project ID: 241736. Moreover, the introduction of the double restrictor and the extension of the modulation range has been funded by Regione Lombardia under the LombHe@t Project - Call Hub Ricerca e Innovazione. These developments are therefore the basis of a scientific and technological work that Ariston Group has considered in preparing its new TDHP platform.

Innovative small capacity gas driven ammonia-water absorption heat pump prototype for space heating and domestic hot water production

Pistocchini Lorenzo a, Villa Giorgio a, Paulin Cesare a, Toppi Tommaso a

aPolitecnico di Milano, via G. La Masa 34, Milan 20156, Italy

Abstract

Gas driven absorption heat pumps are a viable alternative for efficient space heating and domestic hot water production in residential and light commercial buildings with high temperature distribution systems. This work presents a second-generation ammonia-water absorption heat pump prototype, with patent-pending components developed by Politecnico di Milano. The innovative design of desorber and rectifier improves the heat and mass transfer in the generator whilst reducing its height and complexity. All the heat exchangers, except for the generator, are plate heat exchanger and a specifically designed oil driven diaphragm pump is used as solution pump. The overall weight of the prototype, excluding the continuous fin-type outdoor heat exchanger, is kept below 70 kg for a unit with nominal capacity of 10 kW. Variable restrictors for both solution and refrigerant branches are used to improve part load operation and the seasonal efficiency. Laboratory tests confirm high performance over a supply water temperature range between 25 °C and 70 °C and ambient temperatures between -14 °C and 22 °C. The experimental results highlight the importance of installing a variable restrictor on the solution branch to improve performances at partial load, optimizing the generator temperature. The newly designed prototype proved to perform smoothly and to maintain stable operation under the tested steady-state and transient conditions.

1. Introduction

Absorption heat pumps are a reliable and efficient technology as demonstrated by several applications in the light commercial sector where thousands of gas-driven absorption heat pumps (GHP) are used for many years [1]. This technology is also interesting for the residential market to replace condensing boilers in not or poorly insulated buildings, with high temperature emission systems as radiators, a building typology which represents a large share of the existing European residential buildings [2]. In fact, absorption heat pumps achieve high supply water temperatures with limited performance degradation. For this type of buildings, it has been calculated that absorption heat pumps can provide also higher performances than electric vapor compression heat pumps [2], especially in cold and very cold climates where the COP is reduced by the low outdoor air temperature [3]. Furthermore, the possibility to run absorption heat pumps with green hydrogen or a mix of natural gas and hydrogen, can support the decarbonization of the heating sector, handling the peaks of demand without impacting on the electric grid [1], [4]. Experimental tests confirmed that absorption heat pumps provide higher performances than conventional space heating and water heaters appliances. In [5] two prototypes with a nominal capacity of 23.5 kW have been tested and a Seasonal gas utilization efficiency of 1.36 (based on gross calorific value) has been achieved, considering the climate region IV of the American and Canadian Standard [6]. The seasonal gas utilization efficiency (SGUE) is calculated as the ratio between the useful heat provided by the heat pump during the heating season and the natural gas input. For domestic hot water production (DHW), a 9-month field test has been performed in [7] achieving interesting energy savings, compared to traditional gas tank water heaters. Then, an 18-kW absorption heat pump has been also
tested obtaining a Season Gas Utilization Efficiencies of 1.43, 1.38, and 1.24 (all based on gross calorific value) for the warm, average, and cold climates respectively [8], as defined by the European Standard [9] test conditions.

Even if gas-driven absorption heat pumps are a viable alternative to condensing boilers, especially for single or two-family houses with space availability for an outdoor installation, the limited number of manufacturers and the relatively high purchase costs of commercially available heat pumps limit a wide diffusion of this technology [3]. Many different absorption cycles are available, the most suitable ones for the residential sector are the single effect cycle (SE) and Generator Absorber eXchanger cycle (GAX) [10]. The GAX is considered one of the most suitable cycles for residential application because it achieves high performances providing the possibility to heat up the rich solution by recovering part of the heat released in the absorber [11]. To perform this heat recovery, an additional component is needed compared to the single effect cycle. However, the GAX effect is affected by high thermal lift and partial load operation, condition often found in residential applications [5]. Moreover, small-capacity heat pumps in real applications experience frequent load variation and different operating conditions, such as changes in inlet/outlet temperatures, mass flow rates, external temperatures etc. [12]. To improve the performances at partial loads, an optimization of the temperature of the generator is essential. This task can be achieved controlling the weak solution mass flow rate with a variable restrictor in the solution branch [13].

In this project, a compact and cost-effective air-source gas-driven ammonia-water absorption heat pump based on the single effect cycle has been developed and tested. The heat pump is the second-generation prototype of a previous concept, where several innovations have been introduced in the generator (under patent pending), optimized plate heat exchangers have been selected and the variable restrictors for both solution and refrigerant branches have been used. The solution pump is an oil driven diaphragm pump specifically designed for this application. After a description of the prototype, in this work the achieved energy performances are presented and analyzed. Seasonal gas utilization efficiency and other relevant working conditions are shown, highlighting the impact of the use of a variable restrictor to assure efficient operation, and giving evidence of the smooth and stable operation of the heat pump under both steady-state and transient conditions.

2. Prototyping and thermodynamic cycle

In this section the thermodynamic cycle and the peculiarities of the prototype are described.

2.1. Thermodynamic cycle

The small-capacity gas driven absorption heat pump analyzed in this study has been designed for residential and small commercial applications. The single effect cycle shown in Figure 1 has been selected to meet the requirements of this application, strongly driven by space-saving, by the purchase cost for what concerns the economic aspects, and by a wide range of operating conditions for what concerns the technical considerations.

![Diagram of Single Effect Thermodynamic Cycle](image)

**Figure 1: Single effect thermodynamic cycle**
The Single effect cycle is composed by the refrigerant and the solution branches. The refrigerant branch is the left side of the cycle in Figure 1 and it is composed by the condenser (COND), the restrictors (RES 2 and RES 3), the refrigerant heat exchanger (RHX), the Ammonia Storage Vessel (ASV) and the evaporator (EVAP). On the other side, the solution branch is composed by the water-cooled absorber (ABS), the solution pump (PM), the restrictor (RES 1), the solution heat exchanger (SHX) and the generator (GEN) that can be divided in the direct fired generator (DFG) directly connected to the distillation column (COL1+COL2) and the water-cooled rectifier (REC). The combustion of natural gas heats up the ammonia-water pool boiling solution in the direct fired generator creating vapor (point 8). The ammonia mass fraction of the vapor is increased, while its temperature is decreased in the first section of the distillation column (COL1) where it flows counter-current with the rich solution (point 6) (high ammonia mass fraction), promoting an intense heat and mass exchange. On the contrary, the rich solution reduces its ammonia mass fraction while increasing its temperature. Since a high ammonia mass fraction (=99%) of the outlet vapor from the generator (point 11) is needed, a partial condensation takes place in the water-cooled rectifier (REC). Between REC and COL1 there is the second section of the distillation column (COL 2), where the vapor (point 9) meets the liquid produced by the partial condensation (point 4). The outlet vapor (point 11) flows toward the condenser where it is cooled down, providing part of the useful effect, and it is throttled in RES 2 and RES 3. Between the two restrictors there is the ASV that stores/releases the refrigerant when it is required, as described in [1], and the RHX that provides an internal heat recovery between the outlet liquid refrigerant of the ASV (point 14) and the outlet vapor of the evaporator (point 17). The weak solution (point 19) (low ammonia mass fraction) leaves the generator, it is throttled in RES 1 and flows to the absorber (point 21) where it is mixed with the refrigerant (point 18) providing part of the useful heat thanks to the exothermic absorption process. The rich solution (point 1) is pumped up by the solution pump (point 2) and it is heated up (point 3) by the weak solution (point 20) in the SHX providing a remarkable internal heat recovery. Then, the rich solution flows in the generator. Looking at the water circuit, the useful effect of the heat pump is provided by the flue gas heat exchanger (FHX), the condenser, the absorber, and the water-cooled rectifier. The water is pre-heated by the FHX cooling down the flue gas (point 23) and compensating part of their humidity content, then condenser and absorber are connected in parallel (point 24a and point 24b). To conclude, the whole mass flow rate flows in the REC (point 26) providing the cooling for the rectification process.

2.2. Prototype description

The sealed circuit of the 10-kW air-water gas-driven absorption heat pump under analysis is shown in Figure 2. To achieve high performances reducing the manufacturing costs, the design of this prototype is based on a mix of standard components available on the market and customized components.

Figure 2: Two side of the GHP sealed circuit, showing its main components and overall dimensions
The customized components are the generator (under patents pending) and the solution pump, i.e. an oil driven diaphragm pump specifically designed for this application, in order to manage the very low flow, the high head pressure, and especially to ensure the complete tightness and maintenance-free reliability in the long term.

The generator has a fire-tube configuration with an innovative geometry that promotes an intense heat exchange between the flue gas and the ammonia water solution maintaining a compact size and reducing the risk of hot spots and local corrosion.

For what concerns the design of the heat exchangers delivering the useful effect of the heat pump, the high difference between the ammonia-water solution mass flow rate and the water mass flow rate represents the most critical issue [1]. In this prototype, standard and custom plate heat exchangers (PHE) developed by Swep have been used. Where possible, an All-Stainless Steel product has been selected, as for the evaporator. When the required All-Stainless Steel PHE is not available, the nickel brazed stainless steel plate PHE has been selected, considering that the corresponding All-Stainless Steel version can be later implemented and produced at a lower cost once you get from GHP prototype to a commercial product.

The solution heat exchanger (SHX) is characterized by a very long thermal length, in order to transfer most of the heat from the weak solution leaving the generator to the rich solution entering the generator. To achieve such a result a multi-pass PHE with a custom configuration has been selected.

The absorber (ABS) consists of two PHE in series, to achieve the required thermal length and manage the different volumetric flow in the refrigerant side, which is mainly a vapor stream at the inlet and a liquid flow at the outlet.

In the evaporator (EVAP) a brine loop (actually filled by a water-glycol mixture) transfers the heat from the outdoor air to the evaporator. This layout may cause a slightly reduction of the performances of the heat pump due to the additional temperature difference caused by use of the intermediate brine loop, however, it offers higher flexibility in installing the sealed circuit indoor and the air heat exchanger outdoor. Furthermore, this option reduces the heat losses towards the environment, partially compensating the performance reduction. Moreover, the use of a brine-water plate heat exchanger as evaporator reduces the internal volume of the sealed circuit, leading to an ammonia content lower than 2 kg, and the risk of refrigerant store-out from the generator into a fin type air-solution heat exchanger, as in case of direct expansion heat pump, during switching on and transients. In addition, thanks to this layout, different defrosting strategies can be implemented. The combination of a compact generator with the use of plate heat exchangers allows for a design of the heat pump able to keep the weight at about 70 kg and to maintain the dimensions close to the ones of a condensing boiler, i.e. 380 x 350 x 830 mm (excluding the outdoor air-brine heat exchanger), as shown in Figure 2. Small capacity heat pumps installed in residential sector works in a wide operating range and under frequent load transient and variable conditions, thus a flexible design under the operating conditions point of view is essential. To achieve this goal, variable restrictors are installed in the solution branch (RES 1) and in the refrigerant branch (RES 2). In contrast, RES 3 is a fixed restrictor that improves the stability of the thermodynamic cycle by introducing a small pressure drop and an intermediate pressure for the ASV and the liquid side of the RHX. The solution branch variable restrictor provides the possibility to optimize the temperature at the base of the generator controlling the flowrate in the solution branch, while RES 2 controls the evaporation temperature to avoid the flooding of the evaporator. The ASV is installed between RES 3 and the RHX to optimize the operation of the RHX [1].

3. Test methodology

The gas-driven absorption heat pump prototype has been tested in an accredited laboratory in the brine-to-water configuration. Temperature measurement is made by high accuracy RTD Pt100 Temperature Sensors (4 wire 1/10 DIN), which coupled to a high precision monitoring system and periodically calibrated allow us to reach an accuracy of +/-0.02 K in the whole operating range.

Flow measurement in the water and brine lines is made by electromagnetic flowmeters, which are periodically calibrated and guarantee 0.1 % of reading accuracy.

Even the particular oil filled volumetric gas flowmeter is periodically calibrated and guarantee 0.5 % of reading accuracy in a wide range of flow rates.

To simulate the impact of the brine loop that transfers heat from the outdoor air to the evaporator, the inlet temperature of the brine is considered 2 K lower than the temperature of the air, with a temperature variation in the evaporator of about 3 K. Consequently, once the \( \Delta T \) required for the heat transfer between brine and refrigerant is taken into account, the evaporation temperature is about 8-9 K lower than the air temperature, a reasonable value which can be matched when an actual well-designed air-to-brine heat exchanger is used. The
energy performance of a gas-driven heat pump is measured as the ratio between the useful heat provided by the heat pump and the natural gas heat input (Q\text{gas}), which is the measured volumetric flow of methane, corrected on the basis of actual temperature and pressure, times the net calorific value (LHV [MJ/Nm\textsuperscript{3}]). This ratio is the Gas Utilization Efficiency (GUE) and considers as useful effect the heat provided by the condenser (\dot{Q}_{\text{cond}}), the absorber (\dot{Q}_{\text{abs}}), the rectifier (\dot{Q}_{\text{rec}}) and the flue gas heat exchanger (\dot{Q}_{\text{fhx}}) as shown in Equation 1. The Seasonal Gas Utilization Efficiency (SGUE) gives an indication about the performance of the heat pump over an entire heating season and it is calculated as suggested by the European Standard EN 12309 [9]. Both GUE and SGUE can be calculated also on the basis of the gross calorific value (HHV [MJ/Nm\textsuperscript{3}]) simply by substituting LHV with HHV in Q\text{gas} calculation. The Standard gives the possibility to calculate the SGUE for three different outdoor design temperatures (T\text{design}), 2 °C, -10 °C, and -22 °C, that correspond to the three reference climates for Europe, i.e. warm, average, and cold respectively. For each climate, four different climatic curves are available related to low temperature, medium temperature, high temperature and very high temperature applications, to consider different emission systems, i.e., underfloor system, fan coil system, radiators, and high temperature radiators. To define the inlet water temperature, a maximum temperature difference between inlet and outlet temperatures (\Delta T\text{max}) is calculated by Equation 2 as function of the outlet water temperature (T_{\text{w-out}}) [9]. The Standard proposes a calculation method for the SGUE based on the bin method, as for Equation 3, considering the GUE at different load ratios. The partial load ratio (PLR) is calculated as function of the design temperature and the water outlet temperature (T_j) (see Equation 4) assuming that the heating demand of a building decreases linearly with the outdoor air temperature and it is zero when the outdoor air temperature is 16 °C. In this paper, the average climate (T\text{design} = -10 °C) and the high temperature climatic curve, with 55 °C as supply water temperature at design condition (for radiators), have been selected to optimize the initial charge of ammonia and water. For the average climate, the Standard prescribes to measure the GUE under the working conditions in Table 1 for the high temperature climatic curve. Moreover, the seasonal efficiency of the heat pump to deal with the very high temperature application (see Table 2) has also been tested.

\[
GUE = \frac{\dot{Q}_{\text{cond}} + \dot{Q}_{\text{abs}} + \dot{Q}_{\text{rec}} + \dot{Q}_{\text{fhx}}}{Q_{\text{gas}}} 
\]

\[
\Delta T\text{max} = 7 + \frac{T_{\text{w-out}} - 35}{30} \times 10 \tag{2}
\]

\[
SGUE = \frac{\sum_{j=1}^{N} h_j \times \dot{Q}_n(T_j)}{\sum_{j=1}^{N} h_j \times GUE(T_j)} \tag{3}
\]

\[
PRL(\%) = \frac{T_j - 16}{T_{\text{design}} - 16} \times 100 \tag{4}
\]

4. Results

In this section, the experimental results at different working conditions are introduced. Moreover, the additional flexibility provided by variable restrictors is shown.

4.1. Use of valves to control the cycle

The gas-driven absorption heat pump prototype under analysis has variable restrictors for both the solution (RES 1) and the refrigerant (RES 2) branches (see Figure 1). The variable restrictor RES 2 provides the possibility to optimize the evaporation temperature defined as the inlet temperature at the evaporator (point 16), while RES 1 provides the possibility to optimize the temperature at the bottom of the generator.

Figure 3 shows the evaporation temperature variation due to actions on the RES 2 valve. Increasing the aperture of the valve, the evaporator pressure and temperature increase (from point A to point D). This is achieved thanks to an increase of the refrigerant mass flow rate, which reduces the amount of liquid ammonia stored in the receiver and make it available to the thermodynamic cycle. This is normally associated to a lower thermal lift and higher concentration of the rich solution, both beneficial for the efficiency. The higher efficiency is visible from the increase of the difference between inlet and outlet temperatures of the brine circuit. However, when the aperture of RES 2 exceeds its optimal point, the difference between the evaporator temperature and the brine temperature decreases, causing a partial evaporation, which results in the flooding of the evaporator (point E). This phenomenon reduces the heat exchange with the low temperature source and the outlet evaporator temperature decreases. For the selected cycle layout, with the ASV between the condenser and the RHX, a flooded evaporator increases the heat transfer process in the RHX, leading to a higher degree of subcooling in the refrigerant entering the expansion valve. This further increase the flow rate, leading to a deterioration of the performances at the beginning and an interruption of the thermodynamic cycle if this condition persists. To restore a complete evaporation, RES 2 is closed (point F) reducing the refrigerant mass flow rate. As the refrigerant is stored in the ASV and the evaporator temperature decreases, leading to a complete evaporation of the liquid in the evaporator. Thus, the installation of the ASV before the evaporator on the one hand assures the possibility to control the evaporation pressure to optimize the performances, on the other it is required an active control on the restrictor RES 2 to avoid the flooding of the evaporator.

![Figure 3: Effect of a variable refrigerant restrictor on the evaporation temperature](image-url)
Once the control is tuned, the heat pump can operate smoothly and in a stable way under steady-state conditions. This is shown in Figure 4, where inlet and outlet temperatures for both the brine and the refrigerant are reported for a full load (10 kW of heating capacity) condition. The oscillation of all the temperatures is lower than 1 °C with the inlet brine temperature coming from the experimental set-up as the less stable. As for the evaporation temperature, the outlet water temperature variation is lower than 1 °C for the same test (see Figure 5), while the oscillation of the temperature of the weak solution (low ammonia mass fraction) is just slightly higher than 1 °C.

![Figure 4: Experimental evaporation and brine temperatures](image)

4.2. Seasonal performances

The seasonal performance is calculated in compliance to EN 12309 for the average climate condition, with design temperature of -10 °C, and for the high and very high temperature applications, the former with a nominal supply temperature of 55 °C, the latter with 65 °C, as for the test conditions reported in Table 1 and Table 2. The actual test conditions for the high temperature application and the measured GUE are reported in Table 3. The resulting Seasonal Gas Utilization Efficiency is 1.58 on a net calorific value basis or 1.42 on the gross calorific value. Table 4 shows the same information for the very high temperature application. Due to the higher supply temperature, the GUEs are lower than for the high temperature application and so is the SGUE, for which a value of 1.51 based on the net calorific value is achieved.

The climatic room where all the tests have been performed has been kept at 20°C, assuming an indoor installation of the GHP.

It must be mentioned that the amount and the average mass fraction of the water-ammonia solution have been optimized for the high temperature application. One of the constrains that have been applied when designing the heat pump and setting the water-ammonia content and mass fraction is that the maximum temperature at the base of the generator should not exceed 180 °C to avoid corrosion issues and assure reliable and safe operation over the entire lifetime. However, given the water-ammonia solution charge set for the high
temperature application, in Condition #1 of the very high temperature climatic curve, the maximum temperature of the generator is reached in correspondence of a heating capacity of 9 kW. Thus, for this application, with the current settings, the design capacity of the heat pumps is reduced from 10 kW to 9 kW, with the part load conditions recalculated accordingly. However, 10 kW could be reached also for the very high temperature application by properly tuning the solution mass fraction and, if needed, changing the RES 1 to increase the maximum flow rate allowed in the weak solution branch.

4.3. Full load conditions and low temperature conditions

The heat pump has been tested in different full load conditions as shown in Table 5. The first experimental test (Test #1) has an inlet water temperature of 30 °C and an outlet temperature of 40 °C. This condition is important to test that the compact generator works properly. In fact, the combination of relatively low supply water temperature, which is translated in a reduced high pressure (P_high), and the high natural gas heat input, provides an intense boiling process. It may cause the drag of the liquid ammonia-water solution by the vapor stream from the upper part of the generator to the condenser, reducing the performances. In this case, the described phenomenon is not present and a remarkable performance of 1.541 is achieved, with an inlet brine temperature of 0 °C. Then, additional tests are performed increasing the return water temperature, while maintaining the same temperature difference between inlet and outlet water (10 °C). In Test #2, where both inlet and outlet water temperatures were increased by 10 °C compared to Test #1, a decrease of the GUE is measured. Further temperature increase was performed for Test #3 and Test #4 in Table 5, reaching a supply temperature of 65 °C. As expected, the efficiency of the heat pump decreases as the supply temperature is increases, even if the achieved GUE (1.361 with 60 °C as supply water temperature and 1.323 with 65 °C) underline the capability of the heat pump to operate efficiently also at high lift conditions, e.g. when producing domestic hot water (DHW) or when coupled with heating systems that need supply water temperatures higher than the ones considered by the Standard [9]. As additional condition, similar to the ones for domestic hot water production, a higher supply water temperature of 70 °C was set in Test #5, using 15 °C as temperature...
difference between supply and return water. Even in this unfavorable condition for heat pumps, the prototype provides an interesting GUE of 1.295, which is about 30% higher than a condensing boiler operating under the same conditions. Since DHW production is usually needed also during mid-seasons and summer, two tests at higher air temperatures (12 °C and 22 °C respectively) are performed. 40/50 °C and 50/60 °C have been used as return and supply water temperatures, simulating two different phases of the charging of the DHW tank. It can be noticed that at higher air temperatures, the low pressure (P<sub>low</sub>) is higher (4-7 bar), but the thermodynamic cycle works flawlessly, assuring a gas utilization efficiency between 1.45 and 1.60 as shown by Test #6, #7, #8 and #9 in Table 5.

</table>

Moreover, the heat pump has been tested at low air temperature, to verify the operation and the efficiency at cold climatic conditions. Test #10 (see Table 6) shows that the heat pump still achieves a GUE of 1.483 with an inlet brine temperature of -16 °C and a supply water temperature of 35 °C, a condition which corresponds to a system with underfloor heating operating at about -14 °C of outdoor air temperature, usually very severe for most of the heat pumps. The minimum temperature considered by the European Standard for a cold climate is -22 °C [9]. This temperature cannot be reached by the calorimeter where the heat pump has been tested in brine-water configuration, due to freezing protection of the glycol circuit. However, to simulate a possible working condition at -22 °C of air temperature, the evaporation temperature was reduced to -30 °C acting on the variable valve on the refrigerant branch (see Test #12 in Table 6). This process replicates very well the operation of a heat pump at -22 °C, except for the temperature of the refrigerant leaving the evaporator. However, this temperature difference has very limited impact in terms of power due to the shape of the enthalpy-temperature curve of the refrigerant in the last phase of the evaporation process. The achieved GUE of 1.429 is remarkable and indicates that the heat pump can work with high efficiency also in the design conditions of the cold climate. Test#12 is performed at higher water and air temperatures where a GUE of 1.309 is obtained with a supply water temperature of 55 °C and an inlet brine temperature of -16 °C.

5. Conclusions

This work presented the development of a 10 kW single effect ammonia-water driven absorption heat pump and its laboratory performances under various relevant operating conditions. The peculiarities of this prototype are the innovative layout of the generator (under patents pending), the use of variable restrictors for both the solution and refrigerant branches, and the use of commercial plate heat exchangers.

The role of the variable restrictors to optimize the low pressure and the efficiency of the cycle was presented, besides a proof of the stable operation of the heat pump. The efficiency of the heat pump was tested in laboratory conditions on a brine-to-water prototype, taking care of simulating the presence of an outdoor air heat exchanger by means of proper settings of the inlet brine temperatures. A remarkable Seasonal Gas Utilization Efficiency equal to 1.58 was achieved in accordance with the European Standard EN 12309 for the high temperature application, with nominal supply temperature of 55 °C, and the average climate condition. Furthermore, a SGUE of 1.51 was reached for the very high temperature application, with 65 °C of nominal supply temperature. Then, the GHP has been tested also in other relevant conditions which demonstrated its capability to provide hot water up to 70 °C and to operate at an equivalent air temperature of -22 °C.

Compactness, high efficiency in all the operation and the flexibility to operate over the wide range of tested conditions demonstrate that the developed heat pump could represent an interesting and reliable solution for space heating and domestic hot water production in residential application.

Abstract

This paper provides a systematic review of mathematical models for simultaneous heat and mass transfer process modeling. Models were categorized into lumped models, zone models, and numerical methods with information on their computation costs and accuracies. Observing the reviewed models, it was revealed that iterative calculations and complicated analytical corrections on fin efficiency are necessary under fully wet conditions. To provide the explicit calculation for the dehumidification process for micro-channel heat exchangers, regression techniques, like Multiple Polynomial Regression, are applied to modify the effectiveness-NTU method. The improved regression models show advances in accuracy and usability within the common geometries and conditions for heat pump applications.

1. Introduction

In recent years, the mathematical models for the pure heat transfer process in heat exchangers are well developed. Classic models like Logarithm Mean Temperature Difference (LMTD) method and the effectiveness-NTU method provide a reasonable level of accuracy under fully dry conditions. However, once dehumidification occurs in the cooling process, the prediction of simultaneous heat and mass transfer becomes complicated while both sensible and latent capacity needs to be calculated. For instance, the traditional LMTD method is unable to calculate the latent heat during the condensation of humid air. To properly model this dehumidification process, various modified models were proposed, which are worth a systematic review to foster further studies. Hence, this article comprehensively summarizes current mathematical models for the dehumidification process within heat exchangers in section 2. The review reveals that iterative calculation and complicated analytical correction on fin efficiencies are contained in most of those models to approach reasonable accuracy, which shows little practical usability for engineers. To tackle this problem, regression-based modified explicit models, for Microchannel Heat Exchangers (MCHXs), are proposed in section 3. Finally, the proposed regression models are assessed and compared with traditional methods in section 4.

2. Review of mathematical models

For the modeling of simultaneous heat and mass transfer processes, [1] and [2] summarized several methods for the dehumidifying process of fin-and-tube heat exchangers, providing comprehensive reviews on this topic. Further, [3] gives a general framework for the categorization of those models. The existing models for simultaneous heat and mass transfer prediction of heat exchangers could be generally classified into three types: the lumped model, distributed parameter model (multi-node/numerical model), and the zone model. The
lumped models compute the cooling performance based on the lumped parameters, with the advantage of fast calculation. However, the details of the mass transfer process, such as the wetting area along the fin, are not considered. To account for detailed heat and mass transfer processes and approach higher prediction accuracy, numerical models can be used. Those methods tend to compute the cooling capacity of heat exchangers cell by cell. Each cell is treated with lumped parameters. Nevertheless, those methods are usually computationally expensive and hence lack practicality for fast performance predictions. The zone model slots in between lumped models and numerical approaches in terms of accuracy and computational cost. Those approaches divide the heat exchangers into different portions. Each portion is considered a lumped model with distinctive working circumstances. With various partitioning procedures, the calculation accuracy would be improved compared with the overall lumped models, yet the time for computation is reasonable in terms of the numerical methods. Based on these categories, the mainstream methods would be further introduced in the following section.

2.1. Lumped models

Based on the formulation of different models, the lumped models could be further summarized into temperature difference-based, effectiveness-based, and enthalpy difference-based models.

2.1.1. Temperature difference-based models

All the temperature difference-based methods originate from the classic LMTD method. However, modifications have to be introduced since the above equation cannot predict the latent heat. According to [2], the simplest way to modify is by introducing an empirical factor. The empirical factor is expressed as

\[ \xi = \frac{i_{a,i} - i_{a,o}}{C_{pa} \cdot (T_{a,i} - T_{a,o})} \] (1)

The empirical factor transfers the temperature difference into the enthalpy difference to cover the evaluation of latent heat. Although this is a quick method, the empirical factor may vary along the dehumidification process and a large deviation may be caused by that. Concerning that, McQuiston [4] introduced the condensation factor into the overall heat transfer coefficient with a similar idea. The condensation factor is defined as

\[ C_f = \frac{W_a - W_{sat,aw}}{T_a - T_w} \] (2)

The essence of this modification is unifying the sensible heat term and latent heat term in the energy equation and expressing sensible and latent heat by temperature difference.

Several publications modify the temperature difference as well. To reduce the complexity brought by the condensation, the researchers transfer the dehumidification into the equivalent dry cooling process based on the constant enthalpy difference [5], which is named as Equivalent Dry-bulb Temperature (EDT) method. In detail, the dehumidification process 1-2 in the following figure is converted into the 1e-2e process, which owns the constant humidity ratio. The transfer process is shown in Figure 1.
Figure 1 psychrometric charts for illustrating the assumptions of WTD method and the equivalent process of EDT method

Mathematically, the transformation of the heat transfer equation is

\[ Q_t = \frac{h_{\text{wet}} A}{C_{pa}} \left( \frac{i_1 + i_2}{2} - i_w \right) = \frac{h_{\text{wet}} A}{C_{pa}} \left( \frac{T_1^e + T_2^e}{2} - T_w \right) \approx \frac{h_{\text{wet}} A}{C_{pa}} \left( T_{\text{pr},i} - T_{\text{sc},w} \right) \]

The other similar approach, namely Wet-bulb Temperature Difference (WTD) method [6]. This method was originally proposed for the indirect evaporative heat exchangers, aiming to transfer the enthalpy potential on the side of secondary air into the wet-bulb temperature difference. Considering point 1 in Figure 1 as the inlet of secondary air and point 2 as the outlet, those blue lines schematically exhibit this transformation. This method is based on two assumptions. The first is the linear variation assumption between saturated enthalpy difference and wet-bulb difference (shown as Eq.(4)).

\[ K = \frac{\Delta i}{\Delta T_{wb}} \]  

The other one is assuming the lines 1’ 2’ and 1’3 in Figure 1 share the same value of K to simplify the derivation. Based on those two assumptions, the total heat transfer rate, for a parallel-flow configuration, is modified as

\[ Q_t = U_{\text{WTD}} A \left( T_{\text{pr},i} - T_{\text{sc},w} \right) - \left( T_{\text{pr},o} - T_{\text{sc},w} \right) \ln \frac{T_{\text{pr},i} - T_{\text{sc},w}}{T_{\text{pr},o} - T_{\text{sc},w}} \]

Even though this approach is launched from air-to-air evaporators, the air-to-coolant heat exchangers could also use the same idea to rewrite the air-side transfer equation and re-derive Eq. (5) correspondingly.

2.1.2. Effectiveness-based models

As a classic predicting method, Braun[7] stated the effectiveness-NTU method for predicting fully dry conditions,

\[ Q_d = \varepsilon_d \dot{m}_a C_{pa} \left( T_{a,i} - T_{w,i} \right) \]

While under fully wet conditions, the total heat transfer rate is calculated by the enthalpy potential,

\[ Q_t = \varepsilon_{\text{wet}} \dot{m}_a (i_{a,i} - i_{s,w,i}) \]

The effectiveness in Eq. (6) and Eq. (7) is varied in different cases since it is a function of NTU, configurations of heat exchangers, etc. Hence, several basic derivations for effectiveness in different flow
arrangements under fully dry conditions are given by [8] and properly summarized in [9]. Additionally, to facilitate the use of effectiveness, some scholars also put efforts into simplifying the forms of effectiveness through a linear approximation between effectiveness and heat capacity rate ratio [10].

2.1.3. Enthalpy difference-based models

The classic LMED method for the dehumidifying condition was mentioned in several publications [11]–[13]. For instance, the cooling performance for Fin-and-Tube Heat Exchangers (FTHE), using LMED, is calculated as [2]

\[ Q_t = U_{LMED} A_{total} \Delta t_{im} \]  

\[ \frac{1}{U_{LMED}} = b'_w A_t + b'_p A_t \ln \left( \frac{D_{out}}{D_{in}} \right) + A_t \eta \left( \frac{A_{w,in}}{b_{wp}} + \frac{\eta_{f, wet} A_f}{b_{wf}} \right) \]

The \( b'_w, b'_p, b_{wp}, b_{wf} \) represent the linear coefficients between saturated enthalpy differences and temperature differences, normally iterative calculations are needed to obtain accurate values. Detailed calculation procedures are given in [11]. According to Xia et al [14], the above LMED expression assumes the Lewis number as unity, which may cause deviations. Therefore, they fundamentally re-formulated the LMTD method to adapt the non-unity cases.

2.2. Zone models

As mentioned before, the zone models are mainly built on the concept of effectiveness and the major discrepancy is in the wet-dry boundary identification. For instance, [15] re-derived the correlations of effectiveness and NTU for counter-flow DX evaporators. The new correlations are integrated into the dry or wet area under partially wet conditions. Therefore, with the additional constraint from the dew point temperature of inlet air when computing the position of the boundary, the equation set can be closed and the areas of wet and dry could be obtained using those re-derived correlations.

Except for the above methods, another proposed explicit zone model is called Equivalent-Capacitance Approach (ECA) [16]. They found an alternative form for the LTMD method and it could avoid iterative calculation without introducing any further assumptions. Utilizing explicit expressions, they considered the two critical conditions, the just-dry-condition and the just-wet condition for cooling coils [17]. With the energy balances and the assumption of the surface temperature at the boundary is equivalent to the dew point temperature of inlet air, the critical coolant temperatures could be obtained. Comparing the two critical inlet refrigerant temperatures at just-dry-condition and just-wet-condition with actual inlet coolant temperature, the coil could be explicitly decided whether it is the fully wet, partially wet, or fully dry mode. Meanwhile, to partition the dry region into partially wet conditions, they formed an empirical correlation to maintain the explicit calculation.

Except for segmenting the heat exchangers from the airside, due to the phase change of the coolant, some publications proposed methods to separate the sub-cooling, saturation, and superheated regions on the refrigerant side. [18] developed the explicit methods of identifying those three portions through the calculation of volume fraction corresponding to the condensers, evaporators, and air coolers. In addition, [19] further divided the saturation region into region 1 and region 2, which was decided from the experiments. With the other two regions, the paper suggests a separate calculation for each portion through the effectiveness-NTU method and energy conservation equations and iteratively repeats the calculation process until the entire system meets the energy balance.

2.3. Numerical models

The numerical methods indicate the procedure that divides the heat exchangers into a large number of small cells and calculates them independently with basic governing equations. The numerical methods own high flexibility and accuracy on simulations, with the drawback of high computational expense. However, some numerical models would introduce some lumped parameters, such as the fin efficiency, to reduce the calculation time while maintaining reasonable accuracy, which is summarized as the semi-numerical models.
2.3.1. Semi-numerical models

The semi-numerical models introduced in this section indicate the methods that separate the entire heat exchangers into various segments and each segment could be considered as a small independent heat exchanger and is evaluated by lumped parameters. One representative semi-numerical model would be the Finite-Circular Fin Method (FCFM). FCFM originated from [20], they tend to evaluate the dehumidifying process of fin-and-tube heat exchangers segment-by-segment and each segment is equivalently considered as a fraction of a coil with a circular fin. The cooling performance is calculated by lumped LMED method, mentioned in section 2.1.2.

Consequently, they extend this method into the fully dry condition [21]. Distinguishing from the fully wet mode, the actual temperature difference is used. Noticing that the fin efficiency used in FCFM for the equivalent circular fin is derived in [22], for both fully dry and fully wet circumstances. In 2008, they added the evaluation to the partially wet condition using FCFM [23], a complicated analytical circular fin efficiency for partially wet conditions formulated by them. Later, as a comparison, FCFM was combined with the aforementioned EDT method to perform the calculation [24]. It was found that the FCFM based on the EDT method shows higher heat and mass transfer characteristics.

[25] also proposed the element-based approach according to the effectiveness-NTU method. It divides the cross-flow heat exchangers into many tiny elements. Each element is calculated independently. This discretizing method would provide higher simulation flexibility compared with the FCFM method.

2.3.2. Numerical models

To eliminate the use of fin efficiency in semi-numerical models, the grids on the fins are generated and each grid is calculated by basic governing equations. Based on this concept, a straightforward numerical method, named as Semi-explicit Method for Wall Temperature Linked Equations (SEWTLE), is proposed [26]. To provide a general numerical approach for any heat exchangers with complex geometry, this method focuses on describing the heat transfer during fluid cells (air cells or refrigerant cells) and wall cells (fin cells or tube wall cells). The governing equations are

\[ \dot{m}_{\text{flu}} c_{p,\text{flu}} dT_{\text{flu}} = \sum_{j=1}^{n} U_{\text{local}}(T_{\text{w,cell}} - T_{f})dA_{\text{cell}} \]  \hspace{1cm} (10.)

\( n \) represents the number of wall cells surrounding the fluid cells. The heat conduction along the wall cells by the two-dimension Laplace equation

\[ \nabla (k_{\text{local}} \nabla T_{\text{w,cell}}) + \sum_{l=1}^{2} U_{\text{local}}(T_{\text{w,cell}} - T_{f})dA_{\text{cell}} = 0 \]  \hspace{1cm} (11.)

Eq. (10) could solve the fluid temperatures based on adjacent wall cell temperatures and Eq. (11) could obtain the wall cell temperatures based on neighboring temperatures of wall cells and fluid cells. Therefore, an iterative calculation would be performed once initial guess values are given to wall cells.

However, the mass transfer prediction for the dehumidifying condition was missed in SEWTLE. Therefore, [27] extend the application range of the original SEWTLE method into the fully wet condition and re-named it Fin2D-W. Further, the superheated region on the coolant side was also concerned in later research [28]. However, due to the heavy computation issue of this method, they applied the Fin theory on the fin cells to ease the computation process and therefore developed a new model called Fin2B-MB [29]. According to the authors, the introduction of fin theories would make the model overpredict the latent heat transfer rate by about 2%, and underpredict the sensible heat transfer rate by 4%.

Another constraint of the SEWTLE is its inconvenience in evaluating the irregular geometry boundary, such as the edge of holes on the fin. To improve the model feasibility on this issue, [30] mentioned a 2D model, which introduced several coefficients for irregular grids and changed the discretizing form of the 2D Laplace equation, making it could express irregular grids at boundaries.

3. Regression model development

Except for those models derived from classic methods, statistical tools also could be used for the predictions of the thermal behavior of heat exchangers. According to [31], several types of techniques are widely applied for the statistical modeling of cooling systems, including the Artificial Neuron Network (ANN), Genetic Programming (GA), Multiple Linear Regression (MPR), etc. [32] specifically pointed out the basic regression
analysis that can be used, such as the linear/nonlinear regression, the multiple polynomial regression, and the stepwise regression, etc. Further, they gave a representative example of utilizing the MPR analysis on the cooling system. In this case, to maintain acceptable model accuracy, they chose the 8th degree during the regression, which causes 494 terms in the model. It is believed that the usability of this model is reduced by the enormous amount of terms. As a comparison, several studies developed regression models with fewer terms, yet fewer input variables [33]–[35]. In regard, another type of strategy to perform the regression is integrating heat transfer equations. For instance, combining several basic governing equations in non-dimensional forms, [36] proposed simpler performance correlations for indirect evaporative heat exchangers, expressed by Eq. (12).

\[ T_{c,o} = \psi \cdot \Pi_1^a \cdot \Pi_2^b \cdot \Pi_3^c \]  

(12)

\[ \psi, a, b, c \] are empirical coefficients and \( \Pi_1, \Pi_2, \Pi_3 \) are the derived dimensionless parameters.

This type of methodology can be also utilized in the present study. In Section 2, it becomes evident that the majority of dehumidification models require iterative calculations, which increases the computational load for real-time simulation of thermodynamic cycle systems. Additionally, the fin efficiency, which is formulated based on rectangular fin geometry, cannot perfectly suit MCHX due to the assumption of the adiabatic boundary at the middle height of the fin. As result, it causes a deviation in the prediction of heat capacity under both fully wet and dry conditions. To address the raised computational load in fully wet conditions and the accuracy limitations brought about by analytical fin efficiency, a regression-based modification has been made to the explicit effectiveness model under fully wet/dry conditions for two-phase refrigerant in this section. The regression is based on the dataset generated by the numerical model Fin2D-W mentioned in section 2.3.2. The explicit effectiveness-based models for the fully wet and dry conditions are stated in section 3.1 and section 3.2 respectively. In section 3.3, the selected regression variables and corresponding ranges are described to elaborate on the application range of the proposed model.

3.1. Explicit model for fully dry condition

For the pure heat transfer process of MCHX, the classic effectiveness-NTU model is used. With two-phase refrigerant, the effectiveness is described as

\[ \varepsilon = 1 - \exp(-NTU_t) \]  

(12.)

where

\[ C_r = \frac{C_{\text{min}}}{C_{\text{max}}} \]

\[ NTU_t = \frac{U_t A_t}{\dot{m}_a C_p a} \]

\[ U_t = \frac{1}{\left( \frac{t_f}{t_{w-f}} \right) \left( \frac{A_t}{A_{f,t}} \right) + \frac{1}{\eta_{s,f,d} b_{a}}} \]

The overall surface efficiency is calculated as

\[ \eta_{s,f,d} = 1 - \frac{A_{f,t}}{A_t} (1 - \eta_{f,d}) \]  

(13.)

Therefore the \( Q_t \) is calculated by

\[ Q_t = \varepsilon d \dot{m}_a C_p a (T_{e,i} - T_{a,i}) \]  

(14.)

To improve the prediction accuracy, efficiency is the regression objective so that the temperature profile along the fin can be better described within the selected variable ranges.

3.2. Explicit model for fully wet condition

To perform an explicit calculation procedure for fully wet conditions, the expression for total heat transfer rate is re-derived as Eq. (15).
\[ Q_t = \varepsilon_m \dot{m}_a (i_{a,i} - i_{s,r}) \]  

where

\[ \varepsilon_m = \frac{1}{1 + \frac{\varepsilon}{\dot{m}_a c_{pa}}} \]

\[ \varepsilon = \left(1 - \exp \left(-\frac{\alpha \eta_{sf,wet} A_o}{\dot{m}_a c_{pa}}\right)\right) \]

\[ \eta_{sf,wet} = 1 - \frac{A_f \varepsilon}{A_t} (1 - \eta_{f,wet}) \]

\[ c_s = \left(\frac{i_{sat,f} - i_{sat,r,i}}{T_w - T_r}\right) \]

And the sensible heat transfer is obtained by Eq. (16).

\[ Q_s = \left(1 - \exp \left(-\frac{\alpha \eta_{sf,wet} A_o}{\dot{m}_a c_{pa}}\right)\right) \dot{m}_a c_{pa} (T_{a,i} - T_f) \]  

Naturally, to formulate the explicit calculation process, \( c_s \) has to be regressed based on the input parameters. To provide sufficiently accurate \( c_s \), the MPR technique is selected. In addition, to describe the enthalpy profile and temperature profile more accurately, \( \eta_f \) used in Eq. (15) for the calculation of \( Q_t \) and \( \eta_f \) used in Eq. (16) for the calculation of \( Q_s \) are independently regressed. The regression results are exhibited in section 3.4. Overall, the explicit calculation procedure is (i) calculate the \( Q_t \) by Eq. (16), with regressed \( c_s \) and \( \eta_{f,wet} \) for total heat transfer rate, (ii) calculate the tube wall temperature by Eq. (17), (iii) lastly calculate the \( Q_s \) by Eq. (16), with the regressed fin efficiency \( \eta_{f,wet} \) for the calculation of \( Q_s \).

\[ T_w = \frac{Q_t}{h_e A_t} + T_{ref} \]  

3.3. Selection of variables and ranges

To cover most of the influential input variables, nine inputs are selected to design the experiments for dry conditions and ten variables for wet conditions. Selected variables include the mass flow rate of coolant \( \dot{m}_a \), the air velocity \( v_a \), the inlet air temperature \( T_{a,i} \), the inlet refrigerant temperature \( T_{r,i} \), the Relative humidity of inlet air RH, the fin depth \( L_f \) and the fin height \( H_f \), the Air-side Heat Transfer Coefficient (AHTC), expressed by \( h_a \), Refrigerant-side Heat Transfer Coefficient (RHTC), expressed by \( h_c \) and the half spacing of the MCHX is denoted as \( h_s \). All the selected variables are illustrated in Figure 2(a). The input variable RH is ignored under fully dry conditions.

Due to the substantial time cost of the Fin2D-W model, A 5-level 1/8 fractional factorial circumscribed Central Composite Design (CCD) is utilized to minimize the simulation time and optimize the regression results. The travel distance \( \alpha \) between the axial point and central point is set at the value of 3.3636. 147 experiments are generated for dry condition simulation and 149 cases are generated for fully wet conditions. The relations between coded levels and actual levels, as well as selected input variables and corresponding ranges, are listed in Table 1. The value of the AHTC for each case is determined by the simple heat transfer correlation form provided by Wang and Chang [38], which is shown as

\[ j = 0.425 Re \epsilon^{-0.496} \]  

Since the prediction results of Eq. (18) are more moderate compared with the final equation in [38] and the correlation for plain fins provided by [39], meaning a wider range of fin geometry could be represented by the prediction. In terms of the RHTC, it is determined based on [40] for two-phase refrigeration flow boiling and based on [41] for condensing refrigerant flow. Moreover, to extend the range of AHTC and RHTC that contains in this regression, coefficients between 0.5-1.5 are multiplied before they are used in the calculation, which is
explained by Eq. (19) and (20). In other words, all the values of AHTC and RHTC randomly fluctuated by about ±50%. Those coefficients of AHTC and RHTC for cases are shown in Table 1.

\[
h_c' = C_{RHTC} \times h_c \\
h_a' = C_{AHTC} \times h_a
\]

| \(T_{a,i}\)  | \(K\) | 303.15 | 305.18 | 308.15 | 311.12 | 313.15 |

Meanwhile, the test dataset, for the validation of regression models, is generated randomly within the ranges listed in Table 1. 24 cases for the test dataset are picked, as roughly 20% of the training dataset for both dry and fully wet conditions.

4. Result and discussion

In this section, the regression results are listed, and the performance concerning the calculation time and prediction accuracy are elaborated.

4.1. Regression results

(a) Fully wet conditions

The wet fin efficiency \(\eta_{Q_t}\) used in the calculation of \(Q_t\) is obtained by Eq. (47)

\[
\eta_{Q_t} = \eta_{wet}^{\mu_t}
\]

where

\[
\eta_{wet} = \frac{\tanh(mH_f)}{mH_f}
\]

\[
m = \sqrt{\frac{2.1493\alpha}{k_wt_f}}
\]
\[ \mu_1 = 1.7290 \xi_1 + 0.2301 \xi_1^2 \]

\[ \xi_1 = \left( \frac{\alpha_w}{\alpha_l} \right)^{0.0365} \left( \frac{H_f}{L_f} \right)^{-0.1418} \left( \frac{h}{h_s} \right)^{0.1594} \left( \frac{T_o}{T_r} \right)^{-0.3249} \left( \frac{\rho_a V_a H_f h_s}{m_r} \right)^{-0.0331} \]

It should be noted that the regression basis \( \eta_{wet} \), which pertains to fully wet conditions, maintains a similar form to the analytical solution under dry conditions due to its superior predictive performance when compared to other forms. In terms of the wet fin efficiency used in the calculation of \( Q_s \),

\[ \eta_{Qs} = \eta_{wet} \]

where

\[ \mu_2 = -0.8904 \xi_2 + 2.2120 \xi_2^2 \]

\[ \xi_2 = \left( \frac{H_f}{L_f} \right)^{-0.0921} \left( \frac{h}{h_s} \right)^{0.0742} \left( \frac{T_o}{T_r} \right)^{2.2396} \left( \frac{\rho_a V_a H_f h_s}{m_r} \right)^{-0.0138} \]

The regression results of \( c_s \) that are regressed in the form of MPR are exhibited in the Appendix.

(b) Fully dry conditions

The analytical dry efficiency expression is still maintained as Eq. (23).

\[ \eta_d = \frac{\tanh \left( \frac{m H_f}{2} \right)}{m H_f} \]

\[ m = \frac{2 \alpha_w}{k_w t_f} \]

Yet the modified fin efficiency for the single-phase refrigerant is shown as

\[ \eta_{m,d} = \eta_{d}^{\mu_3} \]

Meanwhile, the modifications that apply to the two-phase flow are exhibited as follows.

\[ \mu_3 = 1.9307 \xi_2 + 2.2470 \xi_2^2 \]

where

\[ \xi_3 = \left( \frac{\alpha_w}{\alpha_l} \right)^{0.0670} \left( \frac{H_f}{L_f} \right)^{-0.3489} \left( \frac{h}{h_s} \right)^{0.1753} \left( \frac{T_o}{T_r} \right)^{1.4307} \left( \frac{\rho_a V_a H_f h_s}{m_r} \right)^{-0.1094} \]

4.2. Model assessment

The prediction performance is assessed based on two indexes, the Mean Absolute Error (MAE) and Maximum Error (ME) of training/test datasets, which are shown in Eq. (25) and (26). The performances are exhibited in Tables 2 and 3 for fully dry and fully wet conditions accordingly. Note that the single potential effectiveness-NTU model is used, which is stated in [33].

\[ \text{MAE} = \text{MEAN} \left( \frac{|Q_{num,i} - Q_i|}{Q_{num,i}} \right) \]

\[ \text{ME} = \text{MAX} \left( \frac{|Q_{num,i} - Q_i|}{Q_{num,i}} \right) \]

Based on the test results presented in Table 2, it is evident that the developed regression model exhibits advance in prediction accuracy for two-phase flow conditions. The MAE and ME are improved by 0.1% and 0.3%, respectively. The developed model also shows superior prediction accuracy for dehumidification processes in two-phase refrigerant conditions. For the three types of heat transfer rates, the developed model
shows the advances at both MAE and ME, where the prediction of the sensible heat transfer rate is improved the most. For the sensible heat transfer rate, the MAE is reduced by about 1.2%, while the ME is improved by about 3%.

Furthermore, the developed model exhibits a faster computational process compared to iterative effectiveness-NTU, as shown in Table 4. In a nutshell, the present model is roughly 3 times quicker on average in two-phase refrigerant conditions for calculating one case, compared to effectiveness-NTU. The data presented in Table 4 is gained from the first hundred cases in the training datasets.

### 5. Conclusions

This paper systematically reviews the mathematical models for the prediction of the dehumidification process. Three types of models are classified, and each has its characteristics of computational cost and accuracy. Based on the review models, it is found that most models in wet conditions require iteration computations and complicated correction on fin efficiency based on various geometries. To improve the usability of dehumidification prediction models, fully wet and fully dry explicit models for two-phase refrigerants are proposed based on the analytical effectiveness-NTU method. The regressions are carried out in a wide range of air and refrigerant side conditions, as well as commonly used geometric parameter ranges. Three main advantages of the proposed models are the explicit calculation for dehumidification calculation with improved accuracy as compared with traditional lumped models.

The research carried out here should benefit the academic and engineering communities with the need to conduct fast heat and mass transfer analysis for MCHX in heat pump applications. The regression methods presented here can be employed in the future as part of heat exchanger optimization studies for a wider range of conditions and geometries.

Achievement report of NEDO R&D Project on Innovative Thermal Management Materials and Technologies

Yoichi Fujita*, Tetsushiro Iwatsubo*

* Energy Conservation Technology Department, New Energy and Industrial Technology Development Organization (NEDO), 212-8554 Japan

Abstract

The importance of industrial heat pumps toward decarbonization has begun to be widely recognized worldwide. Japan has developed, and applied industrial heat pumps ahead in the world. This paper overviews the current technology and market status of industrial heat pumps in Japan. It reveals that heat-pumping technology has matured to some degree. However, it shows the importance of accelerating the adoption. This study also clarifies the issues for its widespread adoption by questionnaire survey and barrier analysis and discusses measures for the future.

Keywords: R&D Project; Thermal Management; Unutilized Thermal Energy; Industrial Heatpumps; High-temperature Heatpumps

1. Introduction

On October 2020, Japan declared that it would aim to realizing “carbon neutrality by 2050,” and in April 2021, Japan has also set a new target to reduce greenhouse gas emissions by 46% in FY 2030 from FY 2013 levels. Towards 2050, the new plan seeks to achieve energy transitions and decarbonization, considering the global momentum in this direction and in enforcement of the Paris Agreement, and to pursue all tenable options toward this end.

During Japan's energy distribution process, about 30% to 40% of primary energy, mainly fossil resources such as oil, coal, and natural gas, are lost when they are converted into electricity and fuel [1], and at the final consumption, and it is used only a small portion, so total 60% to 70% of primary energy is considered not to be used effectively but discarded as heat. Authors refer to such artificially discharged heat as “unutilized thermal energy,” and it is the key for realizing thorough energy efficiency to effectively reduce, reuse, and recycle this huge amount of unutilized thermal energy discharged into this environment, and it can be said to be a frontier.

Authors introduce an overview of a national R&D project “Research and Development Project for Innovative Thermal Management Materials and Technologies” which aims to realize thorough energy efficiency promoted by New Energy and Industrial Technology Development Organization (NEDO). Above all, they focus on R&Ds of new high-temperature heat pumps that make use of heat efficient in industrial fields by reusing unused thermal energy for process heating instead of boilers.

2. National R&D Project Overview

The goal of this project is to develop three Rs technology to effectively reduce (via insulation, thermal insulation, or heat storage), recover and reuse (via heat-pump technology), or recycle (via thermoelectric conversion or waste heat power generation) untapped thermal energy. The project also aims to develop basic crosscutting heat management technologies for effective reduction, recovery and reuse, or conversion of the
huge amount of unused heat released into the environment to achieve further energy conservation in the industrial, transportation, and consumer sectors.

Figure 1 shows Organizational chart of “Research and Development Project for Innovative Thermal Management Materials and Technologies”. The project had been executed under industry-academia collaboration of the Thermal Management Materials and Technology Research Association (TherMAT).

In this way, this R&D project is intended for a wide range, but here authors introduce an R&D on high-temperature heat pumps, which are the core of this R&D project and can show high energy efficiency effect.

Fig. 1. Organizational chart of “Research and Development Project for Innovative Thermal Management Materials and Technologies”

Figure 2-1 shows the estimated amounts of nationwide unutilized thermal energy, by sector and temperature based on the survey result from 1,273 factories of 15 industries. The nationwide estimation of the amount of unutilized thermal energy (exhausted as gas) was based on results of questionnaires, approximation calculated by the correlation between energy inputs to factories and unutilized thermal energy as exhaust gas by industry, and FY2015 energy consumption statistics of manufacturing industries. [2]

Figure 2-1: Estimation of amount of heat in exhaust gas from industry by temperature range
On the other hand, Figure 2-2 shows the estimated amounts of heat demand, by heat form and temperature based on the survey result from 1,155 factories of 15 industries. [3] This heat demand area below 200°C becomes 1250 PJ (= 347 TWh) and accounts for 28% of the total industrial heat demand. Another feature is that temperature distribution of exhaust heat and heat demand are overlapping each other.

As shown in Figure 2-2, main heat source is steam below 200°C and usually boilers using fossil resources are used as heat sources as steam for industrial heating applications, and unutilized thermal energy is discharged from each heating process. By reusing this waste heat as a heat source, it is expected to regenerate it to a higher temperature and replace the heat sources from conventional boilers with high-temperature heat pumps.

Figure 2-3 shows the graph picking up the heat demand of hot water and steam from Figure 2-2. The applicable potential of heat pump expands as its supply temperature rises. Although it is largest demand at 150°C to 200°C range, unfortunately there is no heat pump which can supply above 150°C.

In this project, it aims to develop high-temperature heat pumps which can supply high-temperature heat about from 160°C to 200°C with high efficiency (e.g. COP: 3.5 or higher), recovering from waste heat of 80°C or 100°C which is discarded from industrial manufacturing processes, and as the result of penetrating them as alternatives to steam boilers, can contribute to use primary energy efficiently and reduce CO2 emissions.

Figure 3 shows comparison of primary energy basis efficiency between boiler and high-temperature heat pump. Typical conventional heat systems supply steam by boiler with 90% of efficiency. On the contrary COP (Coefficient of Performance) of high-temperature heat pump reaches 3.5, and generation efficiency of thermal power plant is 45%. Therefore, total efficiency of high-temperature heat pump system reaches 158%, which is 1.75 times more efficient than conventional boiler system. It is expected that high-temperature heat pump will prevail by economical advantage.
3. Development of industrial high-efficiency and high-temperature heat pump capable of supplying maximum 200°C

3.1. Development target

In this project, Mayekawa Mfg. Co., Ltd. who is the member of TherMAT, is developing heat pump systems with having the target that can meet the supply temperature range up to 200°C and achieve COP: 3.5 or higher by heating from 80°C to 180°C. [4]

There are 2 type of high-temperature heat pump in accordance with heating methods. Type-1 is steam supply circulating type with small temperature glide by Vaper compression cycle as shown in Figure 4-1. There is constant temperature during heating process which water is changed phase to steam. It is difficult to generate above 150°C of steam with presently available refrigerant. Type-2 is thermal oil or air supply transient type with large temperature glide by trans critical cycle as shown in Figure 4-2. There is no constant temperature during heating process. It is possible to generate above 150°C with presently available refrigerant. Therefore, Type-2 was adopted to achieve 180°C for this development.

---

**Figure 3:** Comparison of efficiency between boiler and high-temperature heat pump

**Figure 4-1:** Type-1 Steam supply circulating type

**Figure 4-2:** Type-2 Thermal oil or air supply transient type
Figure 5 shows the flow diagram of the system. The system consists of heat exchangers, compressors, expansion valve and connecting pipes. The heat exchangers are an evaporator, a gas cooler, and a liquid-gas heat exchanger. Approximately 80°C of waste heat is extracted by the evaporator as the heat source to evaporate the refrigerant which is then compressed and heated to about 200°C in the compressor. The heating medium flowing through the gas cooler is thermal oil with flash point temperature of more than 250°C which is classified as nonhazardous material by the fire service act.

3-2. Development of compressor technology

To achieve the development target, it was necessary to develop an epoch-making compressor that had never existed before and to achieve the maximum operating temperatures of 200°C or higher. Due to the high operating temperatures, the conventional lubricating oil was difficult to use. Therefore, an oil-free centrifugal compressor with magnetic bearings is adopted. To improve efficiency, an optimally designed compressor rotor and a high-speed built-in motor are being used.

Magnetic bearings and built-in motors are one of the most important components in the development of this compressor. The magnetic bearings control the attractive force of the electromagnet and supports the rotating body in a non-contact manner. The built-in motor is located between the magnetic bearings at both ends. In consideration of the maximum operating temperature of 200°C, a three-phase induction motor with high heat resistance was adopted.

3-3. Development of the second prototype

NEDO had reported about 300kW of the first prototype which used R600 (n-butane) as refrigerant in the 13th IEA Heat Pump Conference 2020. [5] R600 which is a hydrocarbon-based refrigerant was adopted with a small GWP and high COP. However, R600 is a highly flammable and the test unit had to be enclosed in a casing to provide 24-hour ventilation and explosion-proof specifications. In recent years, it has become clear that new nonflammable low GWP refrigerants such as HFO (Hydro-fluoro-olefin) are available in the market and the rotation speed of the compressor is expected to be lower than that of R600 refrigerants. Therefore, HFO refrigerant is adopted for the second prototype. Table 1 and Figure 6 shows the main changes between the first prototype and the second prototype.

The second prototype comprises of two sets of compressors each with two stages, which makes it four stages compression compared with three stages compression of the first prototype according to fluid analysis result for different refrigerant. The two impellers being back-to-back structure was adopted with the second prototype to reduce thrust load of axial disk in comparison with the two impellers being same direction structure of the first set compressor of the first prototype.

The gas cooler with a capacity of 300 kW consists of two heat exchangers connected in parallel. The heating medium used is thermal oil and exchanges heat with the refrigerant in super critical state in trans critical cycle.

6
3-4. Next steps

Toward introduction of the heat pumps after the end of R&D, it would be one of most important initiatives to see the effect or value when they apply to actual heat utilization equipment in factories. Especially it will be even more difficult to conduct verification to grasp the energy efficiency effect in the actual environment using the existing systems. Therefore, authors will proceed with activities of model cases studies, assumed actual heat utilization facilities, and based on the results of this studies, calculation and quantitatively evaluation of the effect or value including energy efficiency, cost merit and heat pump system configuration post introduction. As the result of the activities, “visualization” of introduction effect will be progressed and it will be possible to share the installation image of heat pumps in industrial heating processes with customers, which will be able to lead to acceleration of the commercialization.

On this project, NEDO plans to construct equipment utilizing systems with high-temperature heat pumps including attached facilities, proceed with model case verifications that examine optimal applied processes and clarify economic effects, and studies on “visualization” of introduction effect. Through these activities, the newly developed industrial high-efficiency and high-temperature heat pumps will be properly arranged and used for process heating instead of boilers, thereby promoting energy efficiency in factories and contributing to solving energy and environmental problems in the future.

4. Conclusion

“Energy efficiency” is the primary expectation for the realization of “3E + S” (simultaneously achieving Energy Security, Economic Efficiency and Environment, with coming Safety always at first) in Japan and global carbon neutrality by 2050, but most of primary energy is still discharged as unutilized thermal energy without being effectively used, even though various measures have been taken so far. Among energy forms such as fuel, electricity, and hydrogen that are expected to be used in the future, the last remaining form is heat, and decarbonization of all sectors that use this heat can be the key to construct the sustainable recycling society.

Now all the relevant people are required to promote to implement technologies for effectively reducing or recovering a large amount of unutilized thermal energy discharged into the environment including high-temperature heat pumps, to the society with economic rationality, realize significant energy efficiency of the entire society and a “circular economy”; and there can be no doubt that this R&D project had been a driving force for it.

Development of dynamic model of variable refrigerant flow cooling system based on moving boundary method

Jeong Kuk Hong, Hongryul Joo, Min Soo Kim

Department of Mechanical Engineering, Seoul National University, Seoul 08826, Republic of Korea

Abstract

The use of variable refrigerant flow (VRF) cooling and heating systems is gradually expanding, but the development of system dynamic models for optimal operation and fault diagnosis is still in the research stage. Therefore, in this study, we tried to develop a dynamic model of the entire VRF system by modeling the heat exchanger using the moving boundary method. A dynamic model development method for heat exchangers, a receiver, and an accumulator with dynamic variables was presented. In addition, modelling method of shutdown and start-up process in indoor units was also presented. Based on these models, the entire VRF system model was completed by combining static models for components such as compressors. Combining the thermal zone model with the VRF system model, the indoor unit on/off operation of the VRF system was simulated for 2,400 s. The simulation results showed that the developed model simulated the actual VRF system similarly, although there were some errors. However, if the accuracy of the model is increased using actual experimental results in the future, it is expected that the developed model can be used to perform optimal control of the actual VRF system.

Keywords: Moving boundary method; Variable refrigerant flow; Transient model; Dynamic behavior; Digital twin

1. Introduction

The variable refrigerant flow (VRF) heating and cooling system has higher energy efficiency than duct systems, and it is easy to respond to individual indoor loads, so its market size is continuously increasing [1]. However, the optimal operation method according to changes in indoor load and operating conditions is still in the R&D stage.

Many researchers have struggled to find the optimal operation method of the VRF system. Yun et al. [2] developed a load responsive controller for the VRF system which control the evaporating temperature, showing that the new controller could reduce the annual cooling energy consumption by 14%. Moon et al. [3] developed two artificial neural network (ANN) model and two control algorithms for finding unoccupied period. Li et al. [4] proposed the ANN-based dynamic model for a direct expansion air conditioning system. They showed that the ANN-based model can control appropriately the compressor speed and supply fan speed without other logic.

There are many preceding studies, but in most cases, VRF system models depend on Big Data or utilize VRF system models of commercial programs. However, this method does not guarantee model accuracy for situations where data are not accumulated. Therefore, developing a simulation model that reflects the physical phenomena in the VRF system and using it for optimal control can be a versatile solution.

For this reason, in this study, dynamic model of the entire VRF system by modeling the heat exchanger using the moving boundary method is developed. Also, combining the thermal zone model with the VRF system model, the indoor unit on/off operation of the VRF system is simulated.

2. Model development

2.1. Heat exchanger

2.1.1. Refrigerant mass conservation equations

When modeled by the moving boundary method, the heat exchanger is divided into three regions: subcool, two-phase, and superheat region. In this study, each region was numbered as regions 1, 2, and 3 in order of distance from the heat exchanger inlet. The result of applying the refrigerant mass conservation equation for each region is shown in Eqns. (1)-(3).

\[
\begin{align*}
(p_1 - p_{12})L_1 + \left(\frac{\partial p_1}{\partial h_1}\right)_{h_1} + \frac{1}{2} \frac{\partial p_1}{\partial h_1} \left(\frac{dh_{12}}{dp}\right) + \frac{1}{2} \frac{\partial p_1}{\partial h_1} \left(\frac{dh_{12}}{dp}\right) + \frac{1}{2} \frac{\partial p_1}{\partial h_1} \left(\frac{dh_{12}}{dp}\right) + \frac{1}{2} \frac{\partial p_1}{\partial h_1} \left(\frac{dh_{12}}{dp}\right) = \frac{m_{in1} - m_{12}}{A} \quad (1)
\end{align*}
\]

\[
\begin{align*}
(p_{12} - p_{23})L_1 + \left[\gamma \rho_g + (1 - \gamma)\rho_f - \rho_{23}\right]L_2 + \left[\gamma \frac{\partial \rho_f}{\partial h} + (1 - \gamma) \frac{\partial \rho_f}{\partial h}\right] = \frac{m_{12} - m_{23}}{A} \quad (2)
\end{align*}
\]

\[
\begin{align*}
(p_{23} - p_3)L_1 + \left(\frac{\partial p_3}{\partial h_3}\right)_{h_3} + \frac{1}{2} \frac{\partial p_3}{\partial h_3} \left(\frac{dh_{23}}{dp}\right) + \frac{1}{2} \frac{\partial p_3}{\partial h_3} \left(\frac{dh_{23}}{dp}\right) + \frac{1}{2} \frac{\partial p_3}{\partial h_3} \left(\frac{dh_{23}}{dp}\right) + \frac{1}{2} \frac{\partial p_3}{\partial h_3} \left(\frac{dh_{23}}{dp}\right) + \frac{1}{2} \frac{\partial p_3}{\partial h_3} \left(\frac{dh_{23}}{dp}\right) = \frac{m_{23} - m_{out}}{A} \quad (3)
\end{align*}
\]

When a certain section disappears within the heat exchanger, the equation derived from that section is no longer applicable. In that case, when section 1 disappears, the equation \(m_{12} = m_{in1}\) can be applied instead, and when section 3 disappears, the equation \(m_{23} = m_{in3}\) can be applied instead.

2.1.2. Refrigerant energy conservation equations

\[
\begin{align*}
(p_1 h_1 - p_{12} h_{12})L_1 + \left(\frac{\partial p_1}{\partial h_1}\right)_{h_1} + \frac{1}{2} \frac{\partial p_1}{\partial h_1} \left(\frac{dh_{12}}{dp}\right) + \frac{1}{2} \frac{\partial p_1}{\partial h_1} \left(\frac{dh_{12}}{dp}\right) + \frac{1}{2} \frac{\partial p_1}{\partial h_1} \left(\frac{dh_{12}}{dp}\right) = \frac{m_{in1} h_{in} - m_{12} h_{12} + h_{12}}{A} \quad (4)
\end{align*}
\]

\[
\begin{align*}
(p_{12} h_{12} - p_{23} h_{23})L_1 + \left[\gamma \rho_g h_g + (1 - \gamma)\rho_f h_f - \rho_{23} h_{23}\right]L_2 + \left[\gamma \frac{\partial \rho_f}{\partial h} + (1 - \gamma) \frac{\partial \rho_f}{\partial h}\right] = \frac{m_{12} h_{12} - m_{23} h_{23} + h_{23}}{A} \quad (5)
\end{align*}
\]

\[
\begin{align*}
(p_{23} h_{23} - p_3 h_3)L_1 + \left(\frac{\partial p_3}{\partial h_3}\right)_{h_3} + \frac{1}{2} \frac{\partial p_3}{\partial h_3} \left(\frac{dh_{23}}{dp}\right) + \frac{1}{2} \frac{\partial p_3}{\partial h_3} \left(\frac{dh_{23}}{dp}\right) + \frac{1}{2} \frac{\partial p_3}{\partial h_3} \left(\frac{dh_{23}}{dp}\right) + \frac{1}{2} \frac{\partial p_3}{\partial h_3} \left(\frac{dh_{23}}{dp}\right) = \frac{m_{23} h_{23} - m_{out} h_{out} + h_{out}}{A} \quad (6)
\end{align*}
\]
The result of applying the refrigerant energy conservation equation for each region is shown in Eqns. (4)-(6). When section \( j \) disappears, the equation \( \dot{L}_j = 0 \) can be applied instead of the equation derived from each section.

### 2.1.3. Tube wall energy conservation equations

\[
L_1 \dot{T}_{w1} = (T_{W12} - T_{w1})L_1 + \frac{q_{a1} - q_1}{A_w \rho w c_w} \tag{7}
\]

\[
L_2 \dot{T}_{w2} = (T_{W12} - T_{w2})L_1 + (T_{W23} - T_{w2})L_2 + \frac{q_{a2} - q_2}{A_w \rho w c_w} \tag{8}
\]

\[
L_3 \dot{T}_{w3} = (T_{W23} - T_{w3})L_1 + (T_{W23} - T_{w3})L_2 + \frac{q_{a3} - q_3}{A_w \rho w c_w} \tag{9}
\]

The result of applying the tube wall energy conservation equation for each region is shown in Eqns. (7)-(9). The symbol \( T_{w12} \) means the tube wall temperature at the boundary between section 1 and section 2, and the \( T_{w23} \) means that at the boundary between section 2 and section 3. Some researchers have completed the equation by considering both \( T_{w12} \) and \( T_{w23} \) to be \( T_{w2} \) [5-7]. Also, some researchers have assigned different values to \( T_{w12} \) and \( T_{w23} \) according to the sign of the time derivative of the length at the boundary point [8-10]. For example, they used \( T_{w1} \) for \( T_{w12} \) when \( L_1 < 0 \), and they used \( T_{w2} \) for \( T_{w12} \) when \( L_1 \geq 0 \). However, in this study, Eq. (10) and Eq. (11) were used for expressing \( T_{w12} \) and \( T_{w23} \) as introduced in [11, 12] because this method is more numerically stable and has no conditional statements.

\[
T_{w12} = (L_1 T_2 + L_2 T_1)/(L_1 + L_2) \tag{10}
\]

\[
T_{w23} = (L_2 T_3 + L_3 T_2)/(L_2 + L_3) \tag{11}
\]

### 2.1.4. Equation for mean void fraction

\[
\dot{\gamma} = \left( \frac{\partial \gamma}{\partial x_{1,2}} \right)_{x_{o,2}} + \left( \frac{\partial \gamma}{\partial x_{1,2}} \right)_{p, x_{o,2}} \left( \frac{\partial h_{1,2}}{\partial p} \right)_{x_{o,2}} + \left( \frac{\partial \gamma}{\partial x_{1,2}} \right)_{p, x_{o,2}} \left( \frac{\partial h_{1,2}}{\partial p} \right)_{x_{o,2}} \tag{12}
\]

In order to accurately simulate the dynamic behavior of the heat exchanger, the mean void fraction of the two-phase section should be set as a dynamic variable. In this case, one differential equation including quality distribution information within the two-phase section is further required. In this study, Eq. (12) was applied assuming that the refrigerant quality in the two-phase section increases (or decreases) linearly, which was derived in [13, 14]. The subscript \( i, 2 \) means inlet of the two-phase section and the subscript \( o, 2 \) means outlet of the two-phase section.

By arranging Eqns. (1)-(12), the dynamic behavior of the heat exchanger is expressed as equations for the vector \([L_1, L_2, \dot{\gamma}, h_{out}, \dot{T}_{w1}, \dot{T}_{w2}, \dot{T}_{w3}, \dot{\gamma}]\), and the change in state of the heat exchanger over time can be obtained by integrating this vector.

### 2.1.5. The situation where the inlet and outlet of the heat exchanger are closed

In a VRF system, some indoor units among several indoor units may stop operating. In this case, generally the fan of the indoor unit still works, but the valves at the inlet and outlet of its heat exchanger are closed and the refrigerant does not flow until the indoor temperature reaches a certain value. In this situation, since the moving boundary method assumes a situation where the refrigerant flows, the governing equations derived in Section 2.1.1 and Section 2.1.2 cannot be applied.
2.3. Compressor, electronic expansion valve (EEV), and pipe

Since the time constants of a compressor and an EEV are very small compared to that of heat exchangers, a static model is used for the compressor and expansion valve, not a dynamic model. In addition, in the case of a pipe connecting the indoor unit and the outdoor unit, the mass of the refrigerant can be stored therein, but the amount is very small compared to the heat exchanger, the accumulator, and the receiver. Therefore, the static pipe model is also used for pipes.

As a static model for the compressor, refrigerant flow in compressor can be calculated as the product of the compressor frequency, inlet refrigerant density, and stroke volume. The compressor outlet enthalpy can be calculated with an isentropic efficiency. As a static model for the EEV, refrigerant flow in EEV can be

\[
\begin{align*}
\dot{m}_{\text{acc}} &= \dot{m}_{\text{acc,in}} - \dot{m}_{\text{acc,out}} \\
\frac{d(m_{\text{acc}}u_{\text{acc}})}{dt} &= m_{\text{acc}} \dot{u}_{\text{acc}} + m_{\text{acc}} \dot{v}_{\text{acc}} = \dot{m}_{\text{acc,in}} h_{\text{acc,in}} - m_{\text{acc,out}} h_{\text{acc,out}} \\
\dot{u}_{\text{acc}} &= \frac{\partial u_{\text{acc}}}{\partial p} \rho_{\text{acc}} \dot{p} + \frac{\partial u_{\text{acc}}}{\partial \rho_{\text{acc}}} \rho_{\text{acc}} \\
m_{\text{acc}} \frac{\partial u_{\text{acc}}}{\partial p} \rho_{\text{acc}} \dot{p} + \left( u_{\text{acc}} + \frac{\partial u_{\text{acc}}}{\partial \rho_{\text{acc}}} \rho_{\text{acc}} \right) m_{\text{acc}} &= m_{\text{acc,in}} h_{\text{acc,in}} - m_{\text{acc,out}} h_{\text{acc,out}}
\end{align*}
\]
determined by the orifice flow equation, and the outlet enthalpy was the same as the inlet enthalpy. For calculating pressure drop in pipes, Darcy-Weisbach equation was used.

2.4. System configuration

In this study, a dynamic model of a VRF system including one outdoor unit, four indoor units, a compressor, four EEVs, an accumulator, and a receiver was developed as shown in Fig. 3. The simulation was performed only in cooling mode and cooling capacity of the VRF system was set to 30 kW. PI control was applied to the compressor speed so that the accumulator pressure, which is the inlet pressure of the compressor, reached a specific value from the initial condition of 0 Hz. In addition, the openings of the EEVs were also PI controlled so that the superheat at the outlet of each indoor unit be 10 K. In the case of the indoor unit, on/off control was applied, and the refrigerant flow was stopped when the air inlet temperature reached 17.5 ℃, and the valve was opened to allow the refrigerant to flow when the temperature reached 18.5 ℃. Other simulation conditions, parameters, and component geometry not mentioned are shown in Table 1.

2.5. Thermal zone model

Thermal zone models were constructed to simulate the situation where the indoor temperature decreases due to the cooling operation of the VRF system and the indoor unit repeats on/off. The thermal zone modeling method referred to the study of Lapusan et al. [15] Lapusan et al. constructed thermal resistance circuit for the multi-room building considering conduction from ceiling, interior and external wall, windows, and floor; ventilation through the windows; radiation from the sun. By modifying their thermal resistance model, the thermal resistance model to be applied to this simulation was developed as shown in Fig. 4. Cooling effect from the VRF system and heat generation from human beings were added to the previous model.

The size, arrangement, and other simulation conditions of each thermal zone are shown in Fig. 5. The ground temperature was set to 10°C and the amount of solar radiation and heat generation were set to 160 W and 500 W (5 people in each room), respectively. Additionally, mass flow rate of the ventilation was set to 50 m³/h. In term of geometry, each room has an area of 25 m² and a height of 3 m and all four rooms are placed side by side.

Fig. 5. 4-office zone arrangement for VRF cooling system simulation and simulation conditions

3. Simulation results

Fig. 6 shows the dynamic behaviors of the simulated system from 0 s to 2,400 s. At 690 s, inlet air temperature of the fourth evaporator reached the set lower limit, and the valves of that indoor unit were closed.
Then, the pressure of the refrigerant in the indoor unit rapidly increased as heat was supplied from the indoor air. When the temperature of the refrigerant became the same as the room temperature, the heat transfer decreased and it approached a steady state with no pressure change. Sequentially, the other indoor units also experienced the same process. At 1,350 s, inlet air temperature of the fourth evaporator reached the set upper limit and valves were opened. Then, the refrigerant in the indoor unit quickly moved to the accumulator which had lower pressure, and the indoor unit pressure drastically decreased. Although the slope of decreasing pressure was very large, the simulation was robust and worked without showing numerical instability even when this process was repeated.

However, as the simulation time elapsed, the compressor inlet pressure (accumulator pressure) converged to about 620 kPa. This is the evaporation pressure corresponding to the evaporation temperature of -7.6°C, and it shows a difference from the operating data of the actual VRF system. This difference is expected to be resolved through a model validation process that and reduces the error with the experimental results of the actual VRF system changing the main parameters of the VRF system modeling.

4. Conclusions

In this study, the heat exchanger was modeled using the moving boundary method, and the dynamic model development and simulation of the entire VRF system was performed by combining it with the main component models of the VRF system. In particular, a modeling method in the stationary state of the indoor unit, which frequently occurs in VRF systems, was included. In addition, the indoor unit on/off operation of the VRF system was simulated by combining the thermal zone model. Based on the system pressure change data derived through simulation, it was confirmed that the developed model simulated the actual VRF system similarly, although there were some errors. However, if the accuracy of the model is increased using actual experimental results in the future, it is expected that the developed model can be used to perform optimal control of the actual VRF system.

Abstract

This study provides a new calculation method for double spiral ground heat exchangers (GHEs) and involves the combination of the analytical infinite line source (ILS), and infinite cylindrical source (ICS) models with the capacity resistance model (CaRM). Method adopts the concept of fin efficiency, enabling it to calculate underground temperature change easily and accurately, followed by integration into a simulation tool for ground source heat pump (GSHP) systems. Verification was done by comparing the simulation results with actual operating data, measured from a zero-energy building (ZEB) in Sapporo, Japan. Under conditions of instantaneous large heat injection, significant differences were observed between the simulation and the actual measurements during initial 50 h. The number of temperature nodes in the network was increased to effectively reduce the error between simulations and measurements.

Keywords: ground source heat pump system, double spiral ground heat exchangers, capacity resistance model, energy pile, simulation;

1. Introduction

More than 140 countries have pledged to achieve net-zero emissions at the COP 26 meeting held in UK, 2021 [1], this has reaffirmed that climate change is the greatest threat to all of us. Building energy consumption accounts for 40\% of the total global energy consumption, to substantially reduce greenhouse gas emissions, energy supplies for space cooling/heating must be shifted from fossil fuels to renewable energy sources [2].

Ground source heat pump (GSHP) systems are gaining popularity in residential and commercial buildings due to their high energy efficiency, environmental friendliness, and ease of integration with other energy systems. However, the biggest obstacle to promoting GSHP systems is the large amount of land required and the high cost of drilling for ground heat exchangers (GHEs).

Thermal piles have been adopted in recent years to tackle these problems. Thermal pile is a type of energy structure that incorporates the GHEs of GSHP systems through the foundation elements of the building.

Thermal piles can not only support the structure of the building but also serve as GHEs [3]. In this paper, a new simulation tool is developed by combining this calculation method (for temperature change inside the thermal pile) with a ground temperature simulation program for GSHP systems (for temperature change outside the thermal pile) for temperature simulations of thermal piles with double spiral pipe GHEs.

2. Development of the new calculation method for double spiral pipes

In the previous study, several methods were used to calculate the heat transfer inside the spiral tube. Cui et al. [4] proposed a ring-coil heat source model but did not provide exact solutions for the spiral coil source. Zhang et al. [5] made improvements by considering the arrangement and pitch of spiral pipe and simplified the calculation. This new model, however, cannot be applied if the grouting material differs from that of the surrounding soil. Park et al. [6] created an efficient spiral coil source model along with its analytical solution, but its long-term operational efficiency is yet to be verified.

Fig. 2. (a) Sectional view of thermal pile, (b) Top view of thermal pile, and (c) Partial detail of thermal pile

The larger diameters of the thermal pile than the common value of the borehole make it essential to consider the heat capacity of the grouting material when studying the thermal performance of double spiral pipe GHE. Previous works [7] presented a numerical model, CaRM-He, to solve this problem and analyzed the thermal behavior of a short-length spiral pipe GHE.

This study also employed the capacity and resistance model (CaRM) to account for the thermal capacitance of grouting material, temperature nodes were arranged in the radial direction to reduce the amount of calculation while obtaining acceptable calculation accuracy. The volume of the thermal pile is divided into three parts (Fig. 2):

- “core” part: grouting material
- double spiral tube
- “shell” part: thermal pile material between spiral tube and borehole boundary

Fig. 3. Sectional drawing of the thermal pile

The heat transfer processes inside thermal pile consist of three parts [7] [8]:

- heat conduction in the “core” part
- heat convection between flowing circulating fluid and pipe surface
- heat conduction in the “shell” part
As the outer diameter of the pipe $d_{p,o}$ is much smaller than the borehole diameter, the double spiral pipe was considered as a line that injects/absorbs heat into/from the ground in summers/winters [8]. Assuming this, the thermal resistances between “core” part and double spiral pipe, double spiral pipe and “shell” part, and “shell” part and surrounding soil can be respectively expressed in form of equations (Fig. 3):

$$R_{sp-c} = \frac{1}{2\pi l_p \lambda_{core}} \cdot \ln \left( \frac{r_{sp,l}}{r_{core}} \right)$$  \hspace{1cm} (1)

$$R_{sp-s} = \frac{1}{2\pi l_p \lambda_{shell}} \cdot \ln \left( \frac{r_{sp,l}}{r_{sp,o}} \right)$$  \hspace{1cm} (2)

$$R_{s-b} = \frac{1}{2\pi l_p \lambda_{shell}} \cdot \ln \left( \frac{r_b}{r_{shell}} \right)$$  \hspace{1cm} (3)

However, the temperature of the layer between “core” and “shell”, which contains double spiral pipe and grout, is difficult to calculate. We have found a calculation method adopting fin efficiency to solve this problem.

Previous studies proposed a calculation method, Kollmar-Liese method, for the thermal emission of flat floor heating panels with a cylindrical heat source [10]. In a hot-water floor heating system, as shown in Fig. 4 (a), it is assumed that a virtual fin with a width ($d$) equal to the outer diameter ($d_{p,o}$) of the pipe is attached to the pipe. Fig. 4 (b) depicts a combination of a virtual fin and a pipe, fin efficiency $\eta$ of the virtual fin can be calculated:

$$m = \sqrt{\frac{2a}{\lambda d}}; \quad h = \frac{\text{pitch} - d_{p,o}}{2}; \quad \eta = \frac{\tanh(mh)}{mh}$$  \hspace{1cm} (4)

Assuming that the surface temperature of the pipe is $T_H$ and the ambient temperature is $T_L$, the mean temperature $T_m$ of the virtual fin can be calculated using the Kollmar-Liese method [10]:

$$T_m = T_L + \eta \cdot (T_H - T_L)$$  \hspace{1cm} (5)

The vertical section of the double spiral pipe GHE resembles a “vertical” floor heating panel (Fig. 4 (c)). The convective thermal resistance between circulating fluid and pipe surface can be expressed as:

$$R_{sp-f} = \frac{1}{2\pi r_{sp,l} \lambda_{sp,f}} + \frac{1}{2\pi l_p \lambda_{sp}} \cdot \ln \left( \frac{r_{sp,o}}{r_{sp,l}} \right)$$  \hspace{1cm} (6)

Fig. 4. (a) A typical radiant floor heating system (b) Principle of Kollmar-Liese method (c) Similarity between floor heating panel and double spiral pipe GHE

According to Kollmar-Liese method, heat transfer coefficient between spiral tube and “core” grout, spiral tube and “shell” grout can be calculated [9]:

$$K_{f\text{core}} = \frac{1}{2\pi r_{core} l_p R_{sp-c}}$$  \hspace{1cm} (7)
In the analytical model of Infinite Line Source (ILS) and Infinite Cylindrical Source (ICS) models, the heat balance equation in each part can be expressed as:

\[ K_{\text{shell}} = \frac{1}{2\pi r_{\text{shell}} l_p R_{\text{sp-s}}} \]

\[ Z_{\text{core}} = \frac{l_{\text{pitch}} - d_{p,o}}{2} \left( \frac{2K_{\text{core}}}{\lambda_p d_{p,o}} \right) \]

\[ Z_{\text{shell}} = \frac{l_{\text{pitch}} - d_{p,o}}{2} \left( \frac{2K_{\text{shell}}}{\lambda_p d_{p,o}} \right) \]

\[ \eta_{f_{\text{shell}}} = \frac{\tanh(Z_{\text{shell}})}{Z_{\text{shell}}} \]

\[ \eta_{f_{\text{core}}} = \frac{\tanh(Z_{\text{core}})}{Z_{\text{core}}} \]

Using Kollmar-Liese method, the average temperature of the “vertical” panel \( T_{\text{pnl}} \) can be expressed as:

\[ T_{\text{pnl}} = \frac{1}{2} \left( T_{\text{in}} - T_{\text{core}} \right) \cdot \eta_{f_{\text{core}}} + T_{\text{core}} + \frac{1}{2} \left[ \left( T_{\text{in}} - T_{\text{shell}} \right) \cdot \eta_{f_{\text{shell}}} + T_{\text{shell}} \right] \]

Using \( T_{\text{pnl}} \), the heat balance equation in each part can be expressed:

- Circulating fluid in double spiral pipe:
  \[ c_f \cdot \rho_f \cdot \pi \cdot r_{p,i}^2 \cdot l_p \cdot \frac{dT_f}{dt} = c_f \cdot \rho_f \cdot v_f \cdot \left( T_{f,\text{in}} - T_{f,\text{out}} \right) - \frac{T_{f,\text{in}} - T_{f,\text{out}}}{R_{\text{sp-f}}} \]

- The “core” part:
  \[ c_{\text{core}} \cdot \rho_{\text{core}} \cdot \pi \cdot r_{\text{sp,i}}^2 \cdot l_b \cdot \frac{dT_{\text{core}}}{dt} = \frac{T_{\text{pnl}} - T_{\text{core}}}{R_{\text{sp-c}}} \]

- The “shell” part:
  \[ c_{\text{shell}} \cdot \rho_{\text{shell}} \cdot \pi \cdot (r_b^2 - r_{\text{sp,o}}^2) \cdot l_b \cdot \frac{dT_{\text{shell}}}{dt} = \frac{T_{\text{pnl}} - T_{\text{shell}}}{R_{\text{sp-s}}} - \frac{T_{\text{shell}} - T_s}{R_{\text{s-b}}} \]

Our laboratory has developed a high-speed simulation program for GSHP systems in previous research. It is based on the analytical model of Infinite Line Source (ILS) and Infinite Cylindrical Source (ICS) models [10]. In this research, the new calculation method for double spiral GHEs was integrated into the simulation program in MATLAB R2020b, and the calculation flow is illustrated in Fig. 5.

For one time step \( dt = 60 \) s, the calculation procedures are under:

- Electricity consumption \( E_{\text{hp}} \) of the heat pump unit and fluid temperature \( T_{\text{p,in}} \) flowing out of the heat pump unit are calculated using the building load \( Q_2 \) (secondary side), heat extraction/injection from/into the ground \( Q_1 \) (primary side). \( T_{\text{p,in}} \) is equal to the inflow temperature of the circulating fluid \( T_{\text{p,in}} \).

- The heat transfer processes inside the thermal pile and inflow temperature of the circulating fluid \( T_{\text{p,out}} \) have been calculated using the new calculation method proposed. \( T_{\text{p,out}} \) is equal to the fluid temperature \( T_{\text{p,in}} \) flowing into the heat pump unit, which will be used for the next time step.

- The surrounding soil temperature \( T_s \) (outside the thermal pile) is calculated in GroundClub. \( T_s \) is equal to the thermal pile boundary temperature \( T_b \), which will also be used for the next time step.

The simulation results of the GHSP system for long-term operations can be obtained by performing continuous step-by-step simulations of temperature changes in pipe inlet \( T_{\text{p,in}} \), outlet \( T_{\text{p,out}} \), and ground \( T_s \).
3. Results and analyses

The verification work was carried out in a 3-story house in Sapporo, Japan. Table 1 lists the basic information about the house. Energy efficient technologies used in this house include a photovoltaic panel system for electricity supply, heat recovery ventilation system, and GHSP system, FCU (fan coil unit), and radiant air conditioning system. The house has been in operation since 2021/7 and was verified as a nearly-ZEB (zero energy building).

There are 3 GSHP units (rated power 10 kW) and 24 thermal piles installed on each floor of the house to provide space heating and cooling and snowmelt in winter. Figure 14 illustrates the system diagram of each floor. The thermal pile configuration for each floor is as follows: 4 (2 series × 2 parallel) for 1st floor (stores), 6 (2 series × 3 parallel) for 2nd floor (office rooms), 4 (1 + 1 + 2) for 3rd floor (office rooms and meeting rooms) and 10 for snowmelt (Fig. 6 (c)).

Each GSHP unit has temperature sensors and electromagnetic flow meters that collect real time measurements of pipe inlet temperature $T_{p,in}$, outlet temperature $T_{p,out}$, circulating fluid flow $v_f$, and power consumption of heat pump unit $E_{hp}$. Data was collected over a period of one year and was used for the purpose of verification.

**Circulating fluid: 40% ethylene glycol solution**

Table 2 gives the specifications of the GSHP system. In October 2021, an in-site thermal response test (TRT) was performed to determine the thermal conductivity of the ground soil. The data were analyzed using the Kelvin Line Theorem, and the effective thermal conductivity of soil was calculated to be $\lambda_s=1.846$ (W/m·K). By applying this value to the simulation, the verification work was performed by comparing the measured and simulated data and simulation under two cases discussed below:

### 3.1. Space cooling in summer

During the space cooling period, the indoor room temperatures were set to 26 °C. As majority of the rooms on the first floor are occupied, GSHP unit 1 ran the longest. As such we chose this unit for data analyses. The heat injection from the house into ground can be calculated using the hourly recorded pipe inlet/outlet temperature and the flowrate data of the circulating fluid during the space cooling period (Fig. 7 (a)):

$$Q_{injection} = \rho_f \cdot c_f \cdot v_f \cdot (T_{p,in} - T_{p,out})$$  \hspace{1cm} (16)

Then heat injection during this period was used as the primary side load $Q_1$ for subsequent simulations. Except for the preparation time, the verification period was set as 2021/8/1–2021/8/31. Fig. 7 (b) shows the comparative hourly changes of the pipe inlet temperature $T_{p, in}$ for both, measured and simulated data. The RMSE (Root Mean Squared Error) value between measurement and simulation data from 8/1 to 8/31 was reported to be 0.73, indicating the accuracy of the simulation tool. The simulated and measured average temperatures were reported to be 19.71 °C and 19.77 °C, respectively. Changes in both temperatures display similar trends, with minor differences when the temperatures change rapidly.
3.2. Space heating in winter

All GSHP units were set to provide 45 °C hot water during the space heating period, while the indoor room temperatures were set to 22 °C. The recorded data was used to calculate the heat extracted from the ground, the results for which are shown in Fig. 8 (a):

\[ Q_{\text{extraction}} = \rho_f \cdot c_f \cdot v_f \cdot (T_{p,\text{out}} - T_{p,\text{in}}) \]  

(17)

Fig. 8 (b) plots the comparison between measured and simulated data for pipe inlet temperature. Excluding maintenance and holiday time, the verification period was selected from 1/7 to 2/7, which is the coldest period in Sapporo, when space heating is most needed. The results show that the temperatures between measurement and simulation are well matched with an RMSE value of 1.06. This value is acceptable and demonstrates the effectiveness of this simulation tool.
This simulation tool has been designed to generate high accuracy performance assessment results to make sound estimates supporting the early-stage decision-making. The summer and winter verifications show that this simulation tool for performance prediction can be applied in the preliminary design phase of future GSHP systems using thermal piles and double spiral pipe GHEs.

4. Discussion

The measurement results of the TRT test were compared with the simulation results during the verification works, as shown in Fig. 9. Although the two sets of data agree well after a period of 100 h, there are significant errors in both pipe inlet and outlet temperatures during initial 50 h. This means that, when applying the CaRM model, there will be a significant difference in the simulated and calculated temperature changes over a short period of time in case of large instantaneous heat injections.

This is mainly because the CaRM or lumped thermal capacity model assumes that the temperature of each solid is spatially independent (uniform) and can be represented by the same temperature. If the volume of the solids corresponding to the temperature nodes is too large, the represented temperatures may deviate from the actual temperatures.

![Fig. 9. Comparison of pipe inlet & outlet temperature between simulation and measurement](image)

To solve this problem, the size of solid can be reduced so that the network of interconnected thermal resistances and capacities has a finer mesh. The “core” and “shell” part are divided into n regions (Fig. 10 (a)), corresponding to n temperature nodes. With this, the heat load and circulating fluid flow in the initial 50 h of TRT can be used as an input for the simulation, Fig. 10 (b) shows that the deviation between the simulation results and the actual measured data reduces with increase in temperature nodes during the initial 30 h. This thus proves that the simulation tool can also be used for short-term operation predictions.

![Fig. 10. (a) Concept of dividing “core” and “shell” part into n annual regions (b) Comparison of pipe inlet temperature in initial 30 h](image)
5. Conclusion

The proposed new calculation method based on the CaRM model is an improvement over the previous ones as it adopts the concept of fin efficiency and integrates a simulation program for GSHP system. The main findings of this paper are:

- Different from the traditional U-shaped pipe GHE, the double spiral pipe GHE adopts shorter underground borehole, but has a larger area for heat exchange between the ground and circulating fluid without additional drilling work, which saves the initial costs of the GSHP system and promotes its use in the future.
- By replacing the spiral pipe with a “vertical” heat generating/absorbing panel, the temperature changes in each part of the thermal pile can be easily obtained without a huge amount of calculation.
- Verification work carried out in an energy-efficient house proved that the simulation tool produces reliable and high-precision simulation results for the long-term operation of GSHP systems, both in summers and winters. This would assist in the preliminary designing phase of future GSHP systems.
- For short-term simulations of less than 50 h, the simulated results can still agree well with the measured results by adding more temperature nodes to the thermal network.

Abstract

Many gas-fired boilers are likely going to be replaced with heat pumps in the very close future [1], supported by current energy plans. Air-to-water heat pumps will be increasingly used as sources for hydronic heating systems. Consequently, water-based systems need to have low OPEX for obtaining a solid business case with good ROI. As a common pragmatic solution an A/W heat pump is recommended with low temp. heating systems, typically floor heating, where the temperature curve is lower compared to conventional radiator heating system. However, in most boiler replacement cases radiators are installed in residential and residential like buildings. Acceptable ROI is obtained by having superior SCOP of the HP together with an optimized design of the hydronic system, including distribution and heat emission. This paper describes the role of hydronic controls, which in traditional radiator heating systems is governed by TRVs and Hydronic Balancing, the relation to the HP efficiency, with the goal to achieve best ROI. This is realized without compromising comfort, and is a marginal cost of the additional Building Automation and Control devices to be installed or upgraded together with the HP. Investigations and results are oriented to parameters which leads to reduced operational temperatures and longer lifetime for the HP.

1. Introduction

1.1 Methodology

Best practice and system design was investigated through interviews to technical specialist from the industry in focus markets, mainly designers, project engineers and installers in UK, IT, FR and DE and through a wide search of the recent literature (see Bibliography and References) including e.g., associations white papers, technical articles, and best practice manuals, dedicated to application, and design for residential buildings retrofit. Calculations and theoretical simulations were carried out to investigate limitations on hydronic flows for the building heating installation. Analysis of the building stock was made using available data from BPIE to show potential energy savings when reducing indoor temperatures and thus accepting the performance of the existing radiators, working at lower temperatures with a heat pump. Unicity of the work is based on the combined knowledge of the authors on heat pumps technology and on building hydronics. These two perspectives are necessary to optimize the system in retrofit applications, as the main system components in heating distribution and emission of existing old buildings were not designed and commissioned to match the characteristics of heat pumps. The paper formalizes a pragmatic methodology based on steps, that helps installers in the system design evaluation and needed corrective actions when heat source technology is changed.

1.3 Boiler replacement with HP in small systems.

The electrification of heating means a tremendous acceleration of the deployment rate of heat pumps. Heat pumps are used with different technologies and capacities, they can be adapted to natural heat sources (i.e., air and water) or recover energy from waste heat sources that would otherwise be lost. Large scale MW sized heat pumps will typically be used in connection with district energy systems and local planning needs to be done to establish the best size and distribution of the heat pumps in connection with heat source locations. In areas where district heating is not foreseen and in buildings where hydronic heat distribution is already installed, a ground source (W/W) heat pump or an air to water (A/W) heat pump will often be preferred as replacement for a gas or oil boiler.

In contrast to a boiler which has a nearly constant efficiency over supply temperature (condensing boiler efficiency mainly depends on return temperature), the heat pump has a more complex nature to observe if the optimal efficiency should be achieved. The energy output from the heat pump consists of the energy from the heat source and of the electricity provided to create the temperature lift between the heat source and heat sink. The electricity consumption increases with the temperature lift i.e., the supply temperature of the hydronic systems should be minimized to have an optimal COP. In new buildings – or building undergoing deep renovation - this can be done by using low temperature floor heating. However, in buildings where deep renovation is not done, the existing heat emitters are often kept, and the risk is that the newly installed heat pumps run with a far lower COP than nominal. This is often because basic optimization parameters on the buildings hydronic system are not sufficiently observed. With other words, the building hydronic system should be optimized for the heat pump operation to ensure consumers the full potential of the “boiler to heat pump” replacement.

Target objective of this paper is to describe what to observe when a small size boiler (typically wall hanging) is replaced in a single-family house or dwelling where radiators are used as heat emitters.
2. Low temperature readiness of buildings

Following EN14825 “low temperature readiness” of a building means its ability to provide the users good comfort when the energy source delivers supply temperatures at 35°C or lower. The far majority of buildings including their heating systems were designed and built throughout the last century. Past retrofit measures may have changed the primary fuels used to service the building (e.g., coal replaced by oil, then by gas), but many heat distribution components and heat emitters still remain a part of the current heating systems.

2.1. Readiness evaluation

Typical other elements to evaluate the low temperature readiness of the building are:

1) Reduce the basic energy demand: evaluate and optimize the level of envelope insulation. Walls, windows, roofs can be insulated, but also minor means such as improving the backwall of the radiator by installing an insulating/infrared reflecting panel.

2) Optimise the ability to operate at reduced supply temperatures. The size of specific radiators: Often radiators are over dimensioned for the temperatures during boiler operation. This may turn into an advantage for the heat pump operation at lower temperatures, especially when adapting the right controls and using them in the right way. Replacement of critical radiators. A simple way to increase the heat output is change from e.g., 1 panel to multi panel radiators with convectors, of the same installation dimensions. This implies no change on the piping system.

3) Validate and upgrade the installed controls: building automation and control systems play a big role in energy efficiency and the ability to achieve heating needs at lowest possible supply temperatures. Controls should be checked or upgraded to ensure the low temperature demands. E.g., in relation to flow capacity and hydraulic balancing.

4) Behavior of occupants: Are they utilizing the available radiator surfaces in the optimal way by having all radiators emitting heat in a balanced way. Are they able to program the heating according to different time schedule? Low temperature heating needs a more stable temperature setting.

2.2. Resilient buildings

The water flow supply and return temperatures to the heating emitters are impacted by the type of heat source installed. A heating system using traditional boilers operates normally with supply temperatures of 70-80 degrees with temperature drops of 15-20 degrees trough the heat emitters. The high supply temperature is obtained without compromising the efficiency as traditional boilers are much less sensitive on this parameter. When installing a heat pump the supply temperature can be directly set, but this temperature setting has a high impact on the efficiency of the system and thereby also the OPEX. Heat pumps should as a rule of thumb always be operated with the lowest possible supply temperatures.

A good performing heating system, independent of the heating source, relies on efficient controls, appropriate temperature settings, and a well-balanced hydraulic system. A balanced hydraulic heating system provides a uniform temperature drop across all radiators. This temperature drop, at nominal or design conditions, is expected to be 15-20 °C when applying a condensing boiler or even higher with a connection to district heating. With a heat pump, this drop due to the low supply temperature is likely in the range of 5-10°C. It means the heat emitter has a more uniform temperature distribution to compensate for the lower supply temperature.

A properly balanced building distribution enables to reduce supply temperature [2], as the balancing will avoid overflow by specific bad performing radiators or wrong operated TRVs. Specific radiators that are too small to emit the needed heat output at the desired supply temperature should be replaced. This will likely be limited cost wise, compared to the CAPEX for the heat pump. A study across the EU has shown that hydraulic balancing is unfortunately not common, and only 10% of buildings heating systems are correctly balanced. [3]
3. Radiator design and flow

3.1. Hydronic radiators physics

The heat rate, or emission, from a radiator is defined in EN442-2 and depends on the over temperature \(\Delta T\) and the radiator constant \(K_m\). Expressed by:

\[ \Phi = K_m \times \Delta T^n \]

Where:
- \(\Phi\) is heat output in W
- \(K_m\) is the radiator constant.
- \(\Delta T\) is the difference between the mean radiator temperature and the room temperature.
- \(n\) is an exponent, also defined in the radiator model.

Considering that the radiator is not replaced when a heat pump is installed and assuming \(K_m\) and \(n\) is held constant, the only way to maintain the heat output \(\Phi\) is to maintain the \(\Delta T\) of the radiator. \(\Delta T\) can be simplified to the difference between the average temperature of the radiator (\(T_{\text{av}}\)) and the room temperature (\(T_{\text{amb}}\)).

The simplest method is called the arithmetic over-temperature, where:

\[ \Delta T = T_{\text{mean}} - T_{\text{amb}} = \frac{(T_{\text{inlet}} + T_{\text{outlet}})}{2} - T_{\text{amb}} \]

A more representative method, which takes the nonlinearity of the temperature over the radiator into account, is the logarithmic over-temperature, and will be used in this article, where:

\[ \Delta T = T_{\text{mean}} - T_{\text{amb}} = \frac{(T_{\text{inlet}} - T_{\text{outlet}})}{\ln \left(\frac{(T_{\text{inlet}} - T_{\text{amb}})}{(T_{\text{outlet}} - T_{\text{amb}})}\right)} \]

Maintaining the \(\Delta T\) requires that when reducing the \(T_{\text{inlet}}\), should be lowest possible for a good HP COP, \(T_{\text{outlet}}\) should increase, and this requires a higher flow through the radiator [4].

Above simple formulas are used to describe the radiator behavior in a simple way. A more detailed numerical description on the radiator physics can be read in [5].
3.2. COP vs supply temperature

The COP of the heat pump will increase as the temperature lift is decreasing, see Fig 1 [6], the example of a air to water HP. It means the COP can be maximised by realising a heating system that requires a low supply temperature. This should also be considered when retrofitting a radiator system i.e., the supply temperature should be set as low as possible.

![Graph showing COP vs supply temperature](image)

Fig. 1. The COP of air source heat pump operated with R32 under varied outdoor air and supply water temperatures.

3.3. Capacity evaluation and new settings

As mentioned, a challenge when retrofitting is to ensure sufficient capacity or heat emission from the existing radiators when operated at reduced supply temperatures. As described above, the heat emission from the radiators is based on the difference between the mean radiator surface temperature and the room air temperature. E.g., a constant heat emission can be achieved by various sets of inlet and outlet temperatures of the radiator. It basically means by reducing the inlet temperature, the outlet temperature should be increased, and this implies increasing the flow through the radiator. To illustrate this, an example is shown in figure 2, where the flow is uncontrolled, e.g., by a manual radiator valve, RV, and where the flow is controlled, e.g., by a thermostatic radiator valve, TRV.
In the upper figure the uncontrolled situation or no flow control is shown (RV), represented by a constant flow through the radiator. The heat output is a direct result of the supply temperature, thus only one specific supply temperature is matching the heat load of the room. In this case the example of 500W is used at a supply temperature of 55°C and here the flow of 17.1 l/hr fits. On the lower figure the situation is shown where a flow control is applied (TRV or eTRV). The heat output of the radiator is constant independent on the supply temperature. The supply temperature cannot be below 40°C when emitting 500W is to be kept, and even before reaching 40°C, the maximum flow of the radiator or system is reached. It can also be seen that the radiator return temperature increases when the supply temperature is decreased, this to maintain the mean temperature difference of the radiator surface to the surrounding air, and thus maintaining the same heat emission.
When replacing a traditional high temperature heat source with a Heat pump, with the intention of optimising CAPEX and OPEX, the difference of the radiator inlet and outlet temperature, should be in the range 5-10°C. (Fig.3) The radiator’s control concept will therefore need to adapt to the reduced operating temperature. This basically means that the pre-setting and balancing of the radiator and distribution system should have the ability to operate at increased flow levels.

As stated above, it is possible to maintain the heat output of a radiator by increasing the flow rate through it and at the same time reduce the supply temperature (till a maximum acceptable flow level that depends on the radiator, the piping, the flow noise level, the circulation pump head pressure, and control valve capacity). Increasing flow rates create significantly higher head pressure losses and associated higher pump circulator power input. A balance between heat pump COP optimisation, circulation pump consumption and radiator maximum heat emission compared the needs can be simulated. (Fig. 3). The shown COP includes the electricity consumption of the HP and the circulation pump. The HP COP used in the present calculation is based on [7].

As seen from figure 3, then there is a maximum COP. This point represents the situation where the increased flow, due to the reduced supply temperature, results in reduced electric consumption for the HP but at the same time results in a similar increased electric consumption of the circulation pump. If it is possible to operate at maximum COP depends on the factors mentioned above.

A simple mathematical model has been developed to describe radiator heat emission and flows through radiators when a boiler is being replaced with a heat pump. Through this model it is possible to be guided on different options and parameters when analysing the feasibility of the retrofit. (Fig.4)
When a heat pump is introduced in the system [8] the temperature drop over the radiator is to be decreased (if possible in the mentioned interval of 5-10°C) and flows are subsequently to be increased. This implies TRVs should be able to provide higher flows through change in the presetting if applicable. Presetting is the predetermined maximum flow at a given differential pressure the valve will pass through the radiator valve. The feasibility of a higher presetting should be evaluated when rebalancing the hydronic system for HP operation. The circulation pump head pressure must likely be increased assuming a reserve as is available. If the radiator valve (RV) is limiting the flow, they can be replaced to RVs with a higher capacity. In the example of figure 4, going even to a lower supply temperature (below 47°C) would require other and more costly means, like replacing radiators and/or pipes.

The tradeoff is found in balancing the investment costs in relation to the operational saving due to a higher COP. In this example the supply temperature to the radiator is reduced from 70°C to 46°C, and at the same time the COP is increased from 3,05 to 3,46. The flow through the radiator is increased from 10 l/hr to 38 l/hr, basically a factor 4. For this example, the maximum COP cannot be fully reached, due to flow limitations, see red area Fig. 4 marked N.A. The remaining potential for improving the COP is anyhow limited. The steps mentioned here are options, and an example of priority.

3.4. End users’ behaviour and indoor temperatures

BPIE fresh Hotmaps Building Stock Analysis issued in 2022 [9] was used to check energy demand for space heating for the 3 representative abundant building types in 3 European countries (IT, DE, UK), at the hypothesis that heating is turned on when indoor temperature drops below 19-21°C depending on user behaviour. The calculation on equivalent kWh/m²/y thermal need (fig.5) based on national heating degree days shows the space heating demand at different heat ‘turn on’, or heating degree base temperature, starting conditions. Besides saving energy in general, the heat emitting area relative to the heating demand can be increased tremendously for the sake of efficient heat pump operation in the light of the previous section 3.3. Consequently, it is heavily recommended, when a heat pump is introduced in a traditional radiator heating system, to explain end users they should set indoor temperature at a reasonably low but still comfortable temperature (ideally max 19-20°C), to fully benefit from the retrofitted HPt and avoid changing the radiators. The market investigation reveals that in many cases designers and installers, over the last 50 years over dimensioned radiators and further the building was improved thermally during the years resulting in a basis for a potential well working HP.
4. Best practice approach when retrofitting

Previous chapters have described the needed methodology of an efficient retrofit solution. In practice, there are typical measures to evaluate, that can turn the system into low temperature ready. Below is a short description of the different options that should be considered prior to retrofit, improving CAPEX, OPEX and ROI:

- Decreasing basic heating loads/losses: when possible and feasible the thermal demands of the building should be decreased by adding insulation to the envelope (walls and roof), changing the windows, or adding winter gardens. The size and cost of the heat pump is related to the improved heating load and thus ROI should be calculated when deciding which means to go for, especially what to do first when doing staged renovation.

- Adding heat emitters. This should be done in the critical rooms only. In fact, the larger the total surface area of the heat emitters, the lower the required supply water temperature for a given rate of heat transfer/thermal load. Normally some of the radiators are over dimensioned for the given room, at the same time their size is set to provide the needed heat power in the coldest day of the winter, while for the remaining time they are more than adequately sized. This means in many cases there is only a need to adding surface in few selected rooms if at all.

- Changing type and/or size of emitters. This includes panel radiators, fan coils, fan assisted panel radiators, fin tube solutions or radiant heating. By changing the emitters, we refer to the intention of adding radiant surface and have a system that can deliver at lower supply temperature. Mostly it is possible to limit this to the critical rooms and the radiator area can be increased by replacing to multi panel radiator on the same wall surface with the same build in dimensions.

- Auxiliary heat source: evaluate how much space-heating energy is needed during the coldest days, when the heat pump due to the limited upper water temperature cannot provide sufficiently high supply water temperature. During that period, an auxiliary heat source is typically used in combination with the HP. If the amount of energy used under such conditions is relatively small in comparison to the total seasonal heating energy required, it would be reasonable to use the heat pump for the majority of the heating load and rely on the auxiliary heat source on top of the HP for the peak load conditions. This represents a typical hybrid system where the auxiliary heat source can be biomass, solar, or more easily direct electric which can be installed into the tank as an resistance based heat coil or alternatively be electric radiators (or hybrid radiators with a small electric resistance that turns on very limited hours a year) or electric underfloor heating. Traditional condensing boilers still represent a solution for an auxiliary source, but this is a transitional and non-logical opportunity when intention is to move towards a fossil free energy system.
• Evaluate the heat demand/supply profile, also including a thermal storage tank. This is out of scope for the present paper and will be investigated in further studies, i.e.: buffer tank and other components for hydraulic separation are needed to properly use controls and avoid over cycling of the HP.

5. Conclusions

The potential market for retrofitting heat pumps in existing building heating systems is substantially larger compared to new buildings. Thereby this is the first opportunity for decarbonising heating through electrification, also in small applications such as phasing out single-family fossil fuel boilers. Retrofitting of heating systems with heat pumps has its own specific characteristics, of which the high distribution/emission temperature used in existing hydronic heating systems is the most prominent.

Old hydronic systems are often designed for higher heating capacities than the actual design heat demands (especially with climate change!). In that case, the distribution temperatures may be reduced below the original design values. The distribution temperatures (supply temperature) may be reduced further by reducing the specific heat demand (W/m²/y). In all cases it should be ensured that the heat pump in combination with the new controls (not only on the primary circuit but even more on distribution and emission components) really saves energy, by a proper design for the new type of heat source.

Approaching retrofit design through the elements described in this paper potentially using the systematic stepwise approach can make clean heating through heat pumps the financially most attractive choice, create trust, and meet the technology acceleration that climate desperately needs.

Steady state measurements and dynamic behaviour of an absorption heat transformer operating in an industrial environment

J. L. Corrales Ciganda, Asier Martinez-Urrutia

*TECNALIA, Basque Research and Tecnology Alliance, Area Anardi 5, Azpeitia, Spain

Abstract

An Absorption Heat Transformer or Type II Absorption Heat Pump is a thermally driven heat pump able to upgrade approximately half of its driving heat up to a higher temperature level with an almost neglectable consumption of electric power. In the frame of a European project a 200 kW industrial pilot heat pump has been designed and installed in the power plant of a petrochemical facility. This work presents operation data of this AHT prototype operating at industrial scale. The presented results include steady state as well as dynamic performance measurements. The pilot AHT had continuously delivered heat flow rates between 220 and 270 kW with a thermal COP of around 0.5. The comparison of the monitoring results with those of a laboratory prototype present a deviation in the performance of around 20 % in terms of usable heat flow rates, but some explanation for this deviation are presented based on the operating conditions. The use of a dedicated adiabatic absorption chamber on the other side, partially compensate this deviation in performance, confirming the advantages of using an absorber with this configuration.

1. Introduction

An absorption heat transformer (AHT), also called type II or booster absorption heat pump is a device able to split a heat flow at an intermediate temperature level in two heat flows, one at a higher temperature level (upgraded heat flow) and another one at a lower temperature level (rejection heat flow).

These kind of thermal heat pumps are especially suitable for the recovery and upgrade of waste heat from industrial processes. For the European industry, which accounts for the fourth part of the energy consumption in Europe, approximately 70 % of its energy demand is used for thermal purposes, and a third part of this is directly rejected, being the largest part of this waste heat rejected at low-temperatures below 100 °C. The Absorption Heat Transformers (AHT) is a ready-to-market technology that can upgrade these large quantities of available low-temperature waste-heat into a usable temperature level with a very reduced electrical consumption.

Applications reported in the literature concentrate in the pulp and paper (during and lamination processes), chemical and petrochemical (distillation and purification processes) and food and beverage sectors (drying, sterilization, fermentation and mold and bacteria processes) [1–4]. The literature reports present installations with capacities between 100 kW and 5 MW, and agree that AHTs presents attractive payback periods, between 2 and 5 years, depending mainly on their capacity. Furthermore, over the past years some market installations by the manufacturers Thermax and Johnson Controls – Hitachi, offering AHTs between 0.5 and 10 MW, have been documented in their respective websites. Despite these recent advancements, there remains a lack of

* Corresponding author. Tel.: +34667101117
E-mail address:joseluis.corrales@tecnalia.com.
knowledge about the integration and performance of such systems in the industry. Furthermore, there is a noticeable lack of open experimental data available regarding the performance of these systems.

Within the Indus3Es Project (Horizon 2020 Project No. 680738) a single stage AHT has been developed, focusing on its design and on its integration into existing plants and its adaptability into various industrial processes. The developed system is being under demonstration in a real environment at the İzmit facilities of Tüpras, the main petrochemical industry in Turkey, enabling to analyze integration aspects, as well as operational and business-related issues. This work presents the monitored experimental performance data of the pilot scale 200 kW AHT and its comparison with previously presented operational results under laboratory conditions.

2. Description of the Heat Upgrade System based on an AHT

A heat upgrade system including a 200 kW nominal capacity AHT has been installed at the power plant of the petrochemical facilities of Tüpras in İzmit (Turkey) in the final phase of the Indus3Es project. The waste-heat that drives the absorption cycle in the AHT system is the condensation heat obtained from an oily steam drum tank, that was released to the ambient before the installation of the Indus3Es system.

The heat upgrade system combines direct recovery of part of the condensation heat of the oily steam in a plate heat exchanger (HX E-7 in Figure 1) with recovery and upgrade of the remaining part of the condensation heat of the oily steam by means of the AHT.

The demineralized water feeding the boilers of the steam cycle of the power plant enters the heat upgrade system with a temperature that is relatively constant throughout the year at 65 °C. The demineralized water is first preheated to a temperature of around 95 °C at HX E-7, and then further heated up at the heat exchanger HX E-5 by the hot glycol-water stream in the absorber circuit at the temperature level T2.

The heat released by the condensation of part of the oily steam at the heat exchanger HX E-6 heats up the water-glycol stream in the generator/evaporator circuit up to 95 °C, that enters the generator and evaporator of the AHT driving the cycle. The AHT splits this driving heat flow into a heat flow at the heat rejection circuit at temperature level T0 connected to the condenser, and an upgraded heat flow at the temperature level T2 that is transferred by the absorber circuit between the AHT and the heat exchanger HX E-6. The water-glycol in this absorber circuit is heated up to 140 °C by the AHT and heats up the demin-water circuit up to 135 °C before it is sent to the boilers. The temperature of the cooling water entering the condenser at the heat rejection circuit is obtained from the cooling water network of the plant and have a nominal temperature of 25 °C.

Fig. 1. Scheme of the AHT heat upgrade installation
3. Steady State Measurements of the 250 kW Industrial AHT

3.1. Operational Results

From November 2019 to May 2020 (end of the Indus3Es Project), the heat upgrade system has been in operation and monitoring data of the system under different sets of conditions have been analyzed, with the objective of the characterization of the AHT.

The heat upgrade system has been controlled with a dedicated control system developed within the project based on the characteristic equation method with the goal of maintaining the temperature of the demineralized water sent to the boilers at a constant value, that has been changed along the monitoring phase.

A set of valves controlled by the system act on the three circuits connected to the AHT at the temperature levels T0, T1 and T2 according to an internal logic that reduced the use of cooling water from the cooling water network by recirculation at the heat upgrade circuit. The temperature at the circuit T1 is kept as high as possible to make the best possible use of the waste heat. The pumps at the three circuits T0, T1 and T2 are equipped with frequency variable drivers to control the flow rate.

Table 1 presents the nominal, minimal and maximum temperature and flow rate values registered during the first operation phase. The temperature at the condenser inlet was lower than the nominal one because the tests of this first phase took place in wintertime. Lower generator/evaporator temperature than those used for planning were a consequence of the lower-than-expected flow rate of oily steam. Therefore, lower than planned absorber outlet temperatures were measured in this first phase.

</table>

The table also includes the range of values registered for the upgraded heat flow rate, Qa, and the thermal coefficient of performance COP, that is the ratio between the upgraded heat and the driving heat transferred at the evaporator QG and generator Qc.

Although the COP value remains practically constant at around 0.5, the heat flow rate varies between 218 and 248 kW. As shown in Table 1, the design value of the upgraded heat flow rate, 200 kW, is smaller than the measured values, but the operating conditions in the monitored period are different than the design ones.

The main difference found in the operating conditions is on the T0 circuit: although the system was designed for cooling water temperature of 25 °C, the temperature from the cooling water network of the plant was mainly in the range between 16 and 22 °C. Additionally, the system was designed for temperatures at the absorber circuit T2 higher than those at which it has operated for most of the time. The reason for this is that the recirculation valve adjusting the absorber temperature in circuit T2 was not configured for the operation range required by the new cooling water conditions, and thus the set point value could only be achieved when the cooling water temperature approached its design value. The necessary adjustments of the control parameters of the absorption recirculation valve could not be made because the visit planned for parameter adjustment in March 2020 was cancelled due to the irradiation of the COVID-19 pandemic.

A set of 28 steady state points however have been obtained from the first operation phase. Each steady state correspond to a monitored operation period of the system of at least 60 minutes with no relevant change in temperature or flow rate at the three external circuits T0, T1 and T2.
The upgraded heat flow rate and coefficient of performance are presented in the Figure 2 against the cooling water inlet temperatures $T_{0,\text{in}} = T_{0,\text{in}}$. As the Figure 2 shows, most of the monitored points correspond to points with driving temperature $T_{1,\text{in}}$ in the range between 87 and 89 °C and condenser inlet temperatures $T_{0,\text{in}}$ between 16 and 22 °C. As it was presented in [6] for the results of the first laboratory prototype, for constant values for $T_{1,\text{in}}$ and $T_{2,\text{in}}$, a decrease of the absorber capacity or heat flow rate $Q_2$ is expected with increasing $T_{0,\text{in}}$. Although a tendency trend can be observed for this results, no conclusions can be obtained since neither $T_{1,\text{in}}$ nor $T_{2,\text{in}}$ are constant for these measurements.

On the lower section of the figures, the COP values are presented. The values remain constant at a value around 0.50 with the exception of one point with $T_{1,\text{in}}=95$ °C, $T_{0,\text{in}}=16$ °C and $T_{2,\text{out}}=134$ °C (COP=0.42).

For another point with $T_{1,\text{in}}=95$ °C, $T_{0,\text{in}}=18$ °C and $T_{2,\text{out}}=132$ °C however, the monitored COP value was 0.51. For most of the cases, the COP measured for the system is larger than the expected one for the design conditions at around 0.48.

![Figure 2. AHT heat upgrade capacity and COP vs the condenser inlet temperature](image-url)

In order to have a better overview of the operation map of the AHT during the monitored period, the Absorber capacity $Q_a$ and thermal COP values are plotted against the temperature of glycol leaving the absorber $T_{2,\text{out}}$ in Figure 3.
The results of Figure 3 reveal that the AHT has been operating in the monitored period for most of the time with temperatures $t_{2\text{out}}$ between 122 and 123 °C. The diagram also shows, that the AHT is able to operate with delivery temperatures of 132 and 134 °C and heat upgrade capacities between 220 and 240 kW. Due to the difficulties in the control of the valves in the absorber circuit previously mentioned, no measurement values are yet obtained for delivery temperatures $t_{2\text{out}}$ at the design temperature 140 °C. The COP values presented in the lower part of Figure 3 show that the only point measured with a lower COP correspond to the highest delivery temperature $T_{2\text{out}}$. Although this could be intuitively be interpreted as a correlation of $T_{2\text{out}}$ and COP, this makes no sense and would contradict the experimental results presented in [6] and [8], that show that COP higher than 0.45 can be obtained with $T_{2\text{out}}$ as high as 138 °C. More likely, the measurement with the lowest COP correspond to a measurement with NC-gases present in the system [9].

Fig. 3. AHT heat upgrade capacity and COP vs the absorber outlet temperature
3.2. Comparison with laboratory prototype

The results presented in Figures 2 and 3 have been compared with the results previously measured at the laboratory under controlled conditions and presented in [6] and [8]. The measurement results of the first prototype developed within the Indus3Es project have been previously presented in the 12th HPC Conference [6] showing the dependances of absorber capacity and COP with the external circuit temperatures. The measurement results of the second prototype (pr II) developed in the project has been presented in [7] analyzing its differences with those of prototype I. The measurement results of this prototype pr II have been filtered and analyzed in detail in [8], being used also to validate and update the characteristic equation model of an absorption heat transformer.

Fig. 4. AHT Absorber capacity and COP compared to that of the laboratory prototype pr II
The characteristic equation model has been previously used for the upscaling process from the lab scale prototype to the 200 kW industrial prototype. The model can also be used to analyze deviations between the expected performance of the AHT and the monitored results.

As it is presented in Table 2, the laboratory prototype has been upscaled by enlarging the total heat exchanger area of the absorber \((A_A)\) by a factor of around 5. The relations between the heat exchanger area of the absorber and those of evaporator, absorber and condenser of the pilot scale prototype is the same as that of the laboratory prototype, and the solution flow rate and external heat carrier flow rates have been set in order to have equal heat transfer rates at each exchanger.

With these assumptions, it has been expected that the specific heat upgrade capacity of the AHT expressed in \(\text{kW/m}^2\) absorber can be predicted by the characteristic equation line presented in [8].

In the Figure 4, specific absorber capacity and COP of the systems are plotted against the driving temperature difference \(\Delta t\), that can be defined as presented in equation (1). \(\Delta t\) is the double temperature difference and expresses the driving potential of the AHT for heat upgrade. (R is a constant around 1.15).

\[
\Delta t = (t_{\text{gen}} - t_{\text{abs}}) - R \cdot (t_{\text{con}} - t_{\text{eva}}) = R \cdot (t_1 - t_0) - (t_2 - t_1) \quad (1)
\]

As presented in Figure 4, the driving temperature differences during the monitored operation of the AHT are much larger than expected (between 36 and 48 K instead of 30 K). Therefore, the absorber capacities measured for the AHT are larger than the design value. The Figure 4 reveals however, that the heat flow measured are between 12 and 20 % smaller than those calculated by the characteristic equation model.

The difference between measured and expected capacity could be the consequence of two causes. On the one hand, the dissipation temperature in the condenser was lower than expected in most of the cases. There is scientific evidence that the lower the pressure of the lower pressure vessel, the influence of the NC gases could be increased, which would result in the decrease of the performance [9]. On the other hand, the solution flow rate in these tests was 13 % lower than the one defined from the design phase. During the design phase, the flow rate was set to have the same specific flow rate along the tube’s length. Because of cavitation risk, the solution flow rate was set to about 2600 kg h\(^{-1}\), representing a decrease of the 13 %.

The lower diagram on Figure 4 on the other side, explains why the monitored COP values are practically constant. The characteristic equation method predicts that as the absorber capacity increases, the impact of the heat losses and other inefficiencies present in the absorption cycle is reduced, and thus for large \(\Delta t\) values the COP remain practically constant. The monitored COP values exceeding expectations may be due to measurement inaccuracies (uncertainties in the COP of 0.05 have been determined from the uncertainties in the determination of \(Q_A\), \(Q_G\) and \(Q_C\) in the range between 13.9 and 36.0 kW as shown in Figures 2 and 3).

### 3.3. Improved performance using an adiabatic absorption chamber

One technical innovation included with the AHT Pilot Scale Prototype is the two-chamber absorption design with a separated adiabatic absorption chamber with atomizing spray nozzles distribution system. This design has been adapted to increase the contact area of the solution and vapor in the absorber and optimize the adiabatic absorption process increasing the residence time of the solution. This can be done by atomizing the solution into small droplets, as it happens in the dedicated adiabatic absorption chamber installed before the solution distribution system based on a conventional dropping tray as in the lab scale prototype.
This dedicated adiabatic absorption chamber (AA chamber in Fig.5) can be bypassed and cut-off from the system by means of a controlled valve. This valve has been added in order to isolate the adiabatic absorption chamber when desired and analyze its contribution separately.

During the second monitoring phase of the system the AHT was set to work under adiabatic mode. In this second monitoring phase both the installed adiabatic-absorption-vessel and the traditional absorber with distribution tray were in operation, while in the previously presented results.

The performance of the AHT in the second monitoring phase using the adiabatic absorption chamber (AAC) was significantly improved compared to that of the first measurements. It is estimated that the revalorization capacity of the AHT using the AAC is about 12% higher comparing to the non-adiabatic mode, as it is shown in Fig.6. The black triangles symbols correspond to results using the AAC, and the empty circles to results without using it. The main advantage of the use of the AAV is the increase of the temperature entering to the absorber’s tube bundle. With higher temperature at the first row of the tubes, higher temperature energy could be transferred to the external circuit. During the tests performed, it was estimated that the 13% of the absorption rate occurs in the AAC, increasing in about 20 K the entering solution temperature.

![Absorber Capacity / kW](image1)

![COP / -](image2)

Fig. 6. Pilot Scale AHT absorber capacity and COP under Non-adiabatic(○) and Adiabatic(▲) modes.

4. Dynamic behavior of the absorption heat transformer

Although the parameters of the controller of the heat upgrade system could not be adjusted within the lifetime of the project due to the irruption of the COVID pandemic the control system demonstrated that the heat system could operate autonomously adjusting the outlet temperature at the absorber of the AHT, at the given set point. Figure 7 presents continuous monitored data of the AHT operating between the 19 and 24 of February 2020.

The control system adjusts valves in the circuits in order to maintain $T_{2\text{out}}$ at either 120, 125 and 130 °C. Therefore, the flow rate at the absorber circuit $T_2$ experiments relatively strong variations. The flow rates at Generator, Evaporator and Demin Water circuits are kept constant but the efforts made in the heat rejection circuit to change the value of $T_{0\text{in}}$ are sterile, although the flow rate at the condenser suffer strong variations. The main oscillations in the driving heat Temperature $T_1$ are due to oscillations in the flow non-monitored flow rate of oily steam entering the condensing heat exchanger HX-6.
These oscillations are the main difficulty to overcome to find steady state conditions for the analysis of the system and its comparison with the laboratory measurements. Only when this oscillation stops could steady state periods longer than 60 minutes be analyzed as have been presented in the previous figures.

However, although a good comparison between steady state conditions is only possible for some points the results presented in Figure 7 show that the upgraded heat flow rate supplied by the AHT have been continuously above the design value of 200 kW, achieving at moments 270 kW.

5. Final considerations and conclusions

This paper has presented and analyzed the monitored performance of an absorption heat transformer with a design capacity of 200 kW for upgrading heat with up to 140 °C with a driving heat temperature of 95 °C. The monitored results presented a very stable thermal coefficient of performance (useful to driving heat ratio) of around 0.50, but with an uncertainty of around 0.05. The measured upgraded heat flow rates are between 218 and 270 kW for heat upgrade temperatures between 115 and 138 °C, with driving heat temperatures between 88 and 95 °C. The higher-than-expected measured flow rates are due to more convenient conditions than predicted for the operation. The performance is however somehow lower than expected, although some hypothesis can be formulated for this deviation. The use of the innovative adiabatic absorption chamber, on the other side, increases the performance by around 10%.

The pilot plant prototype also included an innovative motor-less non-condensable (NC) gases purge system solution that due to time limitation within the project and irruption of the COVID Pandemic could not be tested within the project. Additionally, the system a control strategy which prevents the cycle from moving into risky operational conditions. The advanced control system ensures safe operation of the heat transformer minimizing the risk of crystallization while it optimizes the performance characteristics. The control strategies used for the chillers implies the modification of current optimization models. The Characteristic Equation Method has been used for the definition of the control system [5]. The advantages of these technological innovations have not been discussed within this work.
The economical performance of a ready-to-market system with this capacity has been discussed in [10] based on the performance results presented in this work. It concluded that the total cost of the system implementation would be about 420,000 €, i.e. about 1,500 €/kW revalorized by the AHT, and that the investment would be completely recovered within 6 years. If the total considered installation would include a 600 kW prototype, the payback period would be reduced to 3 years, and to 2 years in case 1.2 MW AHT is considered.

Abstract

The benefit of ultra-low temperature district heating systems (ULTDH) is their low supply temperature, which increases the heat generation efficiency and significantly reduces the heat loss of the DH network. The present study proposed a dual-effect heat pump system, which in combination of the ULTDH network, fulfills both, comfort floor cooling/heating and domestic hot water (DHW) demands. Depending on the operation the ULTDH system is used as a heat source, DHW preparation, or as a heat sink in cooling operation mode. The application potential of the proposed heat pump unit used for comfort floor cooling has been validated. The cooling experimental tests were performed under designed conditions with fixed heat source temperature (22 °C) and different heat sink temperatures, simulating either DHW preparation or delivering the surplus heat to the ULTDH network. The coefficient of performance (COP) of the dual-effect heat pump system varied from 2.22 to 2.81 in cooling mode, and from 3.0 to 3.4 in heating mode. The cooling capacity ranged from 2.9 kW to 3.4 kW and heating capacity ranged from 3.8 kW to 4.4 kW.

1. Introduction

The amount of energy used for heating and domestic hot water (DHW) is high and will keep increasing [1]. Combined cooling and heating systems can achieve efficient utilization of resources and energy through heat recovery, which is providing sustainable solutions to global warming and the energy crisis [2]. A novel compression/ejection transcritical CO\textsubscript{2} heat pump system for simultaneous cooling and heating can realize the utilization of geothermal energy and solar energy [3]. Heat pumps for simultaneous heating and cooling appear as interesting solutions for electric energy saving and residential buildings with a specific mode for DHW production. An air-source heat pump has been investigated by Byrne and Ghoubali [4], which shows a good potential in producing of hot water and chilled air simultaneously.

The idea of the present study is to indicate the performance and application potential of small heat pump used in household comfort floor cooling and domestic hot water supply. Thus, a comfort cooling heat pump prototype has been set up at Technical University of Denmark (DTU) to conduct the investigation experimentally. Thermal behavior of a small heat pump unit with R134a as working refrigerant has been analyzed based on experimental results. The experimental tests were performed under design conditions: different inlet temperature for the heat source, and a fixed inlet temperature for heat sink, which corresponds to the district heating temperature supply and comfort floor cooling temperature. The variations of the heat pump operation for different temperature combinations of district heat water are outlined. The operation parameters are: 3 kW cooling capacity (50 W/m\textsuperscript{2} for 40 m\textsuperscript{2} room area), with a water temperature inflow of 17 °C and return of 22 °C.

The application potential of the proposed heat pump unit used for comfort floor cooling has been validated experimentally. Thermal behavior and exergy performance of this small heat pump unit have been analyzed. The variations in heat pump operation under different temperature combinations of DHW are outlined. The structure of this paper is summarized as follows. In Section 2, the experimental setup and the configuration of a comfort cooling heat pump system are introduced. Then, the energy and exergy analysis method to assess the performance of the proposed system has been conducted in Section 3. In Section 4, the results are discussed considering the application scenarios. Finally, the conclusions are summarized in Section 5.

2. Experimental setup and configuration description

2.1. Testing system

The heat pump experimental set up installed in DTU is designed for the application of floor comfort cooling and DHW in the DH system (Fig.1 and Fig.2). The test rig includes four sub-systems: a secondary water cycle to illustrate the DHW system and comfort floor cooling system, a refrigerant cycle with R134a as working medium, a shunt-system and a cooling system to regulate designed test temperatures. The main information of each component is listed in Table 1. The selection of each component is calculated based on heating/cooling capacity using Danfoss calculation software.

2.2. Operation conditions

A baseline heat pump system loop (1-2-3-4) used for comfort floor cooling and domestic hot water supply is sketched in Fig. 3, which consists of a compressor, a condenser, an expansion valve, and an evaporator. The dynamic process of refrigerant includes: the saturated refrigerant vapor is compressed, increasing both temperature and pressure. Subsequently, the working liquid is cooled by the water-refrigerant heat exchanger of the condenser. Afterwards, before entering the evaporator, the refrigerant turns into two-phase fluid by passing through the expansion valve. Finally, the refrigerant flows back to the compressor and the cycle is finished.

The tested parameters are listed in Table 2.

The operation conditions are chosen as below,
1) Temperature control (by electric heater and adjusting valve in the shunting system)
2) Flow control (control system to adjust valve in each of the condenser and evaporator cycle)

Parameters setting listed as,
1) Inlet water temperature of the condenser: 30 °C, 35 °C, 40 °C, 45 °C, 48.5 °C;
2) Inlet water temperature of the evaporator: 22 °C–27 °C.

Experiments have been conducted on different combinations of cooling and heating temperature. Table 2 summaries the test cases.
3. Energy and exergy analysis method

3.1. Coefficient of performance (COP) of the heat pump

Due to the compressor heat loss, pipe heat loss, the temperature difference of heat transfer in evaporator and the condenser, pressure drop, and several other irreversible factors, the actual COP of the heat pump cannot reach the value of an ideal cycle. Therefore, the formula of the studied heat pump COP is,

\[ \text{COP}_{\text{heating}} = \frac{\dot{Q}_c}{W} \]

\[ \text{COP}_{\text{cooling}} = \frac{\dot{Q}_e}{W} \]

\[ \dot{Q}_c = c_p \dot{m}_e (T_{e,i} - T_{c,o}) \]

\[ \dot{Q}_e = c_p \dot{m}_e (T_{c,e} - T_{e,o}) \]

where \( \dot{Q}_c \) [kW] is the released heat of condenser/heat capacity; \( \dot{Q}_e \) [kW] is the cooling capacity of the evaporator; \( W \) [kW] is the power of compressor; \( c_p \) [kJ/kg] is the specific heat capacity at constant of water; \( \dot{m}_e \) [kg/s] is the water mass flow rate in the evaporator; \( \dot{m}_e \) [kg/s] is the water mass flow rate in the condenser; \( T_{e,i} \) [K] is the inlet water temperature of the evaporator; \( T_{c,i} \) [K] is the inlet water temperature of the condenser; \( T_{e,o} \) [K] is the outlet water temperature of the evaporator; \( T_{c,o} \) [K] is the outlet water temperature of the evaporator; Figure 1 below is an example which authors may find useful.

The cooling and heating dual-effect coefficient of performance (COP\text{\textsubscript{dual}}) has been used to characterize the efficiency of the system. The measure can be defined as the sum of the absolute values of heating and cooling capacity divided by the input power,

\[ \text{COP}_{\text{dual}} = \left| \frac{\dot{Q}_{\text{cooling}} + \dot{Q}_{\text{heating}}}{W} \right| \]

The second-law efficiency of the heat pump at the dual-effect heating and cooling working condition, \( \eta_{\text{II,\text{dual}}} \) can be defined as [5],

\[ \eta_{\text{II,\text{dual}}} = \frac{\text{COP}_{\text{dual}}}{\text{COP}_{\text{dual,\text{ideal}}}} \]

\[ \text{COP}_{\text{dual,\text{ideal}}} = \frac{T_{c,w} + T_{e,w}}{T_{c,w} - T_{e,w}} \]

where \( T_{c,w} \) and \( T_{e,w} \) are average temperatures of heat supply (hot water flow through the condenser and chilled water flow through the evaporator, which are given by Eq. (8) and Eq. (9).

\[ T_{e,w} = \frac{h_{c,o} - h_{e,i}}{s_{c,o} - s_{e,i}} \]
\[ \hat{T}_{ew} = \frac{h_{e1} - h_{e,0}}{s_{e1} - s_{e,0}} \]  

(9)

### 3.2. Exergy analysis

Compared to conventional energy analysis, the exergy analysis can accurately pinpoint the location of inefficiencies and quantitatively characterize the thermodynamic imperfection of heat transfer process and the possibility for thermodynamic development for heat pump system [6]. Thus, based on the typical thermodynamic cycle of the studied dual-effect HP (Fig. 3 pressure–enthalpy diagram) an exergy evaluation has been carried out corresponding to the exergy flow of each component. The measured quantities of the refrigerant cycle in the present study are temperatures on condenser side and pressures on both sides. The enthalpy value of the refrigerant at each state point (point Nr. 1, 2, 3 and 4, see Fig. 3) can be calculated by REFPROP 10.0 software [7] with the pressure and temperature data recorded in the testing process.

The exergy balance equations of the heat pump components were described in agreement with the work of Rijs and Mróz [8] by

\[ \dot{E}_{in} - \dot{E}_{out} = \Delta \dot{E}_{\text{component}} \]  

(10)

where, \( \dot{E}_{in} \) [kW] is flux of exergy entering the studied thermodynamically open system; \( \dot{E}_{out} \) [kW] is flux of exergy leaving the studied thermodynamically open system; \( \Delta \dot{E}_{\text{component}} \) [kW] is the exergy loss and destruction occurring in the component.

The exergy balance equations of each component can be calculated as,

\[ \Delta \dot{E}_{\text{comp}} = \dot{m}_r(h_1 - h_2 - T_0(s_1 - s_2)) + \dot{W} \]  

(11)

\[ \Delta \dot{E}_{\text{cond}} = \dot{m}_c(h_2 - h_3 - T_0(s_2 - s_3)) + \dot{m}_c c_p(T_{ci} - T_{co} - T_0 \ln \frac{T_{ci}}{T_{co}}) \]  

(12)

\[ \Delta \dot{E}_{\text{TXV}} = \dot{m}_c(h_3 - h_4 - T_0(s_3 - s_4)) \]  

(13)

\[ \Delta \dot{E}_{\text{evap}} = \dot{m}_r(h_4 - h_5 - T_0(s_4 - s_1)) + \dot{m}_c c_p(T_{ei} - T_{eo} - T_0 \ln \frac{T_{ei}}{T_{eo}}) \]  

(14)

where, \( T_0 \) [K] is dead state temperature, (K); \( \dot{m}_r \) [kg/s] is refrigerant mass flow rate of the heat pump cycle, (kg/s);

The exergy efficiency of the heat pump system writes,

\[ \eta_{ex} = \frac{\dot{E}_{\text{use}}}{\dot{W} + \Delta \dot{E}_{\text{HS}}} \]  

(15)

where

\[ \dot{E}_{\text{use}} = \dot{m}_c c_w(T_{co} - T_{ci} - T_0 \ln \frac{T_{co}}{T_{ci}}) \]  

(16)

\[ \Delta \dot{E}_{\text{HS}} = \dot{m}_c c_w(T_{ei} - T_{eo} - T_0 \ln \frac{T_{ei}}{T_{eo}}) \]  

(17)

where \( \eta_{ex} \) exergy efficiency of the heat pump system; \( \dot{E}_{\text{use}} \) [kW] is useable exergy, which is the physical exergy of the heated water via condenser; \( \Delta \dot{E}_{\text{HS}} \) [kW] is exergy change flux of external heat source.

### 3. Results and discussion

#### 3.1. Uncertainty

The temperature, pressure, mass flow, and power consumption were measured using the instruments specified in Section 2.1. The method proposed by Moffat [9] was used to calculate the maximum relative uncertainties of the experimental data (Equation 18). The relative uncertainty of COP arising with respect to the considered parameters are given by the following correlation [10],

\[ \delta R = \left[ \sum_{i=1}^{n} \left( \frac{\delta R}{\delta x_i} \right)^2 \right]^{1/2} \]  

(18)

\[ \delta \text{COP}_{\text{heating}} = \left[ \frac{\Delta m_c}{m_c} \right]^2 + 2 \left( \frac{\Delta T_c}{T_{ci} - T_{co}} \right) \]  

(19)

𝛿COPcooling = [(

∆𝑚̇e 2
𝑚̇e

) + 2(

2 1/2

∆𝑇𝑒
𝑇𝑒,𝑖 −𝑇𝑒,𝑜

) ]

(20)

Energy balances have been calculated based on the measured data, all of them were within the acceptable
range. Thus, the measurements are reliable. Both water flow rate of condenser and evaporator were measured
by ISOMAG-ML210 electromagnetic flowmeter with an accuracy of ±0.2 % and a range of 0 kg/s to 0.288
kg/s in the present study. The temperatures were measured by Type T thermocouples with an accuracy of
±0.5 ℃. The range of condenser side temperatures is from 29 ℃ to 62 ℃, thus, its maximum uncertainty was
1.6%; and for the evaporator side is from 15 ℃ to 36 ℃. Thus, its maximum uncertainty was 2.4 %. The
maximum uncertainty in COPheating and COPcooling were 2.3 % and 3.4%, respectively.

3.2. Thermal performance

Under the proposed operation conditions of simultaneous cooling and heating the temperature of the hot water stream is increased by the heat release from the condenser while cooling down the temperature of cold water stream returned from the floor cooling system. The required temperature of the chilled/hot water differs depending on the demand, and thus sets the operation parameters of the heat pump and determines its efficiency.

Figure 5 summarizes the operation conditions of condenser and evaporator inlet and outlet temperature for the 25 test cases investigated in this study. The colour coding is according to the \( \text{COP}_{\text{dual}} \) reached under these operation conditions (See the colour bar at the bottom of Figure 5). While Fig. 5a provides a complete overview of the tests, subfigures b-d display specific groups which will be discussed in the following paragraphs in a more detailed manner.

Fig. 5 Operation conditions of condenser and evaporator inlet and outlet temperature for the 25 test cases.
All cases displayed in Figure 5b have a low evaporator inlet temperature of 22 °C and an outlet temperature of 17 °C in common. They differ in the water temperature lift on the condenser side. Case 8 exhibits the highest COP dual with a value of 6.79, which results from the low temperature lift from 35.9 °C to 46.7 °C in the condenser. The lowest COP dual is measured for case 21, caused by the high temperature lift from 34.2 °C to 60.0 °C. Increasing the temperature from 30 °C to 60 °C (case 4) results in a higher COP dual. Both cases have a similar pressure level in the compressor. The difference in COP dual is mainly attributed to the lower subcooling temperature reached in case 4 (12.9 K) compared to the subcooling temperature of 7.0 K in case 21. The same effect of the higher subcooling temperature is observed in a comparison of case 1 and case 3. Although the condenser outlet temperature is significantly higher for case 3 (57.0 °C) compared to case 1 (48.9 °C), the COP dual is 0.1 points higher for case 3. Note the subcooling for case 3 is 10.9 K while this is only 5.3 K for case 1.

Figure 5c illustrates a second subset of cases. Note that case 18 and 22 have almost the identical inlet and outlet temperatures. Nevertheless, the measured value of the COP dual varies between 5.8 and 6.1, which is in the range of the measurement accuracy (5% difference), mainly caused by the given accuracy of the measured power consumption. Cases 11 and 25 both exhibit a high COP dual. In case 25, the evaporator inlet temperature is high (35.4 °C) but also the evaporator outlet temperature is high (22.6 °C). The superheating in the evaporator is 7.0 K at a saturation temperature of 17.6 °C. For case 11, the evaporator inlet temperature is 23.6 °C and the outlet temperature is only 19.3 °C. Due to the low temperatures, also the superheating in the evaporator is with 2.5 K low. The high efficiency is caused by the low temperature at the condenser outlet of 54.2 °C. It reveals that a high temperature difference between condenser inlet and outlet temperature is beneficial for the COP due to the increased effect of subcooling and the higher subcooling temperature that can be achieved.

All cases shown in Figure 5d have same evaporator drop of around 5 °C. The highest COP dual is measured for case 10, caused by the high evaporator inlet temperature of 22.7 °C. Compared with case 15, case 10 has a higher temperature lift from 40.3 °C to 55.4 °C, measured a lower superheating of 1.9 K and a higher subcooling of 7.2 K, which results in a higher COP dual of 6.22. Case 12 exhibits the lowest COP dual with a value of 5.84, which results from the lowest subcooling (3.7 K) among these compared four cases and the high temperature lift from 39.4 °C to 53.6 °C in the condenser. Case 15 has a lower temperature lift from 40.0 °C to 50.0 °C and a lower condenser outlet temperature (50.0 °C) than case 12, causing a high COP dual of 6.19.

Figure 6 summarizes the exergy and second-law efficiency under operation conditions of condenser and evaporator inlet and outlet temperature for the 25 test cases investigated in the present study. The colour coding is according to the exergy efficiency ($\eta_{ex}$)/second-law efficiency ($\eta_{II,dual}$) reached under these operation conditions. Exergy efficiency is obtained by dividing the useful exergy gained from condenser by input exergy (Eq. (15)).
Figure 6a shows an exergy efficiency distribution of the studied cases. Figure 6a shows that when the evaporator water inlet temperature ranged from 21.9 °C to 35.4 °C, the exergy efficiency varied from 14.8 to 26.9 %. The exergy efficiency increases with the increase of heat source temperature, which directly reflects the quality of the input energy. The decrease in the exergy efficiency is mainly attributed to the increase in compressor power with superheating degrees. Although Case 25 has a higher heat source temperature in the evaporator side, the temperature difference between inlet and outlet is also high. As the temperature difference increases, the irreversibility of the heat transfer process of evaporator increases, which results in a higher exergy loss corresponding a lower exergy efficiency than cases 18, 22 and 23.

The second-law efficiency of the simultaneous cooling and heating heat pump has been drawn in Fig. 6b based on the experimental results. Second-law efficiency achieved its maximum value at 28.2 % corresponding to a low temperature lift of condenser side and high temperature of DHW. Although the second law efficiency also shows the irreversibility of the system, different from exergy efficiency discussed above, $\eta_{\text{II,dual}}$ used in the present paper takes the useful output of COP_{cooling} into consideration, which is numerically higher than exergy efficiency. Case 25 shows that the lower second-law efficiency ($\eta_{\text{II,dual}}$) is caused by a higher heat source temperature, with a very high ideal COP_{dual} such that $\eta_{\text{II,dual}}$ is significantly reduced to the corresponding 22.5 %.

3.3. Exergy efficiency

The performance of operation conditions with different heat sink temperatures have been studied experimentally. Mass flow rate of the comfort floor cooling water is fixed during testing these working conditions ($m_\text{s}=0.138$ kg/s). Figure 9 shows five different working conditions with different DHW supply temperatures. The exergy and second law efficiency are highly influenced by the temperature of condenser side. Thus, an increment of the DHW temperature produces an increase of the energy quality and therefore, an increase of the efficiency. However, with the increase of DHW temperature, condensation temperature rises gradually, which make the system COP drop correspondingly.

Figure 9 also shows the exergy destruction ratio of each component in the studied simultaneous heat pump system. It can be found that the higher the temperature difference between inlet and outlet temperature of DHW, the lower the compressor exergy destruction ratio. The higher the temperature lift in the condenser side, the higher exergy destruction ratio of the condenser. The condenser side will be the potential component to improve the performance by decreasing the temperature lift when the evaporator side is fixed.

![Exergy destruction ratio, Exergy and second law efficiency, (%)](image_url)

Fig. 9. Effect of temperature difference on DHW side on heat pump system simultaneous performance.
4. Conclusions

A prototype of a water-source heat pump for simultaneous heating and comfort floor cooling was built and tested. Based on the experimental results discussed above, the main conclusions of the present study on steady state behavior of the proposed BHP can be drawn as follows,

- It can be found that the COP heating value varies from 3.0 to 3.4 in the studied conditions, and the COP cooling value ranged from 2.22 to 2.81. Test results showed that the cooling capacity ranged from 2.9 kW to 3.4 kW, heating capacity ranged from 3.8 kW to 4.4 kW.
- The lower domestic water temperature and higher temperature lift in the condenser can achieve a higher COP heating under the studied conditions with fixed cooling settings. A high temperature difference between condenser inlet and outlet temperature is beneficial for the COP dual due to the increased effect of subcooling and the higher subcooling temperature that can be achieved.
- For each cooling load, there exists a corresponding heating capacity area, which can be used to regulate the system to operate at high efficiency. The highest dual-effect COP of the studied is 6.79. The second-law efficiency of the simultaneous DHW heating and floor cooling can reach 28.2% within the studied range.
- The next step is to do the study with ratio of simultaneous DHW heating and cooling needs into consideration. System performance under non-synchronized DHW and cooling demands.

Performance evaluation of multi-functional cascade heat pump system for a residential building

Beom-Jun Kim, Hye-Jin Cho, Soo-Jin Lee, Taek-Don Kwon, Jae-Weon Jeong

*Department of Architectural Engineering, College of Engineering, Hanyang University, Seoul, Republic of Korea

Abstract

With increasing fossil fuel usage in building air-conditioning systems, air-source heat-pump systems are in the spotlight as an alternative HVAC system to reduce carbon emissions. The aim of this study is to evaluate a multi-functional cascade heat pump system for a residential building. A design method suited in residential buildings was applied to evaluate system performance of the proposed system. A reference system as separate two heat pumps was selected in charge of cooling, heating and hot water supply. The target building was set to residential of 100m², 5 occupants are in the building. The thermal load of the target building was derived with commercial transient simulation tool, thermodynamic equations, and model equations built-in EnergyPlus were used. As a result, the proposed system saves 13% energy in cooling mode and 10% in heating mode compared with the reference system. The energy saving effect was occurred at the compression ratio of each high- and low-cycle decreasing due to the effect of recovering unused waste heat in summer and increasing the temperature of the refrigerant in winter.

Keywords: Cascade heat pump; Air-source; Multi-functional system; Building energy-saving; Residential building

1. Introduction

With increasing fossil fuel usage in building air-conditioning systems, air-source heat-pump systems are in the spotlight as an alternative HVAC system to reduce carbon emissions [1]. Heat pump technology can treat indoor air condition and heat domestic hot water through heat absorption in an evaporator and heat dissipation in a condenser [2]. The absorbed heat by the evaporator for indoor cooling should be discharged to outdoor air. In contrast, and the heat should be absorbed from heat sources by the evaporator for indoor or water heating. If the temperature of the heat source is in an extremely low state or the load side requires a high temperature, the temperature difference between the evaporator-condenser increases, which can put a heavy load on the compressor. This may cause problems in that energy consumption increases and system efficiency decreases.

This problem can be solved by reducing the compressor load in each cycle by using a cascade type multi-stage heat pump system. If the heat absorption and heat emission properties of each cycle of the cascade heat pump system are used well, it has the potential to be used as a multi-functional system for zone cooling, heating, and domestic hot water in the building. The previous studies on cascade heat pumps have conducted experimental system performance analysis or optimization according to the refrigerant charging amount and expansion valve opening rate [3,4]. However, the capacity calculation and energy simulation of the system reflects building design constraints, such as thermal load, have not conducted for the case of applying of cascade heat pump system to a building. Therefore, in this study, a design procedure for the application of multi-functional cascade heat pump system was presented, and energy simulation was conducted for a residential building that requires both heating and cooling and domestic hot water. An existing air-source heat pump system responsible for cooling, heating, and domestic hot water was set as a simulation comparison.

2. System overview

2.1. Cascade heat pump system

A cascade heat pump system consists of two heat pump cycles exchanging heat in an intermediate heat exchanger. The low-cycle of the system is in charge of the zone air-cooling, and the high-cycle heats domestic hot water for zone radiant floor heating and hot water supply. It was assumed that the refrigerant of the low-cycle heat pump was R410A, which is widely used in general air conditioners, and that of the high-cycle heat pump was R134a to supply high temperature heat [5]. The proposed cascade heat pump in Figure 1 is to supply zone cooling in the low-stage cycle in summer, and supplies hot water in the high-stage cycle in winter.

Fig. 1. Schematic of cascade heat pump system.

2.2. Reference heat pump system

In order to compare the performance of the proposed system, single heat pump systems were applied for each function required in a residential building [6]. The system to be compared is an air-source heat pump system as same as the proposed cascade heat pump system. A structure of the reference system is illustrated on Figure 2. The R410A refrigerant was used for the zone cooling cycle, and the R134a refrigerant was used for water heating cycles.

Fig. 2. Schematic of reference heat pump system.

3. Simulation overview

3.1. Sizing process logic

The sizing process algorithm for system capacity calculation was shown in Figure 3. First, design constraints for applying the system to residential buildings are set [7]. After the building information is determined according to the design constraints, the transient thermal-load simulation tool was used to calculate the thermal load of the model building [8]. The capacity of the low-cycle heat pump was determined.
preferentially based on the cooling peak load. Finally, the capacity of the high-cycle heat pump that can satisfy the peak load of heating and domestic hot water load was determined.

The parameters of each heat pump can be calculated by thermodynamic equations as follows (Eq.1-5):

\[
\dot{m}_{ref,LC} = \frac{\dot{Q}_{load,zone}}{\Delta h_{evap,LC}} \tag{1}
\]

\[
\dot{m}_{ref,HC} = \frac{\dot{Q}_{load,hw}}{\Delta h_{cond,HC}} \tag{2}
\]

\[
\dot{W}_{comp} = \dot{m}_{ref}\Delta h_{comp} \tag{3}
\]

\[
\dot{Q}_{cond} = \dot{m}_{ref}\Delta h_{cond} \tag{4}
\]

\[
\dot{Q}_{evap} = \dot{m}_{ref}\Delta h_{evap} \tag{5}
\]

3.2. System design constraint

The design constraints necessary to apply the cascade heat pump system to residential buildings were set as follows. First, the air conditioning supply conditions must be 15°C and 80% relative humidity. Second, the target water temperature for floor heating and domestic hot water supply is set to 60°C. Third, the calculated cooling, heating and hot water supply performance of the heat pump must satisfy both the building heat load derived through the heat load simulation tool. R410a refrigerant was used for the LC of the heat pump, and R134a refrigerant was used for high-temperature heat supply for HC. Compressor and heat exchanger efficiencies, which is defined as the ratio of the actual work performed to the work input, were assumed to be 0.75 and 0.8, respectively, and superheat and subcooling degrees were assumed to be ±5°C [9]. Lastly, it is assumed to operate at full load without partial load.
3.3. Building thermal load determination

The building information are shown in Table 1. A 3 m-high building of 100 m² was simulated through the TRNSYS program, and a total of 5 occupants were set based on the ASHRAE standard [10]. After calculating the building heat load, the indoor temperature and humidity conditions and the heat pump simulation were calculated through the EES program.

4. Simulation result

The results of this study were divided into 5 parameters and analyzed. There are capacity of the system derived from the results of the required thermal load simulation, the refrigerant and enthalpy difference by p-h plot, the system COP, waste heat recovery analysis, and primary energy consumption.

4.1. System design capacity

The thermodynamic simulation result of the heat load of the building was shown in Table 2 during peak load in summer and peak load in winter. The cooling cycle HP size was determined based on the summer peak load, and the heating and domestic hot water cycle size was determined based on the heating peak load and domestic hot water load in winter. The capacity of the heating and hot water cycles was designed after the capacity of the cooling cycle was pre-determined.

The designed capacity of cooling cycles, which refers the compressor power, were the same at 1.1 HP on both systems. However, the size of the cycles responsible for heating and domestic hot water was three times higher than the proposed system at 1.8 horsepower in the existing heat pump system.

4.2. p-h graph on peak day

First, to examine the behavior of the two systems, p-h diagrams were drawn for the two systems during peak load in summer, as shown in Figure 4. The low cycle, (i.e. the cooling cycle), showed the same cycle behavior in summer because the cooling operation of the two systems was the same. Since only domestic hot water was needed in summer, one can see that the thermal load is low, and the temperature difference between the evaporator-condenser of the blue-dash line is smaller. The refrigerant was same in both systems in cooling mode (i.e., 0.03018 kg/s of $\dot{m}_{ref}$). In contrasts, the cascade cycle in the hot water cycle needs more refrigerant (i.e., 0.00364 kg/s for cascade heat pump, 0.00350 kg/s for reference heat pump). As for the enthalpy difference, the heat absorption enthalpy difference of evaporator is large and the enthalpy difference in the compressor is small.

Figure 5 shows the system in the winter condition. Under the condition, only the cycle of the cascade heat pump was visible in that cycle. This is because the reference system does not perform cooling operation in winter. The cascade system should be run a low cycle even in winter for multi-stage temperature rise. In winter, both systems were operated at a high cycle because residential buildings require floor heating and domestic hot water. It can be seen that the temperature difference between the evaporator-condenser of the reference system was very large. However, when matching the thermal load of the target condenser at high cycle, the amount of refrigerant in the reference system is operated with a small amount, and the heat absorption enthalpy difference in the evaporator is also small. This is because it is difficult to absorb a lot of heat from the outdoor air because the outdoor temperature is very low in winter, and it can cause the enthalpy difference of the compressor is up to 4 times larger.

Therefore, Cascade heat pump system has a high heat absorption of evaporator in high-cycle (heating), which reduces the required input power of the compressor and reduces the overall energy consumption. As a result, the amount of work that goes into the compressor is greater with the reference system.
4.3. Coefficient of performance

Figure 6 reveals the total COP for each cycle of the heat pump, which was analyzed in 24 hours on the day when the cooling and heating peak load occurred. First, in the cooling mode, Hot water cycle showed higher COP in cascade heat pump system. The compressor load was low by receiving the waste heat of the low-stage cycle and supplying hot water with a higher heat source than the reference system. When operating in the cooling and hot water mode, the COP of the cascade heat pump was relatively high except for the cooling cycle. Conversely, in case of heating mode in winter, the cooling cycle of reference heat pump does not operate in winter, so the COP was zero. Each cycle COP of cascade heat pump is derived relatively high. When operating in heating and hot water mode, the COP of proposed system compared to reference system was relatively higher.

As a result of deriving seasonal COP, the result of high COP of cascade heat pump was derived in each season. This is thought to be the result of relatively low compressor energy consumption of the Cascade heat pump.

4.4. Waste heat recovery in summer

The amount of heat dissipation from the condenser of the cooling cycle in summer was 9621.4 kWh. In summer, the Cascade heat pump recovers heat from the low-stage cycle and uses it as a heat source for the high-stage cycle. About 18% of the waste heat was recovered.

4.5. Primary energy consumption

As a result of energy consumption analysis, along Figure 7, it was confirmed that the energy consumption of the proposed cascade heat pump system was lower than that of the reference system in both seasons. The
Cascade heat pump compared to the reference heat pump in energy consumption was confirmed to save energy by 13% when operating in cooling mode and 10% when operating in heating mode. In the cooling mode operation, there was no significant difference between the two systems in the cooling cycle, but a difference in energy consumption was confirmed in the hot water cycle.

In heating mode operation, the cascade heat pump system operated all cycles, but the total energy consumption was derived less than reference system, which was only operated with HW-Cycle and had any energy consumption of cooling compressor and outdoor fan. In the case of the fan, it was confirmed that the energy consumption of the reference system was slightly higher in the outdoor fan.

5. Conclusion

In this study, when the cascade heat pump system is applied to a building, the High-cycle capacity was determined after the low-cycle capacity is determined according to the cooling load. As a result of the energy simulation, it was confirmed that the energy consumption of the Cascade heat pump is superior to the reference heat pump system (i.e., cooling, heating, and hot water supply, respectively). The cooling season COP improved by 14% and the heating season COP by 22%. In addition, energy consumption during the cooling season was 13%, and energy consumption during the heating season was 10%, resulting in a total annual energy savings of 12%. This indicates that the Cascade heat pump system has a high heat absorption of evap. in the high-cycle (heating), and as a result, the input power required for the compressor is reduced, resulting in a decrease in total energy consumption and an increase in COP. In conclusion, it is considered that each heat pump compressor has a smaller energy load than the compressor of a single stage heat pump system due to waste heat recovery in summer and multi-stage temperature increase in winter. It is necessary to conduct experimental study through future work to validate the energy saving performance of the cascade heat pump system.

Abstract

A new alternative refrigerant has to be tested under real operating conditions to investigate its compatibility with lubricant oil, additives, seals, copper or any metal components and varnish in a compressor driving motor. In this study, oil compatibility characteristics of a low-GWP refrigerant as an alternative to R410A in a compressor test loop is preliminarily studied. To determine short and long-term lubricant oil compatibility of a low-GWP refrigerant in a compressor, a simple heat pump cycle test loop is designed and preliminarily tested under accelerated test protocol. R466A is selected as an alternative to R410A. A 6 hp of compressor for R410A, a 20 kW of condenser are selected. To reduce heat source capacity and to control inlet condition of a compressor, a shell type evaporator with a 15 kW electric heater is designed. An oil characteristic such as a viscosity and a decomposed ion using an ion chromatography are measured after each operation time schedule.

1. Introduction

In accordance with global carbon-neutral policies and refrigerant regulations to limit global temperature rise, alternative refrigerants with low global warming potential (GWP) and heat pump technology using them are being developed. System air conditioners used for heating and cooling homes and commercial buildings, that is, variable refrigerant flow (VRF) heat pumps, currently use HFC (hydrofluorocarbons) R410A refrigerant with a global warming potential of 2088. The US CARB (California Air Resource Board), which leads environmental regulations, plans to use refrigerants with a GWP of less than 750 for new residential and commercial products from 2025 and for VRF systems from 2026 \cite{1}. In addition, the European F-gas regulation stipulates that HFC refrigerant usage in 2030 be reduced by 79% compared to 2015, and from 2025, sales of single-split air conditioners with a refrigerant volume of 3 kg or less that uses a GWP of 750 or more refrigerant would be forbidden \cite{2}.

R410A is a mixed refrigerant composed of 50% R32 (CH\textsubscript{2}F\textsubscript{2}) and 50% R125 (C\textsubscript{2}HF\textsubscript{5}). A mixed refrigerant R466A which is composed of 49% R32, 11.5% R125, and 39.5% R13I1 (CF\textsubscript{3}I) was developed as a replacement of R410A by Honeywell who is one of the representative refrigerant manufacturers \cite{3}. The GWP of R466A is 733, and some manufacturers are developing systems for R466A as the safest A1 class refrigerant.

When a new refrigerant is developed, it is essential to evaluate its compatibility with lubricants, especially in compressors. Oil for lubrication is used in the compressor, and this oil serves not only to lubricate but also to cool frictional heat and motor heat. In addition, it serves as a sealing and anti-rust function in mechanical seals and piston rings. To this end, oil flows into the compressor together with the refrigerant, so the heat pump system can be stably operated only when an appropriate combination of new refrigerant and oil is configured.
As a representative method for evaluating refrigerant oil adequacy, the sample accelerated test technique of ASHRAE (American Society of Heating, Refrigerating and Air conditioning Engineers) standard 97-2007 is used [4]. It is a method of evaluating physical properties after sealing in a test tube mixed with oil in a 1:1 weight ratio and aging at a temperature of 175 °C for 14 days.

Oil and additives are screened through these sample tests, and reliability tests are conducted through actual system operation. R466A has similar physical properties and thermodynamic performance to R410A, and it has been announced in previous studies that the POE (Polyolester) oil used in R410A can be used [5], but the refrigerant-oil compatibility in actual heat pump system operation situation Experimental data are scarce. Therefore, in this study, for the alternative refrigerant R466A, not a sample test, but a core device such as a compressor constituting a heat pump system in an actual operating state, various parts such as valves, and refrigerant-oil compatibility and system reliability were evaluated. Therefore, key factors of the compatibility evaluation method were determined, cycle operating conditions were determined for the accelerated real operation test, and a compressor test loop was designed for the long-term reliability test.

2. Key factors for evaluating refrigerant-oil compatibility

In order to evaluate the suitability of refrigerant and oil, three evaluation factors were determined by referring to the existing literature [4] for the physical property index to be analyzed after deterioration due to long-term real operation of the system.

First, it is possible to evaluate the adequacy with the refrigerant by measuring the acidic product produced by the oxidation of oil as an index of TAN (Total Acid Number). Potentiometric titration using KOH (ASTM D 664) is used.

Second, the degree of decomposition of the refrigerant or oil can be grasped by analyzing the decomposition ions generated by the reaction between the refrigerant and oil as a decomposed ion indicator. When fluoride is detected, the refrigerant is decomposed, and when organic acids such as propanoate and hexanoate are detected, it can be evaluated that oil is decomposed. For this, ion chromatography is used.

Third, the compatibility can be evaluated by measuring the viscosity that decreases with the deterioration of the oil as a viscosity index. Viscosity is measured using a Brookfield viscometer (ASTM D 4402).

3. Previous researches on R466A-oil compatibility

Honeywell's sample accelerated test for R466A refrigerant under the condition of POE oil (ISO 32 3MAF) for R410A and additive combination According to the results of previous research, fluoride was detected at 50 ppm, 25 times higher than 2 ppm for R410A, in the R466A test, and iodide It has been reported that 22 ppm, which is hundreds of times greater than <0.1 ppm of R410A, is detected [6].

Accordingly, after a sample accelerated test in the same POE oil using additives whose components were not disclosed at Honeywell, it was shown that fluoride was 2 ppm and iodide was <1.5 ppm, and compatibility could be satisfied [6].

In addition, it was reported that R23(CF₃H) was decomposed and detected in the combination of zinc-aluminum alloy and R466A-POE base oil [7], and it was also shown that compatibility can be satisfied through the addition of additives. It is evaluated that the iodine component of CF₃I of R466A reacts with oil and zinc-based metal materials.

Some information on the additive material can be obtained from Honeywell's patent, which is a combination of alkylated naphthalene (NA-LUBE), farnesene (C₁₅H₂₄), a diene compound, and BHT (Butylated Hydroxi Toluene), a phenolic compound [8].

4. Test scenario for R466A oil compatibility evaluation in actual operation

In order to evaluate the oil suitability of R466A according to the actual long-term operation of the compressor, a heat pump test cycle was constructed and an operating scenario was determined.

In order to accelerate the deterioration by the refrigerant-oil reaction, test scenario of start-continuous operation (8 hours)-stop was determined under the AHRI (Air Conditioning, Heating and Refrigeration Institute) Standard 210/240 MOC (Maximum Operating Condition) condition or more harsh condition. In this operating condition, refrigerant-oil samples would be taken every 100 hours repeatedly and test loop would be operated for a cumulative 300 hours.

As shown in Table 1, the outdoor temperature standard under the MOC condition is 46.1 ℃, and the corresponding condensing temperature on the refrigerant side is 55.1 ℃, which is 9 ℃ higher by referring to Honeywell’s AHRI 210/240-A condition performance test reference [8], and the evaporative temperature was selected as 7 ℃. Superheating and subcooling were selected as 5.5 ℃.

Cycle design was carried out to derive compressor operating conditions under MOC operating conditions. The cycle was designed using an in-house code that can predict the heat pump design performance using the thermodynamic governing equation, and the calculation was performed using the mixture properties of REFPROP using the composition ratio of R466A.

In addition, calculations were performed for R410A under the same conditions. As shown in Fig. 1, the cycle operating conditions and performance of R466A and R410A under MOC conditions were predicted. The pressure loss was assumed to be 1% in the condenser and 8% in the evaporator.

As shown in Table 2, under the R466A MOC condition, the condensing temperature/pressure was 55.1 ℃/36.0 bar, the evaporative temperature/pressure was 7 ℃/10.6 bar, and the compressor discharge temperature was calculated as 100.1 ℃. Under R410A MOC conditions, the condensing temperature/pressure was 55.1 ℃/34.5 bar, the evaporative temperature/pressure was 7 ℃/9.9 bar, and the compressor discharge temperature was 92.3 ℃. Since the conditions are almost similar, commercial parts based on R410A were used when designing and manufacturing the actual test loop.

![Fig. 1. T-s (a) and P-h (b) charts of R410A and R466A cycles](image-url)
In this study, the main purpose is to evaluate the refrigerant-oil compatibility and reliability according to long-term cycle operation rather than cycle performance characteristics analysis, a simplified test loop for long-term operation was designed and manufactured

5. Design and construction of test loop

For the evaluation of compressor refrigerant-oil compatibility and reliability in accelerated operation, the test loop was designed as shown in Fig. 2. The core cycle devices such as the compressor, heat exchanger, and electronic expansion valve were selected with commercially available parts for R410A, and a rotary compressor with a capacity of 6 HP and an inverter control system was used. In order to simulate the MOC condition in the long term, we tried to simplify the heat source facilities corresponding to the secondary side of the condenser and evaporator. Therefore, after the compressor, working fluid is discharged (state 2), a bypass loop is placed before entering the condenser, so that the refrigerant that has passed through the condenser is expanded in the EEV (Electric Expansion Valve) 1, and the bypassed refrigerant passes through EEV2 and 3. After expansion, it was configured to be mixed in an evaporator. EEVs were selected with Danfoss’ R410A standard commercial product, and the bypass loop is composed of two loops to control the flow rate and expansion ratio fluctuations that may occur when R466A refrigerant is used in the valve. EEV2 and EEV3 are controlled by manual and/or remote signal by PLC controller.

The refrigerant that has passed through EEV1, EEV2, and EEV3 is introduced into a shell containing a 15 kW electric heater and mixed. This shell-type heater operates as an evaporator in order to control the evaporative temperature and superheat of the compressor easily because of uncertain characteristics of R466A. R466A is a mixed refrigerant of three types. In response to the temperature change that can occur during heat exchange, an electric heater that can directly control the temperature is used to allow only gaseous R466A to flow in from the compressor inlet, enabling stable testing.

A visualization window and an oil extraction valve were configured in the loop returning from the oil separator to the compressor after compressor discharge, so that oil sampling was possible, and a mass flowmeter (OVAL, ±0.1%) was installed on the compressor discharge side and the condenser rear side. A pressure gauge (Autrol) of ±0.075% was used at the inlet and outlet of the compressor, and a pressure gauge (Keller) of ±0.5% was used for other parts, and a Class A RTD was used for the temperature, and the pressure gage (Autrol) was used at the inlet and outlet of the compressor, and pressure gauge (Keller) was used for other parts.

6. Conclusions and Future works

For the R466A refrigerant of GWP 733, which replaces the R410A refrigerant of GWP 2088 currently used in commercial VRF systems, a test loop that can evaluate the compatibility and reliability of compressor refrigerant-oil that may occur during long-term actual operation was designed and manufactured.

First, TAN, decomposed ion, and viscosity were determined as indicators to be evaluated through the investigation of the refrigerant-oil compatibility evaluation method. Through previous research analysis, it was confirmed that the use of POE-type oil, the same as R410A, but the use of appropriate additives to suppress corrosion due to the influence of CF$_3$I included in R466A was necessary, and information on target additive candidates was investigated in the refrigerant manufacturer’s patents.

AHRI 210/240 MOC conditions that can simulate accelerated deterioration conditions were selected and the corresponding R466A cycle design was performed, and the cycle operating conditions of 10.6 bar in the low-pressure part, 36.4 bar in the high-pressure part, and 100.1 °C discharge temperature of the compressor were selected. Based on this, in order to simplify the long-term acceleration test, a test loop including a bypass loop after compressor discharge and a shell-type evaporator using an electric heater was designed and manufactured.

Currently, the test loop verification is in progress based on the R410A refrigerant, and after that, the R466A refrigerant drop-in test would be performed to analyze the change in the characteristics of the refrigerant and oil after long-term room operation, and the deterioration of the compressor and accessories.

Heat pump application approach to abate plume generation from a cooling tower

Gilbong Lee*, Junhyun Cho, Bong Su Choi, Bong Seong Oh, Ki-Chang Chang

Korea Institute of Energy Research, 152 Gajeong-ro, Yuseong-gu, Daejeon, 34129, Republic of Korea

Abstract

In Korea, white plume generated by cooling tower is a one of major social conflicts due to its visual pollution. Various methods have been developed to abate plume generation, such as outdoor air condensing, dry/wet hybrid cooling, membrane method, etc. However when cooling towers operate in cold climate without plume generation, both humidity ration and relative humidity have to be reduced with effective methods. Dehumidification and regeneration using heat pump cycle can be a good technical solution for this since it condense water vapor and then reheat the air with condensation heat and compressor power input. The required energy of a heat pump method is 3 to 4 times less than a direct heating method. For further energy reduction, an outdoor air mixing is introduced before heat pump stage and the power input can be reduced up to 10% compared to a direct heating.

Keywords: Cooling Tower; Heat Pump; Plume; Plume Prevention

1. Introduction

Stacks or cooling towers tend to exhaust plume when the outdoor temperature is low and relative humidity is high. The plume is literally water vapor and not environmentally harmful. However it may cause social conflicts due to visual pollution and misperception as fire or smoke [1, 2]. In addition, when the white smoke does not rise and spreads on the road, it may cause icing problems and sometimes cause traffic problems. For this reason, cooling tower plume abatement is one of the biggest technical issues in the related industry.

2. Plume abatement by applying a heat pump cycle

One of the most widely used methods to reduce plume generation from cooling towers is outdoor air mixing method in which exhaust wet air is firstly dry-cooled by lower temperature outdoor air while discharging thermal energy to the outdoor air and reducing water vapor intake. Then the two air streams are mixed together and the humidity ratio and relative humidity of the discharged air of cooling tower are decreased [3]. By adopting this method, it is possible to reduce the absolute discharge of water vapor and reduce water consumption through condensate recovery. This method can be applied with small design changes in existing cooling towers while minimizing additional input energy, but it is difficult to ensure plume abatement in low temperature outdoor condition such as winter morning with high relative humidity or high relative humidity condition such as foggy or snowy weather.

Condensing and removing water vapor using a heat pump can also be another method for reducing plume generation. By applying a more active cooling/heating device, heat pump, it becomes possible to efficiently prevent plume even in sub-zero climate conditions [3]. The heat pump recovers sensible and latent heat from the humid discharged air of cooling tower in the evaporator and the recovered heats is then transferred to the

* Corresponding author. Tel.: +82-42-860-3293.;
E-mail address: giblee@kier.re.kr
discharge stream passing through the condenser. Therefore the relative humidity can be lowered much more than the outdoor air mixing method (Fig. 1). Since air in cooling tower is at high relative state, heat transfer in the evaporator is increased due to condensation, and energy consumption can be reduced by the factor of COP of the heat pump compared to the electric heaters.

Fig. 1. Plume abatement approaches – outdoor air mixing and heat pump

Fig. 2 shows a reference case of heat pump cycle analysis under typical cooling tower flow conditions. The cycle characteristics in the cooling tower flow condition are the high latent heat ratio in the evaporator (latent heat transfer is more than 95% of the total heat transfer) and the high condenser pressure approaching the compressor operating limit. The high latent heat ratio is due to the high relative humidity, and as the evaporator and the condenser operate at the same air volume rate, the condensation pressure has to increase more compared to the general heat pump system. Under the suggested operating conditions in the figure, the air at the exit of the condenser is heated up to 51.5°C, and plume prevention can be expected to about 0°C outdoor air temperature. The estimated COP obtained by the heat pump is 4.0.

Fig. 2. Heat pump cycle analysis under typical cooling tower flow conditions
3. Plume Prediction based on Psychrometric Chart

From a thermodynamic point of view, plume is generated when condensation occurs in the mixing process between exhaust air of cooling tower discharge and low-temperature outdoor air. The occurrence of condensation means that the humidity ratio of the two mixed stream is higher than the value of saturated condition at the mixed temperature. So the saturated humidity ratio to the mixed temperature and the current humidity ratio were selected as the criterion for plume generation. In order to prevent plume generation in certain outdoor conditions and cooling tower outlet conditions, either the outlet air temperature must be raised or the humidity ratio value must be reduced. The figure below shows the process of estimating the minimum value of outlet air temperature increase on a psychrometric chart, and the determination process is briefly presented too.

![Psychrometric Chart](image)

The plume generation prediction method based on the psychrometric chart can be used for following cases:

- **Analysis of outdoor temperature effect**: The result of analyzing the temperature required for plume prevention according to the different outdoor temperature with fixed cooling tower outlet condition of 33°C and RH99% is shown in the below figure and table. When the outdoor temperature is lower than a certain point, the temperature required for plume prevention tends to increase rapidly. For example, for the outdoor temperature of 20°C, only 1.4 °C temperature increase is required. However the required values are increased to 9.9°C at 10°C outdoor and 37.4°C at 0°C outdoor. Reheating temperature prediction tool with outdoor temperature changes makes it possible to derive operational limits for plume prevention in currently constructed facilities.

![Table and Graph](image)

- **Analysis of outdoor temperature effect on plume prevention**
- (Analysis of outlet temperature effect) In order to analyze the cooling tower operating conditions for plume prevention in low-temperature outdoor condition, an outdoor plume reduction temperature analysis was performed at \(-5^\circ\text{C}/\text{RH75\%}\). Considering the fact that the heating temperature rapidly increases as the outdoor temperature decreases in the previous case, the cooling tower outlet temperature was arbitrarily lowered in this case, and the plume prevention temperature increase characteristics were analyzed for 20-29\(^\circ\text{C}\) outlet temperature. The results are presented in the figure and table below, and compared to the case of 15.1\(^\circ\text{C}\) heating requirement a 20\(^\circ\text{C}\) outlet temperature, 42.2\(^\circ\text{C}\) heating is required at 29\(^\circ\text{C}\) outlet (2.86 times more heat required). Therefore, in order to effectively prevent plume, it is necessary to design a control logic that lowers the outlet air temperature and a system in which the output of the heat pump for plume removal is inter-connected with each other.

- (New operation proposal and operation characteristic analysis) As the outdoor temperature decreases, the heating temperature required for plume prevention increases rapidly due to the nonlinearity of the humidity curve. In order to reduce the energy required for plume prevention, a new operating mode was suggested. The new operating concept was designed considering the cooling tower operating boundaries for a power plant. Even if the outdoor temperature is lowered, the turbine back pressure must be maintained constantly. Therefore the temperature change of the cooling tower circulation water should be maintained. In order to maintain the same temperature change, the cooling tower air volume flow rate must be reduced. If the outside air is taken as the amount of the difference between design air flow rate and operation air flow rate and then mixed with cooling tower outlet air, the mixed air becomes supersaturated. Assuming that the supersaturated liquid droplets generated inside the cooling tower can be removed relatively easily by methods such as drift eliminator and fog collector, wet air entering the pump can be assumed to be saturated with low temperature. This mixing and droplet elimination process is represented as “Internal Mix” in fig. 3. Then plume reduction temperature after mixing the excess of the design air volume as above was calculated. The result is as follows. From the table, it can be seen that less energy is required for mixed heating compared to direct heat pump application.
### 4. Conclusion

The characteristics of the heat pump cycle in the cooling tower flow are as follows.
- Since air flow rate is fixed as the cooling tower operating value, the operation conditions of evaporator and condenser are restricted.
- When reheating air flow in condenser with the recovered heat from evaporator, a high condensing temperature is particularly required due to the low heat capacity of air.
- About 50°C discharge air, COP around 4 are expected under typical cooling tower rated conditions

The input energy characteristics for plume reduction are as follows.
- As the outdoor temperature decreases, the input energy needed increases rapidly. (Unsuitable operating conditions even for the heat pump cycle with sub-zero outdoor conditions)
- A design approach that lowers the discharge air temperature of the cooling tower while maintaining the circulating water temperature range is preferred.
- Operation that utilizes the flow rate margin between the design air volume and the operating air volume to take outside air is suggested to reduce the heat pump input energy further.

Heat pump cycle can control the evaporation temperature and condensation temperature. The low temperature heat recovered by heat pump can be upgraded and used for other high temperature purposes. Through this, it is possible to expand heat pump application not only to prevent plume generation, but also to recover and reused waste energy in exhaust gas in energy intense industries such as power generation, petrochemical, and paper manufacturing. The suggested approach will be able to expand its application to cooling towers for building air conditioning, cooling towers for subway heat treatment along with plume prevention for large cooling towers of power generation, petrochemical plants, etc.

Abstract

The European implementation of the Montreal Protocol, the F-gas Regulation, restricts the use of refrigerants with high GWP. Thus, low-GWP refrigerants, in particular R290 (propane), are becoming the standard in the growing heat pump market. Within this contribution the results of the research project “Low Charge 150 g” are shown. The focus is on the reduction of charge needed in heat pumps, favorably below 150 g propane. As part of this project different components were combined in brine to water refrigerant circuits and experimentally evaluated. Conclusions and correlations will be described based on ErP standards and a multitude of measured values. All evaluation focus on the behavior based on charge variation and are used to create four distinct operation modes of a heat pump. Additionally, a test bench for refrigerant distribution testing was built to analyze R290 concentration development in controlled indoor scenarios. All measurements are done with compact plate-to-plate refrigerant circuits. The heating capacity reaches up to 12.85 kW using 124 g R290. The current best solution achieves a specific heating capacity <10 g/kW with a SCOP (ErP) >4.5.

Keywords: propane; R290; heat pumps; refrigerant; charge reduction; safety

1. Introduction

Heat pumps have become the technology of choice for society and policy makers in the European region and increasing in popularity worldwide. Commonly used refrigerants have been regulated recently and they will be regulated/ banned in the near future. Different regions worldwide follow individual timelines. These timelines were agreed upon by participants of an assembly in Montreal in 1987, commonly referred to as “the Montreal protocol” \cite{1}. The European implementations have led the EU-market to an increasing focus on R290 as refrigerant. R290 (propane) has a low GWP of 0.02 \cite{2} and very good thermodynamic properties but is highly flammable and therefore needs special attention regarding safety. The reduction of charge in the system is an elegant solution to decrease the hazard represented by the system. The following contribution will show the basic concept of charge reduction, visualize the impact, and show taken measures.

2. Infrastructure

All measurements presented below were taken at Fraunhofer ISE. To ensure standardized testing, conditioning modules, were used to simulate source and sink and are referred to as secondary modules/circuits. These conditioning modules are standardized equipment in the laboratory and have the following adjustable/ controllable parameters: fluid temperature, pressure drop and mass flow. The conditioning module for the sink side is filled with water and the module on the source side with a mixture of ethylene/glycol and water with a freezing temperature of -20 °C. For evaluation, the heating and cooling capacities on the secondary sides were calculated by the measurement of the mass flow employing a coriolis sensor, combined with in- and outlet

\* Corresponding author. E-mail address: timo.methler@ise.fraunhofer.de
temperature measurement, using submerged PT100 sensors and their applicable specific heat capacities. The electrical power consumed by the driver and compressor was measured between the driver and the power grid. Therefore, all frequency converter losses are included in the results. To estimate the power necessary for external pumps on the secondary side, differential pressures across the heat exchangers on the secondary side were monitored by pressure differential sensors. Controllers were used to control the inlet temperatures to the heat pump. The temperature difference between in- and outlet of the two plate heat exchangers on the secondary sides, were controlled by adjusting the mass flows of secondary fluids. The source side was set to 3 K and the sink side to 5 K temperature difference.

3. Test procedure

All prototypes measured by Fraunhofer ISE were built as the flow chart in Fig. 1. The refrigerant circuits (RC) were built in the workshops at Fraunhofer ISE and named following a versioning system RC-version. All manufacturing guidelines are coordinated with partners in the project’s advisory board and with component manufacturer, as well as the component manufacturers.

The components used, were all selected to be able to provide 8 kW heating capacity in their upper rating range. Generally, all pipes were insulated by 1cm foam insulation. The heat exchangers were set up to operate in counter flow arrangement.

All measurements are taken as charge variations since the main focus lies on the low charge behavior of refrigerant circuits. For this purpose, a special charging station was developed and constructed for automated charging and safe discharging of up to three refrigerant circuits mounted at the same time processed individually. To control the direction of the R290 mass flow the charging station can be heated or cooled. In-depth explanation of the charging station can be found in the article of [3].

For the measurements the charging unit charged an initial amount of refrigerant to the circuit (for instance 80 g). With the initial amount several operation points were measured, which includes several different parameters set by the secondary modules, frequency converter and EEV. Those operation points were measured for 30 minutes in stable conditions, respectively. After running through this measurement matrix of different operation points the charging unit automatically charged 10 g extra refrigerant and the operation points of the measurement matrix were measured again. The procedure continues until high pressure protection is tripped, this commonly occurred between 200 g to 250 g of refrigerant R290 in the circuit. Within the refrigerant circuit the following parameter are recorded: Temperature and pressure in suction and discharge line, temperature in liquid and injection line, pressure difference across the heat exchangers and amount of refrigerant charge. The collected data is compiled in a combined database and enhanced by additional documentation including all pipe lengths, all pipe diameter, insulation type, insulation diameter, pictures, component list, oil type, oil amount, sensor connection length and diameter for differential pressure sensors. The additional base information is used in some following corrections mentioned below. During operation the suction side super heat of the refrigerant circuit is controlled with an electronic expansion valve (EEV), the reference temperature sensor in the suction line, was implements as submerged PT100 sensor. All set values are added to the measurement database and are used in the evaluations below.

![Fig. 1. Simplified Refrigerant Circuit Flowchart](image1)

![Fig. 2. Log (p) - h diagram visualizing heat pump operation of RC8-21 at B0/W35/SSH10/F40 for the special attention points A-D, as marked in Fig. 3.](image2)
4. Operation with different charge

Fig. 3 shows five stacked graphs ((a)-(e)) with a common x-axis, which displays a full charge variation measurement for refrigerant circuit RC8-21 at operation point B0/W35/SSH10/F40 (brine inlet temperature: 0 °C; water flow temperature: 35 °C; suction super heat: 10 K; frequency: 40 %). When considering the full range of a charge variation measurement as described in Chapter 3, there are four major operation points, where different thermal and fluid dynamic effects have significant impact on the circuit. These four operation points are marked with A-D in Fig. 3. Point A is under charged with refrigerant. The necessary super heat is not achieved. In point B the desired super heat is achieved, but the system did not reach the maximum efficiency and heating capacity. Point D is over charged with refrigerant. Efficiency drops significantly. Most common operation is point C, which is widely regarded as baseline heat pump cycle. The presence of sub cool is considered essential for the baseline cycle.

Fig. 2 shows point C’s cycle in a log(p)-h diagram marked with stars. Operation C is expected to have 0-2 K sub cool, which is difficult to measure reliably in the tight physical arrangement. Therefore, the team is using alternative measured values to determine marginal sub cool. The behavior of the EEV (shown in Fig. 3 (b)), is used as main indicator for marginal sub cool. The EEV’s task is the expansion of the refrigerant, this can be considered as forced pressure drop. Pressure drop is strongly dependent on fluid velocity, which in term is strongly dependent on density. For this reason, the EEV behavior shift from being strongly charge depended to largely independent, is considered the turning point of marginal sub cool. For this reason, the EEV opening is used to define the “minimal sub cool” points. This is also considered the minimal optimal charge in [3]. The additional charge, with point C as reference, does not significantly impact the EEV and therefore no significant density/ velocity changes in front of the EEV are occurring. This shows the existence of sub cool, it does not quantify sub cool reliably but considering fluid dynamics sub cool has to be present. Fig. 3 (d) shows condensation temperature and liquid line temperature; subtracting them from each other results in the sub cool of the system. With increasing charge increasing sub cool is present in the system. Additional charge will accumulate inside the condenser, if no collector is present, the additional inventory reduces the available area for condensation and desuperheating. The loss of available area is balanced with a forced increase in temperature difference and therefore condensation temperature. This is particularly prominent at operation D, where overfill has occurred. Fig. 3 (d) shows the significant increase in condensation temperature and therefore pressure. Fig. 3 (b) on the other hand shows the reaction of the EEV to create additional pressure drop the cross-sectional area of the EEV has to be reduced. The significance of the change in operation is also visualized in Fig. 2 where operation D is indicated as extreme undercharge, B undercharge, C minimal optimal charge and D overcharge operation.
triangles. Additional side effects are the increased pressure ratio to be covered by the compressor. This leads to an additional increase in discharge temperature and drop down of COP shown in Fig. 3 (d) and (a) respectively.

When reducing charge, with C as reference point, the reduction will have different impacts. First effect will be the reduction of sub cool below 0 K sub cool. This will force the condenser to have two-phase flow, marked in Fig. 3 as operation A/B. This will change the requirements for the expansion valve drastically and any expansion valve made for liquid entry state will reach its physical limit quickly, which is the major difference between operation A and B. As discussed earlier due to the higher velocities with two-phase flow and a considered constant mass flow. Mass flow can be considered constant, for points B-D, due to constant rotational speed of the compressor in combination with the constant pressure and temperature at the compressor inlet shown in Fig. 3 (d) and Fig. 2. Operation A does have altered mass flow compared to the operation B-D, due to the reduced inlet pressure and increased super heat which leads to lower densities at compressor inlet. This works to reduce the velocity increase at the EEV, which is still dominated by the decrease in density due to two-phase operation. The suction temperature displayed in Fig. 3 (e) shows the constancy of suction side temperature over the full charge range, due to the consistent secondary side source temperature. At operation A, where the decreased density and with it required additional EEV opening, exceeded the operation limits of the EEV. As a result, the low pressure is reduced lower than necessary for 10 K SSH, this leads to uncontrolled increase super heat in the circuit and is the dominant reason for the decreased pressure at the compressor inlet. Both operation states are visualized in Fig. 2 B as circles with the EEV at maximum operation envelop and A as squares with the EEV operated outside of its operation envelop. During their investigations the team Palm et. al. in 2006 found the same correlations for COP and temperature developments over charge, these are shown and discussed in [4]. Additional visualization can be provided by employing IR pictures of the cross section of condensers. The concept of using IR pictures for distribution evaluation was used and described nicely in [5]. In this case the same concept can be used to show the inventory level in condensers rising with charge during the previously described charge variation. For this visualization, a charge variation of refrigerant circuit RC8-17 at B0/W24/SSH10/F10 has been selected to show charge inventory in the condenser. Operations B, C and D are marked and selected similar as RC8-21 discussed before (see Fig. 4 ((a) - (c))). For circuit RC8-17 the IR pictures of the condenser cross section for operations B, C, D and an additional point are shown in Fig. 5. Refrigerant flow is downstream from top right to bottom right of the heat exchangers. The first picture of Fig. 5 (B) represents an underfilled system with a total charge of 114 g R290. Except the hot gas region in the upper region of the heat exchanger the IR picture indicates a homogenous temperature profile starting 26 on the y-axis to the bottom part of the heat exchanger. The homogenous temperature profile reflects the process of condensing the refrigerant. Pure liquid phase is not reached. At the outlet of the heat exchanger the refrigerant is still in two phases.

Fig. 4. (a) - (c)). Charge variation of RC8-17 at operation point B0/W24/SSH10/F10 stacked graphs showing, (a) COP and heating capacity, (b) EEV opening in %, (c) temperatures in discharge and liquid line as well as condensing temperature. Marked for special interest are charges B-D representing B undercharge, C minimal optimal charge and D overcharge operation.
The second picture in Fig. 5 (C) shows RC8-17 at the minimal optimal charge operation with 147 g R290. The upper region of the heat exchanger shows almost no change in temperature, compared to the image of operation B. Whereas the bottom region demonstrates a slight change in temperature level. This indicates a completed condensation and starting of sub cooling of the refrigerant at the bottom of the heat exchanger. This is reflected in Fig. 4 (c) where the condensation temperature ($T_{HP\_liqR290}$) and measured outlet ($T_{liq}$) are shown. The temperature differential represents the measured sub cool. Fig. 5 shows an additional image for 169.3 g of charge to visualize the development of the sub cool region, visible at the bottom of the heat exchanger. The final picture of Fig. 5 (D) refers to an overfilled system with a total charge of 193 g R290. As explained earlier for overfilled systems, the discharge temperature rises. The increase in discharge temperature can be seen at the top region of the heat exchanger in a displayed dark red color. Furthermore, with additional charge, the condenser works as a collector. All unnecessary charge stays in the condenser in front of the EEV. The sub cooling increases and the area used for condensing the refrigerant is getting smaller. This can be seen in the blue bottom part of the heat exchanger. The earlier discussed behavior of charge varied refrigerant circuits is applicable to all circuits measured during the project, which were not changed by adding additional components. Therefore, qualitatively visualized process in Fig. 2 applies.

5. Design rules for charge reduced heat pumps

To design low charge heat pumps the following design rules should be in mind to keep the amount of refrigerant low and use the charged refrigerant as efficient as possible.

5.1. Heat exchanger manifolds

Heat exchangers have connection ports/ manifolds/ headers to distribute or collect the refrigerant to/ from the plates and channels. Those ports are often designed to be very simple and easy to manufacture. They are not optimized regarding refrigerant efficiency and often they are holding some amount of refrigerant/ oil which is not used in the circuit. For example the manifold and outlet port of a plate heat exchanger condenser are commonly punched with the same tool as the secondary side ports. This leads to manifold diameters 2-3 times
larger than necessary, and therefore to charge inventories 4-9 the needed mass and volume. Manifolds could be designed much smaller to safe unused refrigerant, for this reason port design is an important part of charge reduced design.

5.2. Oil reduction/ absorption

The oil, commonly used in refrigerant circuits, absorbs 5-18 weight% (depending on the oil) of the refrigerant. The knowledge of adsorption can be measured and is widely known, a good example of behavior can be found in Ginies work of 2016. One example of the work is shown in Fig. 6 [6]. These absorption values occur during heat pump operation. The amount of refrigerant which is absorbed by the oil depends on several factors. The type of oil and refrigerant is important, as well as the physical conditions of the oil (temperature and pressure). The main amount of oil in a refrigerant circuit is present in the oil sump in the compressor. Therefore, it makes a difference if the oil sump is on the suction side or discharge side of the compressor.

The team did not elaborate on the benefits or negatives of either solution and found no clear indication for which system is charge optimal. The general rule in regards of oil remain, avoiding oil traps, reducing oil sump, considering the oil type, will all reduce or impact the required total amount of refrigerant.

5.3. Liquid line

The liquid line should be designed as short and thin as possible. Due to the high density of the refrigerant in the liquid line (see top left Fig. 2) it has a high effect on the total charge of the system.

5.4. Operation strategy

For reverse operation via 4-way-valve the condenser and the evaporator are switched in the refrigerant circuit. This is used for deicing or active cooling mode. In those operation modes much more refrigerant is needed due to higher volumes in the evaporator (evaporator fills up with liquid refrigerant). For highly charged reduced refrigerant circuits other deicing modes are recommended and passive cooling could be an alternative.

5.5. Super heat optimization

Different suction super heat values require different amounts of refrigerant for their minimal optimal charge operation, marked as C in Figure 7. The higher the super heat the lower the required refrigerant charge. Though the suction super heat has a high impact on the efficiency of the unit. The lower the super heat the higher the efficiency.

In some scenarios to achieve a certain maximum refrigerant charge it can be useful to use the suction super heat to regulate the required refrigerant charge. All prototypes during the project had a charge delta between 5 K SSH and 15 K SSH of 20 g to 70 g, main reason for the widespread is the charge absorbed in the oil, due significant impact on oil sump/ suction gas temperature, as well as different inner volumes in evaporators, where the varied super heat has a significant impact on the average density in the evaporator.
5.6. Heat exchanger

A major amount of refrigerant charge in refrigerant circuit stays in the two heat exchangers. The larger the inner volume of the heat exchanger the more charge is needed. In the design process should be kept in mind, that the selection of the heat exchangers has a large impact on the final charge. Specifically additional plates due to safety margins should be considered carefully when designing a charge reduced system. Other options for charge reduction are asymmetric heat exchangers, which enable low secondary side pressure drops but low inner volumes on the primary refrigerant side. A recent publication of Will et. al. showed increased necessary charge if any maldistribution is present. The investigation was done purely theoretically and simulation based, never the less all five most common models for two phase charge estimation were in agreement. [7]

5.7. Heat exchanger

Normally filter dryer are used in the liquid line in refrigerant circuits. The filter dryer is holding liquid refrigerant with a high density. For very compact systems the share of the total refrigerant charge can be quite high. To avoid some refrigerant from the filter dryer in the liquid line, the filter dryer can be shifted to the suction line of the refrigerant circuit where the refrigerant is in gas phase and has a lower density. Due to high gas velocities the filter dryer needs to be larger than in suction line. Nevertheless, some refrigerant can be saved, the team saved 50 % charge during pre-evaluations. Though, the filter dryer in suction line has additional pressure losses which harm the efficiency of the complete unit, the actual impact will vary on a case-to-case bases.

Another option is to renounce the filter dryer completely. The amount of saved refrigerant is the highest. The manufacturing process and needs to be a very careful to have no particles in the refrigerant circuit. And the evacuating needs to be very accurate to remove almost every humidity from the unit.

6. Safety analysis outlook

To evaluate the safety of propane heat pumps during and after a leakage, knowledge of the propane concentration in its surroundings is essential. Of interest are the behavior of concentration development over time in the casing of the refrigerant circuit (heat pump) as well as in the installation room around it. To be able to measure distribution of propane, inside and outside of the casing, a test installation room (see Fig. 8) has been installed at Fraunhofer ISE. The dedicated room enables the team to test the distribution development over time in a controlled environment. The leaked mass of propane is not limited; however, the leakage mass flow rate is limited. This flow rate represents small leakages to rupture leaks varying between 0.001 g/s to 2 g/s, respectively; and the leakage position can be varied within the casing, focusing on critical positions such as brazing joints, any specific component necessary to evaluate.

The test installation room is built with sandwich panels with a volume of approximately 21 m³ (3.5 m x 2.5 m x 2.4 m), representing a typical size of a cellar. The installed test room includes, a gas warning system, a ventilation system and measurement equipment. The ventilation system can be used for cleaning the installation room during or after a leakage test. Measurement results with desired resolution are recoded with more than 30 gas sensors, temperature sensors and differential pressure sensors, which are installed in the test installation room. The gas sensors (Dynament propane gas sensors with ATEX certificate) detect propane concentration by infrared

![Fig. 8. Installation room for leakage testing of heat pumps](image-url)
measurement principle and have a response time of ~1.2 s. The gas sensors are installed within the casing and within the test installation room around the casing. As part of the project “Low Charge 150” three types of casings have been defined for testing: (1) without casing / very permeable casing, (2) with a casing that is individually designed, based on the refrigerant mass in the circuit, (3) with a casing, that has a fixed volume according to the “white goods” volume with 60 cm x 60 cm footprint. Casing (2) and (3) are built to have custom side panels to be able to accommodate new designs and component-based additions to housings. The dedicated measurement campaign for “Low Charge 150” will start beginning of 2023. The desired outcome will be, whether a casing can be designed to include a passive safety concept intrinsically. A further goal is the definition of an upper limit of propane with a fixed casing volume and this passive safety concept. The main benefit of such a concept would be to eliminate additional active safety devices in the casing or in the installation room.

7. Conclusions and outlook

The described behavior in Section 4 has been present in more than 20 refrigerant circuits measured during the project “Low Charge 150” and all circuits with no additional components. The thermodynamic relations between the individual components and the thermodynamic behavior with charge reduction has been very consistent and conclusive. Overall charge reduction has a long chain of dependencies attached. The authors summarize the full chain as follows.

Reduced charge (below the minimal optimal charge point) leads to gas parts in the liquid line (saves charge). This reduces the available enthalpy delta in the condenser (reduce heating/ COP). The gas phase in the liquid line leads to additional non desired expansion. This in turn leads to higher super heats. Additional super heat reduces absorption in the compressor oil (saves charge). Lower evaporation temperatures/pressure created by the additional expansion increases the necessary compression ratio (increases electric use/ reduces COP). The rise in suction side super heat and the additional pressure ratio increases the hot gas temperature. Rising hot gas temperature leads to the less efficient gas-based heat transfer in the condenser (reduce COP). A similar conclusive argument chain forms for overfilling which is explained in section 4, but does not represent special interest for charge reduction.

To summarize the described effects and relations the Fraunhofer ISE derives seven rules for designing charge reduced heat pumps

1. Oil reduction
2. Minimal liquid line
3. Heat exchanger manifolds/ ports
4. Operation strategy
5. Super heat strategy
6. Heat exchanger inner volume/ distribution
7. Minimal / suction side filter dryer

These rules are described in detail above in section 5. Most if not all of the rules can be respected when selecting components. The fundamental relations also give strong areas of attention for future developments. Testing and implementing new oils with lower absorption of refrigerant are a strong contributor to charge reduction, as well as the general reduction of oil. On the thermal dynamics side the quality of fluid-distribution in heat exchangers has an impact on the efficiency as well as on charge efficiency.

Transcritical CO₂ heat pump for tap water heating: experimental validation of an auto adaptive algorithm for high pressure optimization

Chiara Corazzol*, Giovanni Rossanese, Sergio Maria Capanelli, Luca Mattiello

CAREL Industries S.p.A., Brugine 35020, Italy

Abstract

Recent developments pushed by F-gas regulations and European guidelines for the renovation of domestic heating systems have led the HVAC market to use new alternatives to propane (R-290) and fluorinated refrigerants. CO₂ (R-744) heat pumps are a consolidated solution for domestic hot water (DHW) applications, with the advantages resulting from using an environmentally friendly, not toxic and not flammable refrigerant. Another benefit of CO₂, when used in DHW applications, is that high-temperature hot water (up to 70°C) can be obtained without the use of a supplementary heating system. In this case, heat rejection pressure has a strong influence on the efficiency of the unit, and there’s an optimal value that makes the system reach the maximum coefficient of performance (COP). In this work, the performance of a real transcritical air/water CO₂ heat pump for tap water heating has been investigated and compared at different heat rejection pressure values. Considering that the optimal pressure value is strictly affected by the variability of the operating conditions (such as water inlet temperature, water outlet temperature or evaporating pressure), an auto adaptive algorithm has been adopted and the consequent results are reported. The algorithm is based on the CO₂ thermodynamic properties calculated via Artificial Neural Network by the controller; one of its main advantages is that it does not require the system modeling and it is not dependent on the use of a specific unit or component.

Keywords: Carbon dioxide, Heat pump, Domestic hot water, Pressure optimization algorithm, Auto-adaptive.

1. Introduction

The crisis due to the conflict in Ukraine and geopolitical instability in general is causing significant repercussions on the European energy market: the uncontrolled increase in gas and electricity prices due to the cut in supplies has led to an increase in costs in various sectors, especially in industrial processes and home heating, markets that have historically relied on gas and other fossil fuels.

Hence the European Union’s decision to establish a very aggressive plan for the transition of energy-intensive processes and the technological evolution of systems towards alternatives to gas for residential and industrial applications, focusing the actions above all on the heat pump market: REPowerEU [1] has identified heat pump technology as one of the key technologies for reducing Europe’s dependence on fossil fuels in the short and medium term.

In conjunction with these initiatives, which on their own will drive significant market growth, a new proposal has been drafted for the revision of the F-Gas Regulation 517/2014. When the F-Gas Regulation 517/2014 [2] came into force in 2014, it caused a major upheaval in the market, impacting the prices of refrigerants and bringing about the decommissioning of commonly-used refrigerants in the HVAC/R market, to a great extent than if they had actually been banned by law. The proposed revision [3], published on 5 April 2022, aims to introduce further restrictions on the use of HFC and HFO fluids as early as 2024, setting a GWP threshold of 150 for refrigerants used in air conditioning and refrigeration applications. These new limitations, combined with other proposals to ban the use of compounds containing PFAS, chemicals found in many...
refrigerants currently on the market or the result of their degradation, clearly define the European Union’s intention to favour the use of natural refrigerants only in HVAC/R equipment in the near future. The majority of manufacturers have already addressed the use of hydrocarbons, such as propane R-290, as refrigerants in all segments of units intended for the residential air conditioning and heating market. This type of refrigerant has a series of important benefits in terms of operating range, efficiency and design of the units compared to established fluids such as R-410A, as seen in Capanelli [4], yet its high flammability means it is not easily usable in all applications and unit configurations required by the market. CO2 (R-744) is a natural refrigerant, with GWP=0, and has countless benefits, especially with a view to being used for domestic hot water heating, even if today the main applications are all in the refrigeration market.

It is therefore extremely important to understand and assess the potential of this fluid also in residential applications, so as to define the best combinations of unit design, component selection and process efficiency, and thus make CO2 a potentially usable option for home air conditioning.

A transcritical unit efficiency can be maximized by correctly managing the working condition. A key-factor on this side is the high pressure of the system which must be tuned in order to get the highest Coefficient of Performance (COP). Liao et al. [5] correlation is extensively used in this field; however in heat pump systems, COP depends also on the secondary fluid capacity, which is a factor not considered in Liao’s correlation. An option to improve the high pressure regulation is to use model-based optimization approaches or “ad hoc” correlations, derived from experimental data, such as Zhang et al. [6]. On the other hand, these solutions are often tailored to specific system structures with poor generalization properties. Cervato et al. [7] proposed the use of an Extremum Seeking Control (ESC) that is a real-time optimization approach that does not use a priori model, relying instead on measurements obtained by monitoring the system. Anyway, the COP real-time calculation may result in a burdensome task due to certain limitations and technological constraints typical of industrial scenarios.

To overcome this complications, the present work characterizes the system efficiency by means of a suitable index, defined as simple as possible to be calculated, but accurate enough to guarantee the unit performance. Besides, we use a simple hill climbing algorithm [8], that is an iterative optimization technique.

2. Test Rig Description

Fig. 1 depicts a simplified scheme of the test rig. The unit has two rotary compressors (C1 and C2) Toshiba DY45NIFB-10FU with a 45·10^4 m^3 individual displacement. Lubrication is ensured by the oil circuit, which includes an oil separator (SP) and a solenoid valve (SV). A double-wall plate heat exchanger (H) Swep B16DWHx37/3P carries out the heat rejection while a finned-coil evaporator (E) gives the heat load. A receiver (R) is provided to build up a three-pressure levels cycle. The heat rejection and receiver pressures are regulated by V_H and V_R valves respectively, while the evaporating pressure is controlled by the evaporator fan and the superheat at the evaporator outlet is regulated by V_E valve. The secondary fluid for the heat rejection is brine with 16% volumetric concentration of ethylene glycol; the brine circuit includes a variable-speed brine pump (BP) and a volumetric flow meter, measuring the brine flow rate (V_B).

---

Temperatures on heat rejection side (\(T_D\) and \(T_{H,O}\)) are measured with \(\frac{1}{2}\)DIN PT100 probes with a 4-wires connection, while on brine side T-type thermocouples are installed (\(T_{B,1}\) and \(T_{B,O}\)). Power consumption of each compressor and its speed-drive is measured by energy meters with \(\pm0.5\%\) of reading accuracy. Brine volumetric flow rate and pressures ranges and accuracies are reported in Table 1.

### Table 1. Measuring ranges and accuracies of brine volumetric flow rate and pressures. RDG: of reading, FS: full scale.

### 3. Experimental Tests

The heat pump performance depends on the two fluids capabilities of rejecting and receiving the useful heat load. The unit Coefficient Of Performance (COP) is influenced by the thermodynamic conditions of both \(CO_2\) and brine sides in terms of pressure, temperature and flow rate. For these reasons, a universal correlation able to identify the optimal working point of a particular unit is hard to find, as stated in Fornasieri et al. [9].

The developed algorithm aims to match the two fluid streams through online thermodynamic calculation and simplified modeling of the heat rejection phenomena, without the complication of pure system perturbation as suggested by Cervato et al. [7]. To do so, the measurements on both the heat rejection side (\(P_D\), \(T_D\) and \(T_{H,O}\)) and brine side (\(T_{B,1}\) and \(T_{B,O}\)) are used as inputs of an Artificial Neural Network (ANN) architecture. The ANN has been trained off-line using static data set of \(CO_2\) properties and then implemented inside the unit controller in order to perform the thermodynamic calculations needed.

Assuming that the most stringent constraint is on the brine side, in terms of delivery temperature level, the focus of the present work is dedicated to \(CO_2\) side in terms of heat rejection pressure regulation. During the tests, the discharge pressure \(P_D\) has been considered as the independent key-variable to focus on; in fact, the pressure drops recorded across the heat rejection side are comparable with \(P_D\) pressure transducer accuracy. The target of the proposed algorithm is then to search for the optimal \(P_D\) that maximizes the unit COP, adapting to the imposed brine side conditions.

In the present work, the COP is defined as the ratio between the heat load rejected to the brine side (\(Q_B\)) and the electrical power absorbed by the compressors (\(PWR_C\)):

\[
\text{COP} = \frac{Q_B}{PWR_C} = \frac{\dot{V}_B \rho_B c_{PB} (T_{B,O} - T_{B,1})}{PWR_{C1} + PWR_{C2}} \quad [-]
\]

\text{Eq.(1)}

Where \(\dot{V}_B\) is the brine volumetric flow rate, \(\rho_B\) is the brine density and \(c_{PB}\) is the brine specific heat capacity at constant pressure (both calculated using Refprop [10]). Power consumption of the evaporator fan is excluded from the COP calculation, as well as the negligible contributes of variable-speed brine pump and electronics (valves and controls).

The algorithm capability to find the optimal \(P_D\) has been tested through different sets of conditions of \(T_{B,1}\), \(T_{B,O}\) and \(T_{EV}\) parameters, while maintaining a 10K constant superheat at the evaporator outlet and a fixed compressors mechanical speed equal to 100rps. Table 2 reports the investigated conditions during the experimental tests.

### Table 2. Investigated experimental conditions.

<table>
<thead>
<tr>

<td>15</td>
<td>55 / 65 / *</td>
<td>-8</td>
</tr>
</tbody>
</table>

* \(T_{B,O} = 70^\circ \text{C}\) not investigated due to system technical limitations.
T_B,1 is guaranteed by an auxiliary external chiller, while the brine pump controls T_B,O. Finally, T_EV is controlled at the desired set point by the evaporator fan.

To prove the algorithm quality, the optimal pressure P_{D,OPT} of each investigated condition has been experimentally determined within the transcritical regime 75<P_D<105 barg. To do so, a step-by-step approach has been adopted: for each condition reported in Table 2, P_D has been progressively varied in order to find out the value realizing the maximum COP. Afterwards, the same conditions have been maintained letting the algorithm free to control P_D and converging to a calculated value.

Two indexes are defined for the comparison of the experimental optimal pressure P_{D,OPT} and the algorithm-calculated pressure P_{D,ALG}:

\[
\text{dev}_P = P_{D,OPT} - P_{D,ALG} \ [\text{bar}] ; \quad \text{dev}_{\text{COP}} = \frac{\text{COP}_{\text{OPT}} - \text{COP}_{\text{ALG}}}{\text{COP}_{\text{OPT}}} \cdot 100 \ [%]
\]

Eq.(2)

These two deviations are considered as representative of the algorithm quality, as they account for both optimal pressure determination accuracy and resulting relative unit performance.

4. Results

Fig. 2(a) reports, by way of example, the experimental curves of Q_h and PWR_c against P_D, while Fig. 2(b) reports T_D and T_{H,O} experimental curves against the same variable. The points resulted by letting the algorithm free to operate in the same conditions are also depicted. The charts are plotted for condition “a” of Table 2 with T_{B,O}=55°C.

![Image](https://via.placeholder.com/150)

**Fig. 2.** Condition “a”, with T_{B,O}=55°C, curves of Q_h, PWR_c (a) and T_D, T_{H,O} (b) with their respective ALG points.

By looking at Fig. 2(a), as expected, both Q_h and PWR_c increase as P_D increases. However, while the first presents a progressively decreasing slope, the second one has a near-linear trend. This justifies the concave shape of the resulting COP curve. It can be also seen that the algorithm is capable of identifying a point where the Q_h curve slope equals the PWR_c curve slope, which is directly related to the optimal point for the heat rejection phenomena. This is also confirmed by Fig. 2(b), as the algorithm point of convergence is close to the change in slope of T_{H,O} curve, i.e. the minimum P_D capable of ensuring a small temperature approach (T_{H,O} - T_{B,1}) and an optimized heat rejection. A further increase in P_D, in fact, would have led to a considerable PWR_c increase with a limited increase in Q_h and negligible temperature approach variation.

As additional way of example, the same condition “a” of Table 2 with T_{B,O}=55°C is reported in Fig. 3, showing the behavior of the algorithm during a convergence test. It can be seen in Fig. 3(a) an initial pressure set point P_{D,SET} forced to 93 barg, then at 00:10 the algorithm is let free to operate. It starts from a value of 88 barg, which is the average of condition “a” P_D range, identifying the optimal P_{D,SET}. After 10 minutes the algorithm starts to swing around the calculated value of P_{D,SET} close to 86 barg and regulates the respective measured pressure P_{D,MEA}. The logic correctly reduces P_{D,SET} as the COP increment is visible: from 3.5 to 3.7 as mean values. Correspondingly, Fig. 3(b) shows T_{B,1}, T_{B,O} and V_h for the same time-frame. It can be seen that V_h is correctly regulated by the BP in order to maintain T_{B,O}=55°C, so a flow rate reduction is necessary as P_{D,MEA} decreases.

It must be underlined that the BP modulation is completely independent from the algorithm calculation routines. Furthermore, the P_{D,MEA} spike noticeable in Fig. 3(a) at 00:20 (due to an oil refill procedure), does
not destabilize the convergence itself, indicating that the embedded logic is able to bypass harsh disturbances and instabilities.

Fig. 3. Condition “a”, with $T_{B,O}=55^\circ C$, curves of $P_{D,SET}$, $P_{D,MEA}$ and COP (a) and $T_{B,I}$, $T_{B,O}$ and $V_B$ (b).

Fig. 4(a) shows the tests carried out for condition “a”, Fig. 4(b) for the condition “b” and Fig. 4(c) for condition “c”. Each figure reports the COP trend (Eq.(1)) as a function of $P_D$ for different $T_{B,O}$ ($T_{B,O}=55^\circ C$ light blue curve, $T_{B,O}=65^\circ C$ green curve and $T_{B,O}=70^\circ C$ red curve).

P$_D$ varies within a predefined interval with a higher points density close to the optimal value P$_{D,OPT}$.

As expected, the obtained COP curves are concave functions so that they have a maximum in correspondence of the optimal pressure P$_{D,OPT}$ (i.e. the pressure that allows the best matching of the two fluid streams). For each condition reported in Fig. 4, P$_{D,OPT}$ increases as $T_{B,O}$ increases, causing a consequentially reduction of the COP$_{OPT}$. As a final step, the auto adaptive algorithm has been tested for the same working conditions: the results are reported in Fig. 4 (solid colour fill markers). It has to be pointed out that the COP$_{ALG}$ reported in the plots are the averages of all the pressure values collected over an observation period of 15 minutes, after the convergence of the algorithm itself.

Results show that the proposed algorithm is capable of converging to a value of COP sufficiently close to the maximum one in all investigated conditions. In fact, dev$_{COP}$ (Eq.(2)) is always less than 1%. Consequently, the resulting discharge pressure P$_{D,ALG}$ is close to the optimal value P$_{D,OPT}$ as -0.6<dev$_P$<1.5bar.

By comparing conditions “a” and “b” it can be noticed that a decreasing in $T_{B,I}$ leads to an increasing of COP$_{OPT}$ for the same $T_{B,O}$ value. This is coherent assuming that the heat rejected is proportional to the brine temperature difference as reported in Eq.(1). Despite the COP$_{OPT}$ values increment, P$_{D,OPT}$ values seems not heavily affected by the different $T_{B,I}$.

By comparing conditions “a” and “c” it can be noticed that a decreasing in $T_{EV}$ causes a decreasing of COP$_{OPT}$ for the same $T_{B,O}$ value. This is coherent assuming that the PWR$_C$ is proportional to compression ratio and this negatively affects the COP value as reported in Eq.(1). Also this comparison shows that P$_{D,OPT}$ values are not heavily affected by the different $T_{EV}$, even with lower COP$_{OPT}$ values.

Table 3 reports the comparison between the optimal discharge pressures experimentally determined P$_{D,OPT}$ and the ones obtained by the algorithm P$_{D,ALG}$ along with their relatives COP$_{OPT}$ and COP$_{ALG}$. All the values are referred to the heat load Q$_B$ ranging between 12.9 and 17.8kW.
The values of dev$_T$ are influenced by the arbitrary choice of the pressure values P$_D$ selected to build up the experimental curves in Fig. 4. On the other hand, the values of dev$_{COP}$ are related to the COP resolution chosen (number of significant digits), which justifies the null values appearing in Table 3.

Results indicate that the condition that mostly influences the optimal pressure P$_{D,OPT}$ is the T$_{B,LO}$: The variations of T$_{B,LO}$ and T$_{EV}$, have a significant effect in the values of the COP but not a great influence on the optimal pressure determination. The experimental results stated the ability of the proposed auto adaptive algorithm to locate the optimal pressure P$_{D,OPT}$ in all the investigated conditions with a satisfactory approximation.

5. Conclusions

An auto adaptive algorithm for optimal transcritical heat rejection pressure determination has been developed and experimentally investigated on a CO$_2$ air/water heat pump unit for a Domestic Hot Water (DHW) application. The Artificial Neural Network (ANN) architecture used by the algorithm allows local thermodynamic calculations in order to match the refrigerant and secondary fluid streams so to reach the highest unit Coefficient Of Performance (COP). Experimental tests have been carried out for two levels of evaporating temperature (-5°C and -8°C) and two levels of water inlet temperature (10°C and 15°C) with three values of water outlet temperature (55°C, 65°C and 70°C), maintaining the heat rejection pressure inside the transcritical regime between 75barg and 105barg.

The algorithm showed uniform convergence behavior and robustness against noises and disturbances. Response timings are related to PIDs calibration, which will be considered in future developments.

As expected, the optimal pressure depends on the coupling of CO$_2$ and water streams capacities. The proposed algorithm is capable of identifying a pressure that matches these two streams, converging on a value close to the optimal one. In fact, the maximum experimental pressure deviation is 1.48bar, resulting in an experimental COP deviation always less than 1% with respect to the maximum. Results show that water outlet temperature is the major factor influencing the optimal pressure, bringing the algorithm to regulate between 85barg and 102barg.

Due to easiness of implementation, a great advantage of such algorithm is the possibility of its inclusion inside an industrial controller with standard computational performances. Furthermore, the absence of a pure system perturbation approach brings significant simplification on its application. Its versatility makes it also suitable for “in situ” direct regulation application as well as laboratory tests on prototype units with the aim of characterization/optimization.

Future works are focused on testing the ability of the algorithm to adapt on different system features such as (but not limited to): fixed-speed water pump with modulating compressors, extended temperature range on water and evaporation sides, heat recovery integrated design, secondary circuit layout coupling.

Abstract

Electrochemical compressor (ECC) can produce pressurized refrigerant through electrochemical reaction, and ion selective electrolytes. It can be an ideal replacement for mechanical compressor (MC) that have low compression efficiency and noise problem caused by driving parts. Considering the piston rotating at high speed about 25~30 RPS, it is very difficult to cool the incoming fluid and the gas pressure and temperature increase due to adiabatic compression. However, ECC is prone to lowering temperature of the discharge side as it does not have a driving part, and the surface area of membrane is wide. Therefore, since sufficient intercooling can be performed by attaching heat exchangers on multi-stage compression, an isothermal compression process can be achieved. It means, since it is not compressed by volume reduction, compression close to isothermal compression is possible. In this study, a performance of the isothermal compression refrigerator system using ECC is compared with the mechanical compression system. When cooling the ECC with outside air, adiabatic compression is implemented at the compression front-end and isothermal compression at the rear-end.

Keywords: isothermal compression; Electrochemical compressor; mechanical compressor; refrigeration cycle; multi-stage compression;

1. Introduction

The efficiency of refrigeration systems has improved a lot over the past decades due to the rapid increased in cooling loads caused by abnormal climate. The Carnot refrigeration system achieve the highest possible cycle efficiency, which consists of two isentropic processes and two isothermal processes. However, this cycle is not feasible due to various unavoidable irreversibility such as friction, pressure drop, throttling expansion, etc.\cite{1} In particular, the mechanical compressor consumes a lot of energy and the increase in the irreversibility by superheated vapor compression makes it difficult to achieve the refrigeration system closer to the Carnot system.\cite{2} Because the compressor consumes a lot of work in the refrigeration cycle, it is a well-known fact that if isothermal compression is achieved, the efficiency of entire system can be greatly improved.\cite{3} To implement the isothermal compression with the mechanical compressor (MC), it is natural to proceed with multi-stage compression and intercooling. The concept of intercooling is that isothermal compression can theoretically be performed if a cooling step is applied in between each compression stages, and the number of stages becomes infinite. However, in many studies, there is a lack of analysis on how much compression work can be reduce by multi-stage compression and intercooling in practical case. Therefore, in this paper, an analysis of that with MC is included.

The another most potential method to make isothermal compression in the refrigeration cycle is the using electrochemistry.\cite{4} That is called Electrochemical Compressor (ECC), and it can attain an isothermal...
compression efficiency greater than 90%. In ECC, the low GWP refrigerant can be used because the gas that can permeate through the ion exchange membrane in an ion state can be used as cycle refrigerants. It also has no moving parts, so the compression process can be performed without lubrication oil, noise, or vibration. Therefore, in this study, a mechanical multi-stage compressor using intercooling and an ammonia refrigeration system with ECC are analyzed, and a practical cycle modeling considering heat exchanger is conducted.

2. Isothermal compression of multi-stage intercooling compression

2.1. Comparison of configuration and work with number of stages

In this chapter, an ideal case that can make isothermal compression using mechanical compressors (MCs) is analyzed. The intercooling is carried out between each stage of the MC, and this cooling is performed at the outside air or condenser temperature, so that adiabatic compression can be realized in the front-end of compression and isothermal compression in the rear-end compression. The intercooling proceed as the condenser temperature, and ideally, the effectiveness of the heat exchanger is set to 1. The cycle condition is shown in the Table 1. In an ammonia refrigeration cycle in which the evaporator temperature is 5 ℃, the condenser temperature is 50 ℃, and in the case of a 6-stages MC with an isentropic efficiency of 0.75 at each stage to approach practical cycle [5], and assuming that the degree of superheat (DSH) is 5 ℃, the cycle as shown in the diagram below the compressor of cycle is composed.

The single-stage MC consumes the work about 280.94 kJ/kg, multi-stage MC’s work input is 263.13 kJ/kg, so the work reduction from single to multi stages is 6.34%. COP of multi-stage MC can improve approximately 6.78% higher than single MC in standard vapor compression. If the number of stages becomes infinite, isothermal compression can be achieved theoretically.

Consider the case where the number of stages is 100, like the T-s diagram in Fig. 2. If adiabatic compression occurs at the front-end and multi-stage intercooling compression is performed at the rear-end, isothermal
compression can be theoretically implemented at the rear-end. As the number of stages increases, the amount of work required by the compressor will decrease. As shown in Fig. 2, isothermal compression is realized at the latter stage of compression, and the effect of approaching the Carnot efficiency can be obtained. The convergence value of work under the current conditions is about 256.6 kJ/kg in Fig. 3.

### 2.2. Practical cycle of intercooling multi-stage MC

Practical cycle is considered including heat exchanger modeling with compression model. The cycle analysis conditions used for this are shown in Table 2. The simulation model was developed using MATLAB, and the thermal properties were loaded from the REFPROP data base. [6]

A copper double pipe heat exchanger was used to analyze the heat phenomenon of the two fluids with counter flow, and for the more physically approaching the practical refrigeration cycle the finite volume method (FVM) was used which is one of the most popular numerical methods used to solve heat transfer problems. [7-8] The secant method was used as a numerical analysis method of cycle. The Secant method is similar to Newton's method. Newton's method finds a solution using the gradient at a given point, while the Secant method finds a solution at the gradient of two given points. Unlike Newton's method, which requires knowing the exact function form, the secant method makes it possible to derive a solution without knowing
the exact function of the given graph. The method of finding the approximate value of the solution by the secant method is as follows.

\[ x_n = x_{n-1} - \frac{y_{n-1} - x_{n-2}}{y_{n-1} - y_{n-2}} x_n, \quad n = 2, 3, \ldots \]  

(1)

\( x_0 \) and \( x_1 \) are assumed to be random values from the beginning. The desired solution can be found by repeating the above formula until the approximate value falls within the error range of the actual value. In this simulation, assuming \( P_{\text{cond}} \) and \( P_{\text{evap}} \) by changing the values of \( T_{\text{cond}} \) and \( T_{\text{evap}} \), the calculation is repeated until the results of each heat exchanger analysis and the enthalpy of cycle point 3 (condenser outlet) and point 4 (evaporator inlet) converge within 1% of the error range.

First, looking at the results of the single MC stage, in this cycle, ammonia has a large vapor compression irreversibility, so it appears as a T-s plot as in Fig. 4. At this time, the condenser temperature and evaporator temperature were 53.99 °C and 5.6 °C, respectively, and the work consumed by the compressor was 309.4576 kJ/kg when the isentropic efficiency was 0.75.

Next is the result when using multi-stage MC including intercooling instead of single MC in the same cycle in the Fig. 5. The effectiveness of the intercooling air heat exchanger between the compression processes was set as an ideal value by obtaining the effectiveness value when the isentropic efficiency is 1 so that the refrigerant at the condenser inlet does not become 2-phase state. When the isentropic efficiency in all stages was given as 0.75, the work input was 230.2457 kJ/kg, which significantly reduced the irreversibility compared to the single-stage MC. As the number of stages approaches infinity, isothermal compression approaches and Carnot efficiency approaches.

In the thermodynamic cycle, the second-law efficiency indicates the degree to which the actual process is close to the reversible process. In this case, the cooling COP can be expressed as the actual performance and the reversible process can be expressed as the Carnot efficiency as shown in the following equation. The second-law efficiency of the multi-stage MC analyzed in this study is 76.77%, and if intercooling and multi-stage compression can be implemented in real, it can be approached close to the Carnot cycle.

\[ \text{COP}_{\text{R}} = \frac{Q_{\text{evap}} / W_{\text{comp}}}{T_{\text{evap}} / (T_{\text{cond}} - T_{\text{evap}})} \]  

(2)

However, it is actually hard to realize multi-stage compression and intercooling using mechanical compressors.[9] This is why compression using interstage cooling has not been studied much. As shown in Fig. 6, there are studies on two-stage compression with refrigerant injection. [10-11]
In contrast, Electrochemical Compressor (ECC) is a technology that compresses gas through an electrochemical reaction and is based on the isothermal compression principle. In the next chapter, the principle of ECC and the practical isothermal compression refrigeration cycle with ammonia ECC are analyzed.

3. Isothermal compression of Electrochemical compressor (ECC)

3.1. Electrochemical Ammonia Compressor

Electrochemical ammonia compressor is an electrochemical compressor that uses the movement of NH$_3$ from the suction side to the discharge side using H$_2$ as a carrier gas when the ion exchanger membrane is charged with DC voltage. As shown in Fig. 7, ammonia and hydrogen transfer the membrane at a ratio of 2:1, and the half reaction at each electrode is as follows. [12]

\[
2NH_3 + H_2 \rightarrow 2NH_4^+ + 2e^- \quad \text{(anode)} \quad (3)
\]

\[
2NH_4^+ + 2e^- \rightarrow 2NH_3 + H_2 \quad \text{(cathode)} \quad (4)
\]

Due to the potential difference, H$_2$ is oxidized to H$^+$ ions at the anode, and NH$_4^+$ ions are generated and passed through the polymer electrolyte membrane. At the cathode, NH$_3$ gas and H$_2$ gas evolve again. Through pressure sealing on the discharge side, gas compression effect is provided as the number of molecules increases without changing the volume.

Unlike traditional MC that is limited by ideal gas law (PV=nRT), the ECC is governed by the Nernst equation and ohmic loss, activation loss, etc. $E_0$ is standard hydrogen electrode potential, and it is zero because the half reactions on both sides of the membrane are opposite. Where $P_{\text{cathode}}/P_{\text{anode}}$ is the ratio of pressures across the membrane, and the voltage required for compression is a function of this ratio. [13]

\[
V_{\text{comp}} = E_{\text{Nernst}} + \eta_{\text{ohm}} + \eta_{\text{act}} \quad (5)
\]
\[ E_{\text{Nernst}} = E_0 + \frac{R T_{\text{ECC}}}{n_F} \ln\left( \frac{P_{\text{cathode}}}{P_{\text{anode}}} \right) \]  

(6)

dU = \delta Q + PdV 

(7)

This relationship describes isothermal compression. From a thermodynamic point of view, the internal energy \( U \) is a function of \( Q \) and \( W \) as shown in the equation (7). In the adiabatic process, if the pressure rises without volume change, \( \delta Q = 0 \) and \( dV = 0 \), so the change in internal energy is zero. Since internal energy is a function of temperature, isothermal compression can proceed as the temperature change also becomes zero. In addition, since there is no physical driving part, it is a great advantage that there are no problems with noise or lubricating oil.

In comparison with mechanical compressors explained in the previous chapter, the most ideal compression of MC for isothermal compression is adiabatic compression. As can be seen in Fig. 8, multi-stage adiabatic compression is needed intercooling, and it results in high capital and operating cost. The ECC performs isothermal compression like in Fig. 8.

![Compressor temperature profiles during compression with multi-stage MC and ECC](image1)

![T-s diagram in practical cycle of semi-isothermal compression using ECC](image2)

3.2. Practical case of isothermal compression cycle modeling with ECC

Practical cycle with ECC was analyzed including single-stage MC compressor in the low-pressure compression part. The cycle analysis conditions used for this also are shown in Table 2. For isothermal compression using ECC, MC with an isentropic efficiency of 0.75 was used at the front-end to adjust the condenser refrigerant inlet temperature to the cycle like Fig. 9, and the isothermal efficiency of ECC is set 0.9. Since the compression of ECC is not volume compression but compression due to the increase in the number of molecules at constant volume, so it cannot be represented as a state point in the T-s plot, but it is plotted in a sense of entropy per mass for better understanding.

From eq. (6), the required work to compress from the MC outlet pressure to the condenser pressure is calculated by dividing the isothermal efficiency (\( \eta_{\text{isothermal}} \)). The work equivalent to the remaining work increases the enthalpy of the refrigerant as a loss of ECC like an eq. (8). So, the refrigerant which temperature determined at the ECC outlet with isothermal compression efficiency flows into the condenser. The ECC consumes the work as 155.84 kJ/kg, and total compression work is required as 243.583 kJ/kg, which is confirmed that the work could be reduced compared to single-MC cycle. Compared to Fig. 4, the cycle using ECC takes advantage at work in the superheat vapor compression over the condenser temperature part and performs close to isothermal compression instead of MC cycle which is barely to implement real intercooling and multi-stage systems.

\[ W_{\text{thermal,loss}} = RT_{\text{ECC}} \ln\left( \frac{P_{\text{ECC, out}}}{P_{\text{ECC, in}}} \right) \frac{n_F}{n_F} \frac{1-\eta_{\text{isothermal}}}{\eta_{\text{isothermal}}} = h_{\text{ECC, out}} - h_{\text{ECC, in}} \]  

(8)

In other words, due to irreversibility caused by cell resistance, overvoltage is required than Nernst voltage, and it generates heat corresponding to remainder of the isothermal compression efficiency. To maintain
constant performance, this heat must be removed. Normally, the isothermal compression efficiency of ECC is known to be about 93% [4], but if you make a stack to achieve a high-pressure ratio, you must have a thermal management solution [14].

Fortunately, ECC makes it easy to implement intercooling between unit cells in the stack unlike the MC. Since the gas distribution channels are in contact between the cells, the surface area for heat removal is sufficient. Tao et al. proposed an intercooler design to implement isothermal compression in ECC stack. The intercooling has an open channel design using air or a heat exchanger design using water, so the system is not complicated. Therefore, it can be said that it is the closest process to practical isothermal compression.

The second-law efficiency of the Fig. 9 cycle is 73.87%, which is the closest to the Carnot cycle. However, even in this cycle, the effect of isothermal compression is reduced because MC is used for the front-end compression to satisfy the condenser temperature. Therefore, it is necessary to study refrigerant cycles or membranes with low condenser temperatures for use in refrigeration cycles. ECC has a cation exchange membrane and an anion exchange membrane. Research is being conducted on a low GWP refrigerant that can pass through the membrane in a positive ion state by obtaining H⁺ while using hydrogen gas as a carrier gas. The most anticipated refrigerant is the HFO series. The biggest barrier to using ECC as a compressor in the refrigeration cycle is the operating temperature of the ECC. In the case of Nafion membrane, which is the most used, since it is mainly used at 5-60°C, the condenser temperature is around that temperature or rather, it requires heating to apply to the cycle and cooled again after compression. Therefore, it is necessary to increase the potential of the refrigeration system through the development of ECC with high efficiency in the low temperature region.

4. Conclusion

In this paper, the concepts of multi-stage mechanical compressor (MC) with intercooling and electrochemical compressor (ECC) are proposed for practical implementation of the isothermal compression. The most ideal and theoretical compression using MC is adiabatic + intercooling compression. With given isentropic efficiency, the work consumed in the refrigeration cycle of single-stage MC and multi-stage MC with intercooling was compared, and the numerical analysis of the cycle reflecting practical elements was performed. As a result, as the number of stages increases, it becomes closer to isothermal compression and the work can be reduced. However, considering the high-speed rotating piston, it is almost impossible to cool the inflowing fluid, and multi-stage compression using MC is not feasible due to the problem that the pressure and temperature of the gas rise simultaneously due to adiabatic compression.

On the other hand, since ECC is not compression by volume reduction, compression close to isothermal compression is possible. In addition, there is no driving parts, and the surface area of the membrane is wide, so it is easy to lower the temperature of the discharge side. Therefore, since sufficient intercooling can be performed by attaching a heat exchanger during multi-stage compression, the possibility of implementing an isothermal compression process is high.

However, when applied to the refrigeration cycle, since the condenser temperature must be matched, the temperature of isothermal compression must still be raised using MC at the compression front-end, and it is difficult to approach Carnot efficiency due to the few stages of isothermal compression. In addition, in the case of ECC, the range of refrigeration cycles that can be applied is not expected to be wide because the operating temperature is high at 5-60 °C. Nonetheless, ECC has potential for low GWP refrigerants and as membrane technology improves, it can potentially improve the efficiency for the vapor compression systems.

Abstract

Non-vapor compression air-conditioning systems were proposed to overcome the limitation of the traditional air-conditioning systems. It was reported that the membrane heat pump(MHP) has a high energy saving potential. The sensible heat and latent heat removal process can be separated by the system. A membrane-based vacuum dehumidification system(MVD) is the latent heat removal systems, consisting of a membrane mass exchanger and a vacuum compressor. The water vapor discharge type membrane-based vacuum dehumidification system(W-MVD) and condenser combined membrane-based vacuum dehumidification system(C-MVD) show high performance among the several structure of MVDs. One system can show a higher performance than another system according to temperature and humidity conditions, but there is lack of discussion about the ideal COP values for actual system design, analysis, and optimization. In this study, the ideal dehumidification COP of the two systems were defined by reversible cycle analysis. It was achieved by removing all irreversibility of system consisting of membrane mass exchangers, vacuum compressor and heat exchanger, and the ideal COP formulas were derived. Exergy analysis and compressor consumption modeling methods were used to verify the formulas, and the COP values calculated by them show a high consistency. when comparing the ideal COP of the MVDs based on the results, the W-MVD shows higher performance than the C-MVD in unsaturation outdoor air condition.

Keywords: Membrane-based vacuum dehumidification system, Membrane mass exchanger, Vacuum compressor, Irreversibility, Ideal dehumidification COP;

1. Introduction

As the demand for building air conditioning increases worldwide and regulations on fluorine-based refrigerants are strengthened, the problem of using the existing vapor compression air conditioning system continues to be raised. At the same time, with the development of sensible load management technologies such as passive house technology and high-efficiency sensible heat control air conditioning system technology, the importance of the humidity control system is increasing to maintain thermal comfort for residents. Accordingly, a membrane heat pump (MHP) that can overcome the shortcomings of the existing dehumidification system has been proposed as one of the promising technologies \[1\].

The membrane heat pump uses the principle that water vapor can be separated from indoor humid air by utilizing a dense membrane with selective permeance to water vapor. Fig. 1 shows the change in the state of the theoretical air conditioned by each dehumidification system on the psychrometric chart. Unlike a condensation dehumidification system that simultaneously removes sensible heat and latent heat, the membrane heat pump can separate the sensible heat removal and latent heat removal process. Since it is not necessary to overcool the air and then reheat it, it is possible to take a thermal gain by the cooling path in the psychrometric chart. Since dehumidification using a desiccant is an isenthalpic process, thermal gains by the cooling path cannot be expected, but the disadvantages of desiccant that consume a large amount of heat during the regeneration process can be compensated. However, the coefficient of performance(COP) should be considered along with the state change of humid air to evaluate how efficient the system operates under certain cooling load conditions.

Chun et al. constructed a system that combines the membrane-based vacuum dehumidification system (MVD) and the air carrying energy radiant air conditioning system to calculate the COP [2]. Since the dehumidification performance of the MVD varies depending on the vapor separated from humid air discharge structure, various structures have been studied to improve performance. Scovazzo & Scovazzo proposed a system that reduced the compression ratio of the vacuum compressor by bypassing a portion of the dehumidified air [3]. Dais Analytic proposed a system in which two membrane material exchangers were installed at the inlet and outlet of the vacuum compressor to reduce the compression ratio and vapor flow rate at the same time [4], and Bui et al. proposed a system in which a condenser was installed at the outlet of the compressor [5]. Lim et al. compared the dehumidification COP of each system and analyzed the effect of outside air conditions [6].

Fig. 1 Cooling path of each system on psychrometric chart; (a) condensation (H-C1-C2-S) (b) desiccant (H-D-S) (c) MHP (H-R-S)

Certain substances can be selectively permeated and separated from the mixture by the membrane, and permeation occurs due to chemical potential differences between two sides of the membrane. In the gas-gas separation membrane, it is divided into a porous membrane and a dense membrane according to the presence or absence of a physical pore through which gas molecules can pass, as shown in Fig. 2, the difference in partial pressure of each gas acts as a chemical potential difference. The permeation performance of the membrane is expressed in terms of permeance, which means the transmittance of a specific material per unit chemical potential difference. The permeation performance of the dense membranes used in the MVD mainly affect the dehumidification capacity and COP of the system, but they are in trade-off relation as shown in Fig. 3, so it is important to select the appropriate membrane according to the situation. Accordingly, experimental studies are being conducted to accurately measure the permeation characteristic values of the membrane under the operation conditions of the system to be actually used. Lee et al. measured the water vapor permeance and selectivity of the water vapor selective dense membrane that can be used in the MVD according to the pressure difference before and after the membrane and the transmission direction of water vapor and air [7].

Fig. 2 Gas separation by partial pressure difference between two sides of membrane; (a) porous membrane (b) dense membrane
In previous studies on the performance of the MVD, the analysis was conducted assuming a membrane that completely blocks dry air and transmits only water vapor, that is, a membrane with infinite selectivity. However, since even a selectivity of the membrane is infinite, there is irreversibility by finite pressure difference as driving force of permeation process. So, this study aims to calculate the ideal dehumidification COP of MVDs by removing all irreversibility for systems design and optimization.

In other previous studies on the ideal performance of air-conditioning system, ideal COP of liquid-desiccant dehumidification and condensing dehumidification system were proposed by Zhang et al. as shown follows [8]. The ideal COP of isothermal dehumidification by perfect gas separation without considering the water vapor discharge process was proposed by Bui et al. as shown Eq.(4) [5]. And Labban et al. proposed ideal COP of generalized air-conditioning system discharging water vapor to ambient using exergy analysis as shown Eq.(5) [9]. This exergy model was used as an evaluation criterion of the ideal COP of MVDs.

\[ \text{COP}_{\text{des, Zhang}} = \frac{1}{R} \frac{T_{\text{ISO, ISO}}}{T_{\text{ISO, ISO}}} \]  
\[ \text{COP}_{\text{con, Zhang}} = \frac{T_{\text{DPJ}}}{T_{R-T_{DPJ}}} \]  
\[ W_{\text{sep}} = -nRT(X_a \ln X_a + X_w \ln X_w) \]  
\[ \text{COP}_{\text{MVD, Bui}} = \frac{m_w h_f g}{\Delta W_{\text{sep}}} \]  
\[ \text{COP}_{\text{DH, Labban}} = \frac{m_w (h_{wet} - h_{dry})}{m_w \delta w + m_d \delta r d r - m_w \delta w e t} \]  

2. Simulation methodology

2.1. Idealized reversible MVDs

Fig. 4 shows the structure of water vapor discharge type MVD(W-MVD) and condenser-combined type MVD(C-MVD), which are analysis target systems of this study. W-MVD has two membrane mass exchangers installed at the inlet and outlet of the vacuum compressor, and C-MVD has a membrane mass exchanger installed at the inlet and heat exchanger at the outlet of the vacuum compressor. Assumptions to define the ideal dehumidification COP of the two systems were shown below.

- Both permeance and selectivity, the permeation characteristics of the membrane, are infinite.
- The effect of concentration polarization near the membrane surface is negligible.
- The water vapor adiabatically compressed to outdoor dry-bulb temperature and isothermally compressed to outdoor vapor partial pressure within non-condensation conditions.
- There is no irreversibility by temperature difference in the condenser of the C-MVD.
- The mass flow rate of indoor and outdoor air passing through the membrane mass exchangers is sufficiently large compared to the amount of water vapor permeation.
2.2. Mass transfer and compression model

The dense membrane separates water vapor from humid air according to vapor permeance and selectivity defined by Eqs. (6) and (7), respectively. Permeance is a property of a membrane determined by the water vapor transmission amount through the membrane under the partial pressure difference between the feed and the permeate side. The higher the water vapor permeance, the greater the amount of water vapor permeated through the membrane per unit area, per unit pressure difference, and per unit time. Selectivity is another property of a membrane determined by the transmission ratio between water vapor and dry air. The higher the selectivity, the more water vapor can transfer. Most previous studies have defined a membrane with infinite selectivity that can only permeate pure water vapor from humid air as an ideal membrane.

\[
\beta = \frac{\dot{m}}{A \Delta P} \tag{6}
\]

\[
\alpha = \frac{\beta_w}{\beta_a} \tag{7}
\]

Eq. (6) can be rewritten in the explicit form for mass flow rate of water vapor \( \dot{m} = \beta A \cdot \Delta P \) where the formulation is similar to the heat transfer process. When the cross-sectional area is finite, infinite permeance is assumed for a reversible isothermal mass transfer process, such as assuming an infinite overall heat transfer coefficient for a reversible isothermal heat transfer process. Therefore, in this study, a membrane with infinite vapor permeance and selectivity was defined as an ideal membrane for dehumidification, and mass transfer through such a membrane is reversible.

Since the pressure difference between the feed side and the permeate side is zero in the ideal membrane, the inlet pressure of the vacuum compressor is the same as the water vapor partial pressure of the indoor air in both MVDs. The vacuum compressor outlet pressure is the same as the water vapor partial pressure of outdoor air in the case of W-MVD, and the water vapor saturation pressure at the outside temperature in the case of C-MVD. At this time, the suction and discharge pressure of the vacuum compressor must not exceed the saturation pressure at each temperature so that water vapor does not condense. If the indoor water vapor partial pressure is higher than the outdoor water vapor partial pressure, indoor water vapor can be discharged to the outside with only the membrane mass exchanger. This is a passive ventilation process, and MVD is unnecessary. Therefore, this case is out of analysis range. Only the case where the outdoor vapor partial pressure was higher than that of the indoor was considered. Fig. 5 is a T-s diagram showing the compression process of MVDs under the condition that the indoor and outdoor relative humidity is 100%. Since the water vapor partial pressure of outdoor air is the saturation pressure, the two MVDs are expressed in the same diagram. Due to the feasibility of isothermal compression, the water vapor would be adiabatically compressed from point 1 to 2'. Then the temperature difference between the vacuum compressor outlet and the outdoor air cause heat exchange. Since this irreversibility should be removed for ideal dehumidification of MVD, it is assumed that adiabatic compression from point 1 to point 2 and isothermal compression from point 2 to point 3 are performed. Assuming that water vapor is an ideal gas, the dehumidification COP are as follows.

\[
COP_{DH} = \frac{\dot{m}_w h_f}{\dot{W}_{cool} + \dot{W}_{cool}} = h_f g \left[ \frac{kRT_1}{k-1} \left( \frac{k-1}{r_{p1}} - 1 \right) + R T_2 ln r_{p2} \right]^{-1} \tag{8}
\]
2.3. Theoretical dehumidification performance

Fig. 6 is a T-s diagram showing the approximate compression process of MVDs under conditions where indoor and outdoor relative humidity is less than 100%. Water vapor separated from indoor humid air is compressed to outdoor water vapor partial pressure in W-MVD and saturation pressure in C-MVD. That is, the outlet pressure of the vacuum compressor depends on both the condenser temperature and humidity in the W-MVD, but on only the condenser temperature in the C-MVD. Therefore, in order to remove irreversibility by heat transfer under unsaturated conditions, water vapor must be isothermally compressed at the dew point temperature of the outdoor air in W-MVD and at the dry-bulb temperature of the outdoor air in C-MVD. The permeation driving force of the membrane mass exchanger is the partial pressure difference of each gas, so the point I and O of W-MVD and point I of C-MVD can be approximated by saturated vapor points on the same pressure line, i.e., points 1 and 3 of W-MVD and 1 of C-MVD. Accordingly, the two MVDs approximately is a rectangular-shape open cycle on T-s diagram, such as a Carnot refrigeration cycle. That is, the ideal dehumidification COP of W-MVD can be expressed as a Carnot refrigeration COP, where the high temperature is the outdoor air dew-point temperature and the low temperature is the indoor air dew-point temperature, as shown in Eq. (9). Similarly, the ideal dehumidification COP of C-MVD can be expressed as a Carnot refrigeration COP, where the high temperature is the dry-bulb temperature of outdoor air and the low temperature is the indoor air dew-point temperature, as shown in Eq. (10).

\[
COP_{W-MVD.\text{ideal}} = \frac{f(P_{wI})}{f(P_{wO}) - f(P_{wI})} = \frac{T_{DPJ}}{T_{DPJ} - T_{DP1}}
\]  
(9)

\[
COP_{C-MVD.\text{ideal}} = \frac{T_{DPJ}}{T_{O} - T_{DP1}}
\]  
(10)
The dehumidification COP of both MVDs was calculated by Eq. (8). In the calculation process, the explicit method using MATLAB was applied based on MVD component modeling, and the thermodynamic properties are based on REFPROP 9.0. The results were mutually verified by comparing the ideal dehumidification COP calculated by Eq. (8) and Eqs. (9), (10). And the values and the theoretical maximum isothermal dehumidification COP calculated by Eq. (5) were compared. The detailed conditions applied to the performance analysis are shown in Table 1. The constraints conditions to analyze the effects of indoor and outdoor air conditions were represented as values in brackets. Both the isentropic efficiency and isothermal efficiency of the vacuum compressor were assumed to be 1.0, and the pump consumption of the C-MVD was ignored. Changes in indoor and outdoor air due to dehumidification and water vapor discharge were ignored, and the atmospheric pressure was assumed to be 101.325 kPa. Since the water permeance and selectivity of the membrane are assumed to be infinite, the compressor inlet and outlet conditions are the same as indoor and outdoor vapor conditions each. The temperature and humidity conditions were based on the ASHRAE 55 standard and KS C 9306 standard.

3. Results and discussion

Fig. 7 shows the ideal dehumidification COP ratio of the two MVDs according to outdoor air relative humidity calculated by Eqs. (9) and (10). By the absence of irreversibility, the ideal dehumidification COP of C-MVD is consistent with the dehumidification COP of W-MVD with 100% outdoor relative humidity. However, under unsaturated conditions of outdoor air, the ideal dehumidification COP of W-MVD is always higher than that of C-MVD, because the dry-bulb temperature is always higher than the dew-point temperature. Under the dehumidification conditions of KS C 9306 standard (T_i=24°C, RH_i=62.66%, T_o=24°C, RH_o=84.22%), C-MVD shows about 63.21% of W-MVD. Since the result of Eq. (9) is consistent with the result of Equation (8) under the saturation condition of outside air, the performance of W-MVD and C-MVD was analyzed with Eq. (8) in the subsequent result analysis.
Fig. 8 shows the theoretical dehumidification COP according to the outdoor air dew-point temperature for each indoor dew-point temperature calculated by Eqs. (5), (8), and (9). The indoor temperature is 24.0°C and the relative humidity is 62.66% to 100%, and the outdoor temperature varies from 16°C to 30°C and the relative humidity is 100%. The values obtained by the three methods are almost identical, and the ideal dehumidification COP of W-MVD and C-MVD under outdoor air saturation conditions is equivalent to the theoretical maximum COP of any isothermal system that discharges water vapor into the outdoor air.

### 3.1. Influence of temperature and humidity

In order to consider the effects of climate conditions on dehumidification COP of MVDs, dehumidification COP variation according to outdoor temperature and relative humidity were analyzed. Fig. 9 shows variation by climate conditions. It is assumed that the temperature of the indoor air is 24°C, and the relative humidity is constant at (a) 100% or (b) 50%. The outdoor temperature changed from 23°C to 40°C, and the relative humidity changed from 50% to 100%. As the temperature or relative humidity of outdoor air increased, the dehumidification COP decreased under all conditions. This is because the water vapor separated from the indoor air and passed through the membrane must be compressed to a higher pressure as the partial pressure of outdoor water vapor increases, resulting in an increase in vacuum compressor power consumption. This can also be explained by the fact that under the $T_{DP,I}$ condition set in Eq. (9), the larger the $T_{DP,O}$, the smaller the dehumidification COP, and is consistent with the intuition that the dehumidification system has higher COP in dryer climates.

Fig. 9 Ideal dehumidification COP of MVD variation as outdoor air conditions of $T_I=24°C$; (a, left) RH$_I$=100%, (b, right) RH$_I$=50%

Fig. 10 Ideal dehumidification COP according to indoor air conditions of $T_I=24°C$; (a, left) RH$_I$=100%, (b, right) RH$_I$=50%

Since indoor conditions change when an air-conditioning system is operated, the effects of changes in indoor conditions on dehumidification COP under specific climate conditions was analyzed. Fig. 10 shows the ideal dehumidification COP variation according to the indoor air temperature and relative humidity. It is
assumed that the outdoor air temperature is 24°C and the relative humidity is constant at (a) 100% or (b) 50%. The indoor temperature changed from 10°C to 34°C, and the relative humidity changed from 100% to 50%. As the indoor temperature or relative humidity increased, the ideal dehumidification COP increased. This is because the compression ratio of vacuum compressor decreases as the partial pressure of indoor water vapor increases. This can also be explained by the fact that under the $T_{DP,O}$ condition set in Eq. (9), the larger the $T_{DP,I}$, the larger the dehumidification COP, and is consistent with the intuition that the dehumidification system has lower COP in the humid state at the beginning of dehumidification.

3.2. Irreversibility analysis

The assumptions of the MVD are not valid in a real system due to the inevitable irreversibility, so the actual dehumidification COP of MVD cannot reach the ideal values. Considering the finite permeance of the membrane, the finite pressure difference on both sides of the membrane mass exchanger is required as the driving force of mass transfer, which acts as irreversible. The inlet pressure of the vacuum compressor should be lower than the indoor vapor partial pressure, and the outlet pressure of the vacuum compressor in W-MVD should be higher than the outdoor vapor partial pressure, so the compression ratio increases and the energy consumption of the vacuum compressor increases. Fig. 11 and Fig. 12 (a) show the dehumidification COP according to the outdoor air temperature for each finite pressure difference between both sides of the membrane with finite water vapor permeance and infinite selectivity of W-MVD and C-MVD, respectively. It was assumed that the indoor temperature was 24°C, the relative humidity was 62.66%, and the outdoor relative humidity was 84.22%. The lower the water vapor permeance of the membrane, the greater the required water vapor partial pressure difference, the higher the irreversibility of the system, so the dehumidification COP is lower than the ideal value. If the pressure difference is not required due to infinite water vapor permeance, the dehumidification COP is consistent with the ideal dehumidification COP.

![Fig. 11 Dehumidification COP reduction in W-MVD due to finite pressure difference ($T_I=24°C$, RH$_I=62.66\%$ and RH$_O=84.22\%$)](image)

Fig. 10 (b) shows the dehumidification COP of C-MVD with infinite membrane permeance and selectivity for each temperature difference in the condenser. Like the pressure difference between both sides of the membrane, the dehumidification COP approaches an ideal value as the temperature difference decreases, because water vapor must be compressed more at a temperature higher than the outdoor temperature dew to the finite temperature difference. In all results, the finite pressure difference and temperature difference were assumed to be uniform.
In the compression processes of the ideal MVD, the water vapor separated from the indoor humid air was isothermally compressed at the outdoor temperature. However, in practice, it is difficult to implement isothermal compression as discussed in section 2.2, and a single adiabatic compression causes MVD to consume more energy as it is compressed to a temperature higher than the outdoor air temperature. Fig. 13 compares the ideal dehumidification COP and the dehumidification COP in this case. Systems that have a single adiabatic compression show lower performance under all temperature and humidity conditions than systems that have an ideal compression process.

4. Conclusion

The ideal dehumidification COP of MVDs was analyzed in this study. Assuming that there is no irreversibility of the membrane mass exchanger, vacuum compressor, and heat exchanger, the ideal dehumidification COP of W-MVD and C-MVD was defined by Carnot cycle analysis. This was compared with the thermodynamical maximum dehumidification COP values calculated by exergy analysis and components modeling. Based on the newly defined ideal dehumidification COP, the influence of operation conditions and irreversibility of actual systems were analyzed. The results of this study were as followed.

✓ The dehumidification COP values calculated by the three methods matched. These results show dehumidification COP of MVDs can be predicted by only the temperature and humidity conditions of the indoor and outdoor air where MVDs are operated.
✓ The ideal W-MVD has a thermodynamical maximum dehumidification COP, which is 58.2% higher than the ideal dehumidification COP of C-MVD under reference condition.

✓ The dehumidification COP of the systems is better in cold, dry climates. The values near the asymptote are very high because the water vapor partial pressure of indoor air is higher than that of outdoor air or the difference is too low. The MVD is not useful in these conditions, however, it is possible to identify temperature and humidity conditions in which the dehumidification can be performed with low energy consumption or only simple passive ventilation without operation of the systems.

✓ Under the desirable temperature and humidity requirements, the ideal dehumidification COP of W-MVD is approximately 50-100 and considering the irreversibility inevitable in real systems such as finite pressure difference in mass transfer process or finite temperature difference in heat transfer process, the actual COP is lowered according to the degree of the irreversibility. The presented equations for the ideal dehumidification COP of MVDs can be used as a basis for research on performance of MVDs and for system design and optimization.

Abstract

Considering the overall limited availability of renewable electricity and (district) heat together with the competing demand by industry and transport, deep thermal renovation (TR) of buildings and a rapid phase out of fossil-based heating systems is crucial to achieve the overall climate targets. Independent of the actual choice of the path to the required phase-out of fossils, it will lead to significantly increasing shares of renewables (RE) in the electricity system. This increasing share of RE will lead to a significant reduction of the CO\textsubscript{2} conversion factor in DH, when, as anticipated to a large extent central large-scale HPs are involved. The dilemma is that in such a scenario, with proceeding time, the deep TR of buildings and the further integration of onsite PV (coupled to HPs) will not any more influence the CO\textsubscript{2} emissions of the building in a relevant way. This would lead to a decreasing motivation to implement high ambition targets on building level. However, high ambition levels will be required to reach the overall goal of the phase-out of fossil energy. This requires an energy policy approach instead of market incentives, i.e. CO\textsubscript{2} tax will not sufficiently trigger the required transition process but instead CO\textsubscript{2} budgets have to be defined.

Keywords: Heat Pumps; Renewables; Thermal Renovation; Phase-out; Energy Scenario; Building Stock; Transition; CO\textsubscript{2}; Dilemma

1. Introduction

1.1. Buildings and Energy Transition

On European level (EPBD), ambitious goals have been set implementing nearly zero energy buildings (nZEB) and the target to integrate onsite (or nearby) renewables [1]. Massive integration of renewables (RE) shall lead to Net Zero Energy Buildings (NZEB) or even Positive Energy Buildings (PEB). Extending the system boundary to blocks and districts allows to unlock efficiency potentials of the electric and thermal energy of neighborhoods leading to the goal of Positive Energy Districts (PED) (IEA EBC Annex 83, IEA HPT Annex 61), see e.g. [2].

Contrariwise, with the recently growing need to rapidly phase-out fossil energy-based heating systems, a trend can be seen that HPs and direct electric (DE) heating are implemented in existing buildings (i.e. without thermal renovation) as an apparently cheaper and faster solution (IEA HPT Annex 50).

However, due to the overall limited availability of renewable electricity and (district) heat together with the competing demand by industry and transport, deep thermal renovation (TR) of buildings and a rapid phase out of fossil-based heating systems is crucial to achieve the overall climate targets. The change from gas- or oil-based heating systems to heat pumps (HP) is (often) only technically feasible in combination with deep TR and generally only recommended in combination with it. However, there are both technical and non-technical barriers and challenges [3].

A rapid phase out of fossil-based heating systems requires a significant boost in the exchange rates. The heat demand of buildings will increasingly be covered by HPs and district heating (DH) and in a minor part by DE systems. Biomass, partly in combination with solar thermal can only be applied up to its limited availability and taking into account the need of biomass in the industry and traffic sector [4]. A decarbonized DH system will consist of biomass CHP, heating plants, large-scale HPs and to some extent geothermal and solar thermal. Therefore, a significant increase of DH’s extents and a massive increase of HPs should be taken into consideration [5].

Constraints are next to the limit of available biomass for the building sector (with the competition of other energy consuming sectors and growing food). the limit of economically expanding DH networks and the large-scale production and installation of HP and RE. In addition, a number of barriers/gaps have to be addressed in such a transition process, which are acc. to [3]

- Technical gap: Replacing (decentralized) oil, gas and E-boilers in multi-apartment buildings requires solutions for which currently dedicated HP (system) solutions are not available on the market.
- Owner-user gap: The building owner is often not the beneficiary of the investment, but the tenant is.
- Social gap: Mixed housing (tenant, owner structure) might be an unbreachable obstacle, if e.g. some parties did replace gas boilers recently, while others alternatively replaced windows.
- Financial gap: Renovation might be economically feasible considering life-cycle costs, but high investments are required immediately, which may surpass liquidity constraints.

Without energy efficiency measures in buildings, the electric energy demand increases when switching from fossil energies to HP-based heating systems. This would lead to an increase of the so-called winter gap [6] in a future energy system based on volatile renewable resources (wind, PV).

In the perspective of the energy transition the infrastructural and technological lock-in in the building sector is a limiting aspect considering the long lifetime of buildings and building components [7]. Since building components have a typical lifetime of several decades, insufficient measures taken now will have a long-term effect [8]. This so-called ‘carbon lock-in’ highlights the need of rather deep TR measures than fast incomplete measures. As an example, a newly installed gas boiler with a lifetime of 20 years becomes a ‘stranded asset’ and will prevent phase-out of gas but replacing it before end of life is critical in terms of economic considerations. In this perspective, the role of buildings with the possibility of deep TR and switching from fossil-based to HP-based heating systems is of primary importance in achieving the goals of the energy transition and has to be seen as one of the important columns of the energy policy strategy.

1.2. Aim of and structure of this work

In such a scenario of the energy transition, with proceeding time, the deep TR of buildings and the further integration of onsite PV (coupled to a HP) will not significantly influence the CO₂ emissions of the building, which would lead to a decreasing motivation to reach high ambition goals on building level. However, high ambition levels will be required to reach the overall goal of the phase-out of fossil energy in the electricity system and in district heating networks.

Using a simple building stock model, different scenarios of deep TR and integrating HPs and RE will be discussed in terms of environmental impact (i.e. CO₂ emissions) highlighting possible strategies to overcome this energy transition dilemma.

In section 2, Methods, the model and the assumptions are described and different scenarios are developed. In section 3, Results, the scenario results are shown in terms of secondary energy and CO₂ emissions and are discussed from the perspective of the building stock and from the perspective of an individual building. From the results strategies are developed and summarized and concluded in section 4.

2. Method

2.1. Building Stock and Energy System Model

The model represents a generic district and analyses the primary energy demand (P-E) and CO₂ emissions considering transport and conversion for a given useful energy demand (U-E) and consists of (from right to left in the Sankey in Fig. 1):

- the demand, i.e. the useful energy (UE): space heating (SH), domestic hot water (DHW) as well as appliances and auxiliaries,
the heating systems: fuels (oil, gas, biomass), direct electric (DE) heating, heat pump (HP) and district heating (DH) and

- the energy system consisting of combined heat and power (CHP) and district heating plants (DHP).

The supply side (left), the required secondary energy (S-E), is provided by fossil energy sources (oil, gas), biomass (bio) and to some extent renewable electricity (RE E: hydro, wind, PV) and renewable and waste heat (RE H: industrial waste heat, waste incineration, geothermal, solar thermal).

Using conversion factors (see section below), from the S-E the primary energy (P-E) and CO₂ emissions are calculated.

![Sankey Diagram](https://www.mathworks.com/matlabcentral/fileexchange/75813-sankey-diagram)

**Fig. 1. Sankey Diagram** of the Baseline system with high share of fossil (oil, gas) for direct use in buildings (boiler) and for combined heat and power plants (CHP) as well as district heating plants (DHP) and existing (inefficient) building stock with high space heating demand (SH), central heat pumps (cHP) in district heating (DH) play a minor role as do decentral heat pumps (HP) in buildings for space heating (SH) and domestic hot water (DHW).

### 2.2. Decarbonization Scenarios

The year 2025 is considered as baseline (see section below for details) and the scenario is developed until 2050. For the Building Stock (BS) and for the Energy System (Electricity E and District Heating DH) each three ambition levels (AL) are considered.

- **Const (= BAU)**
- **IMPROVE**
- **AMBITION**

For the Building Stock, BAU means no (relevant) reduction of the HD, IMPROVE means a reduction from 80 kWh/(m² a) to 55 kWh/(m² a) and AMBITION means a reduction to 30 kWh/(m² a) until 2050.

For the Energy System, BAU means slow phase-out of fossil fuels (oil, gas) and no relevant increase of RE in the electricity system and district heating systems, IMPROVE means a relevant reduction of fossil energies and AMBITION a high ambition level, thus that fossils are reduced (directly switching from fuels to electricity (E) and district heating (DH) and indirectly in E and DH) to a remaining very low share. This leads to a massive extension of RE (Biomass CHP as well as wind and PV) in the electricity mix and involves Biomass CHP and HPs in DH.

Furthermore, two different paths are defined, one with focus on individual (i.e. building-wise) HPs and one which is DH dominated and thus includes a higher share of central HPs. This leads to 18 variants in total as shown in Fig. 2.

---

Fig. 2. Overview of Scenarios (transition paths) starting from the baseline with two different paths (individual HP or DH) and with different Ambition Levels (AL) for Electricity (E) and District Heating (DH) as well as for the Building Stock; B: BAU, I: IMPROVE, A: AMBITION

2.3. Building Stock Model - Baseline

The simple building stock (BS) model consists of 100 buildings (i.e. 100 %) with an average treated area of $A_T = 150 \text{ m}^2$. The BS with constant number of buildings with the following properties (Table 1) is heated with a mix of fuel, direct electric heating (DE), decentral heat pumps (HP) and district heating (DH) as in Table 2. In all scenarios fuels for heating are reduced to minor shares of 2.5 % in terms of energy demand. Direct electric heating (DE) is assumed to increase from 10 % in 2025 linearly to 15 % in 2050. In all scenarios a switch from fossil fuels to biomass is assumed but considering that the absolute amount of biomass is limited for the building sector. Gas boiler (condensing) are assumed to have an overall thermal efficiency of 85 %, while oil and biomass boilers are calculated with 80 % efficiency. The share of DH increases in the DH-path from 25 % to 60 % and in the HP-path to 35 %.

2.4. Energy System - Baseline

For sake of simplicity the energy system is modelled by means of annual balancing starting from the baseline until 2050 in steps of 5 years and consists of fuels (oil, gas and biomass), an electric grid and DH. Both systems, electricity and DH are coupled on several levels: directly via CHP, and indirectly via central HPs in the DH system and decentral HPs in buildings and are influenced by the choice of the ambition level in the building stock (BS) through the reduction of SH demand in the DH and via DE and HP in the electricity demand, see also Fig. 1 (above).
Depending on the choice of the ambition level in the BS and the path (DH or HP) the energy demand in the DH can either decrease or increase. The electricity demand can either remain constant (in the DH path and in case of high ambition level), or in all other cases will increase.

The overall goal is to compare different paths for the phase-out of fossils. As shown in Fig. 1 (above) this can be achieved on building level by different combinations of (deep) TR, switching from fossil-based heating to biomass-based heating, DH or HP and by decarbonizing the electricity and DH. Both in the electricity mix and the DH system biomass is present. Due to the limited potential of biomass for energetic use, biomass is limited as direct fuel or as fuel in CHP or District Heating Plants (DHP) in all scenarios to a maximum increase of 100 % with respect to the baseline.

2.4.1. Electricity
The electricity system consists of fossil (gas) and biomass CHP, Hydro (with a constant absolute contribution), Wind and PV. Coal and nuclear energy are excluded in this scenario (baseline 2025).

In a scenario with increasing electricity, to some extend biomass CHP can be increased, the rest hast to be covered by extending wind and PV. On-shore and off-shore wind are not distinguished. Furthermore, onsite (building integrated) and ground-mounted PV are not distinguished. Imports and exports of electricity are disregarded (i.e. either not existing or balanced). The absolute contribution of hydro is assumed to be constant (limited extension potential).

2.4.2. District Heating
District heating (DH) refers to (sufficiently) large DH systems with CHP (block heating is accounted to single building heating systems, here). The contribution to DH of the baseline is summarized in Table 4. DHP are assumed to have an efficiency of 80 %. The thermal efficiency of CHP plants is 40 % and the thermal energy is limited by the electric output (electricity-driven CHP). DH losses are assumed to be 10 % with respect to the useful energy. Waste heat, geothermal and solar thermal absolute contribution is assumed to be constant.

Table 4. District heating (DH) system of baseline, share in %.

2.4.3. Heat Pumps
Heat pumps play the predominant role in both paths (HP and DH). The central and decentral HPs are modelled with a simple Carnot based approach with a Carnot performance factor $\eta_c$:

$$COP_{HP} = \eta_c \cdot COP_e$$  \hspace{1cm} (1)

$$COP_e = \frac{T_{max} - T_{min}}{T_{max} - T_{min}}$$  \hspace{1cm} (2)

$$COP_{Sys} = (1 - a) \cdot COP_{HP} + a \cdot COP_{DE}$$  \hspace{1cm} (3)

For the decentral (building- or flat-wise) HPs, the following assumptions were made: a Carnot performance factor of 0.36, a flow temperature of 65 °C at an average ambient temperature of 10 °C and share a of direct electric (DE) heating of 15 % with $COP_{DE} = 1$ (bivalent system) the system COP = 2.
For the central HPs (DH level), the flow temperature is assumed to be 95 °C, the average source temperature is 15 °C and the Carnot performance factor is $\eta_c = 0.44$. This results in an average HP and system COP of 2.

It is noteworthy that a COP of 2 is relatively low with respect to other studies. However, if a fast and broad implementation of HPs in the building stock is assumed, a high-quality low-temperature heating system cannot be hypothesized. Hence, the assumption of higher COP would be very optimistic. In case of the scenario with high ambition level in the BS, a lower heating load and a lower required flow temperature could be expected, which would lead to a slightly better COP. The influence on the resulting electricity demand would be still relatively low as also the demand is anyway significantly lower. As an example, with a COP of 2.5 instead of 2, the required additional renewable electricity would be 25 % less for HPs in DH and 50 % less for building-wise HPs with high ambition level and a COP of 3 as shown in Tab. 3.

Table 3. Influence of COP of the HP on the electric energy demand $w_{el}$ of the building stock (BS).

2.5. Combined Heat and Power

For gas and biomass fired combined heat and power plants (CHP) a CHP coefficient (power to heat ratio) of $\sigma = 1.0$ ($\eta_{el} = 0.4, \eta_{th} = 0.4$) is assumed. It is defined as the ratio between electricity generation ($W_{el}$) and thermal generation ($Q_{th}$):

$$\sigma = \frac{W_{el}}{Q_{th}}$$

(4)

The CO2 emissions allocated to the electric energy and the thermal energy are evaluated using the Carnot Method. The Carnot-Efficiency $\eta_C$ is calculated based on the maximum i.e. the flow temperature of the DH system (assumed to be 160 °C) and the minimum temperature, i.e. the ambient temperature (10 °C):

$$\eta_C = 1 - \frac{T_{min}}{T_{max}}$$

(5)

The so-called fuel fraction of electrical and thermal energy can be calculated based on the thermal and electric efficiency and the Carnot efficiency.

Fuel fraction of electrical energy $A_{F,el}$:

$$A_{F,el} = \frac{(1-\eta_{el})}{\eta_{el} \eta_{th}}$$

(6)

Fuel fraction thermal energy $A_{F,th}$

$$A_{F,th} = \frac{\eta_{el} \eta_{th}}{\eta_{el} \eta_{th}}$$

(7)

The CO2 conversion factor is determined based on the fuel fraction and the thermal and electric efficiency.

$$f_{CO2,el} = A_{F,el} \cdot f_{CO2, gas} / \eta_{el}$$

(8)

$$f_{CO2,th} = A_{F,th} \cdot f_{CO2, gas} / \eta_{th}$$

(9)

CHP is assumed to be purely electricity driven.

2.6. CO2 emissions

The total CO2 emissions are determined based on the secondary energy (S-E) and the CO2 conversion factors (eqs. (10) to (11)) and parameters in Table 4 with hy: hydro, wi: wind, PV: photovoltaic, bCHP-

\[
f_{\text{CO}_2,\text{el}} = f_{\text{pp}} \cdot \text{CO}_2,\text{pp} + f_{\text{waste}} \cdot \text{CO}_2,\text{waste} + f_{\text{PV}} \cdot \text{CO}_2,\text{PV} + f_{\text{fCHP}} \cdot \text{CO}_2,\text{FCHP} - E + f_{\text{fCHP}} \cdot \text{CO}_2,\text{FCHP} - E
\]

\[
f_{\text{CO}_2,\text{DH}} = f_{\text{waste/RE}} \cdot \text{CO}_2,\text{waste/RE} + f_{\text{fCHP}} \cdot \text{CO}_2,\text{FCHP} - \text{DH} + f_{\text{fCHP}} \cdot \text{CO}_2,\text{FCHP} - \text{DH} + f_{\text{fCHP}} \cdot \text{CO}_2,\text{el}
\]

\[
\text{CO}_2 = W_{\text{electric}} \cdot f_{\text{CO}_2,\text{el}} + Q_{\text{DH}} \cdot f_{\text{CO}_2,\text{DH}} + E_{\text{Bio}} \cdot f_{\text{CO}_2,\text{Bio}} + E_{\text{Gas}} \cdot f_{\text{CO}_2,\text{Gas}} + E_{\text{oil}} \cdot f_{\text{CO}_2,\text{oil}}
\]

3. Results and Discussion

3.1. Phase-out of Fossil

The phase-out of fossil fuels and the transition to renewable electricity and renewable DH is shown in Fig. 3. In spite of the high ambition level in the building sector (i.e. deep thermal renovation) and a high share of DH the electricity demand is increasing. A major part of the DH is covered by large-scale central HPs which contribute with a relevant share to the increase of the electricity demand. The additional electricity demand is covered by a large extent by PV and wind.

Fig. 3. Transition from fuel-based heating to HP and DH as well as decarbonization of electricity and DH from baseline to AMBITION level scenario.
3.2. Ambition Levels and influence of deep thermal renovation

Fig. 3a, b and c show exemplarily the Sankey diagram for the highest ambition level in terms of electricity and DH and three different ambition levels for the building stock (a: AMBITION, b: IMPROVE, c: BAU). The higher ambition level in the building stock leads to the lowest CO₂ emissions, and significantly reduced required amount of electricity for HPs (central and decentral) and this in consequence to a significantly reduced need to extent renewable electricity.

![Sankey diagram](image)

Fig. 4 Sankey diagram of energy system case "AMBITION" with (a) deep thermal renovation (AMBITION), 41.9 ton CO₂ (b) thermal renovation (IMPROVE), 61.6 ton CO₂ and (c) no thermal renovation (BAU), 107.8 ton CO₂.

3.3. Decarbonization Strategies and Ambition Levels

The resulting development of the CO₂ emissions (Fig. 4a), the electricity (Fig. 4b) and the DH (Fig. 4c) demand as well as of the required extension of PV and wind (d) in the different decarbonization paths (see section 2.2) are summarized in the following diagrams. From Fig. 5 it can be derived that the HP-path leads to the overall lowest CO₂ emissions. However, the implementation of HPs in existing buildings is technically very challenging. It can be seen for all variants that without deep TR, switching from fossil to HP-based heating
will significantly increase the energy consumption of the building stock. The mere phase-out of oil and gas is not sufficient to reduce the CO$_2$ emissions.

Fig. 5. Development of the annual CO$_2$ emissions (a), total electricity demand (b), DH demand (c) and extension of PV and wind electricity (d) according to the different paths (left: DH and right HP) and according to the different ambition levels of the building stock (legend: energy system AL – building stock AL).

The IMPROVE energy scenarios do not reach sufficient reduction of CO$_2$ emissions without ambitious renovation. Instead, in the AMBITIOUS energy scenario a diminishing influence of the ambition level in the BS can be seen, i.e. deep thermal renovation does not seem to change the picture. However, this goes on cost
of a significantly extension of the electricity generation. Without high ambition level in the building sector, the AMBITION scenario in the energy sector can only be achieved by massive extension of PV and/or wind. This would lead to an increasing mismatch between winter and summer (winter gap, see section below). The DH-path requires a massive extension of DH grids with a large number of central HPs. As in all AMBITION scenarios (and to a lower extent also in the IMPROVE) the CO₂ conversion factor will relevantly decrease, CO₂ tax on electricity and DH will lose its relevance with proceeding time, as also shown in the next section.

3.4. Single Building Perspective

Based on the results of the scenario, the CO₂ emission on building level can be evaluated using conversion factors for electricity and in case DH. The resulting conversion factors are summarized in Fig 6.

In all scenarios the conversion factor for electricity reduces. It reaches nearly zero in 2050 in case of high ambition level (12.4 g/kWhₑ). The conversion factor of DH is connected to that of electricity (due to the central HPs) and also reduced to almost zero in 2050 in case of high ambition level (7.4 g/kWhₜh).

For the building, if no regulations are supposed except phase-out of fossil for a given point of time, any measure or combination of measures could be chosen: DE, HP or if applicable DH

Additional measures are optional
- Thermal renovation (standard, deep)
- Onsite renewables (PV)
Assuming the building is equipped with a gas-boiler, and has the average characteristics as described in Table 1, the CO₂ emissions can be calculated for different combinations of measures and different points of time (i.e. switching from fossil-based heating to either DE or HP or DH in 2025, 2030, 2035, 2040). Here exemplarily, the results for a switch in 2025 and 2035 are shown. Independent of the point of time of the implementation of the measure, in 2050, the emissions are very low with respect to the baseline. The additional thermal renovation does not significantly influence the CO₂ emissions and even to a lower extent if the measure is implemented later. Hence, a CO₂ tax would, if switching from fossil-based heating to electricity-based, be of minor influence and would not trigger the additional thermal renovation.

3.5. Winter gap and seasonal storage

Additional electricity demand “generated” by means of insufficient efficiency measures (i.e. DE instead of HP, insufficiently or not renovated buildings) has to be provided by RE, i.e. by wind turbines or PV. While the main electricity demand occurs in winter (in particular in case of inefficient buildings), the contribution of PV (and also of hydro) will be available mainly in summer. Wind energy has a less seasonally pronounced characteristic but is volatile, too. If - as can be expected - the share of PV will be dominating because of higher public acceptance, there will be a strong seasonal mismatch between demand and supply. This seasonal gap (also called winter gap) requires (seasonal) storage capacities. To some extent pumped hydro storage may be available, but the main contribution will have to be covered by renewable hydrogen (and/or methane). The cycle efficiency of electrolysis-hydrogen-(mechanization)-storage and re-electrification (with fuel cell or gas turbine) is with optimistic assumptions in the range of 30 %. Consequently, for each kWh of electricity that has to be stored, 3.33 kWh have to be generated in summer at correspondingly very high costs.

3.6. Strategies

From the results of the scenarios, the following strategies for the building stock and energy policy can be derived:

- Develop a clear and transparent energy policy that includes the building stock as a major column;
- Evaluate measures in the building stock from the macro-economic instead of from the micro-economic perspective;
- Identify lock-in effects and avoid/prevent all measures that lead to lock-ins;
- Focus on energy efficiency in the building stock first, then renewables;
- Restrict direct electric heating (neither for SH nor for DHW);
- Set absolute limit for final energy for electricity (or heat in case of DH) for buildings;
- Direct fundings/subsidies in-line with the overall climate and energy policy goals. Cancel all contra-productive fundings/subsidies;
- Balance investments in the building sector with reduced need to invest in the energy system (PV, wind, energy storage);
- Develop a clear long-term strategy for the extension of DH and define dedicated districts;
- Set a CO₂ budget (per person) instead of a CO₂ long term target.

4. Conclusions

This increasing share of RE in future electricity and DH system will lead to a significant reduction of the CO₂ conversion factor for electricity with also a relevant influence on the CO₂ conversion factor of DH when HPs are involved. The dilemma is that in such a scenario, a high ambition level with respect to deep TR, or the further integration of onsite RE coupled to a HP will not significantly influence the CO₂ emissions of a building. Instead, a high ambition level on building level and massive onsite PV will be required to reach the goal of the phase-out of fossil energy. This requires an energy policy approach instead of market initiatives, and for example e.g. CO₂ budgets or other limits and conditions will have to be defined. This dilemma can only be solved if the building sector is seen as part of the energy policy.

Insufficient ambition goals on building level lead to the so-called lock-in, which prevents or delays reaching the climate goals on energy system level. A purely micro-economic focused approach will inevitably lead to fail. The building stock has to be considered as a part of the energy system and planning and implementation of any measure has to be evaluated in the context of the transition to a sustainable (and affordable) energy system. A CO₂ budget (per person) until e.g. 2050 (better 2040) instead of target of CO₂ emissions in 2050 (or
2040) is required. Transparent and reliable goals have to be set for the building sector with limits for the final energy consumption instead of non-directed incentives.

As outlook, an economic analysis should be performed as a next step and also the need of (seasonal) energy storage should be considered in future works.

Simulation-assisted development of a mini-split air-to-water façade-integrated heat pump for minimal invasive renovations

William Monteleone*, Fabian Ochs

*Unit for Energy Efficient Building, University of Innsbruck, Technikerstraße 13, 6020 Innsbruck, Austria

Abstract

One of the challenges in renovated multi-apartment buildings is the upgrade or substitution of existing systems delivering space heating (SH), domestic hot water preparation (DHW) and cooling (SC). Construction and installation works are complex and their related costs are high. The European heat pump market currently lacks compact and cost-effective solutions for minimally invasive, so-called serial renovations, which at the same time exhibit high efficiency, an aesthetically pleasing design and low sound emissions. Façade-integrated decentralised small-scale heat pumps (HP) are regarded as a promising solution to increase the general acceptance for flat-wise heating solutions. Because of the compact design, they require a deeper investigation of the fluid-dynamics within the outdoor unit (evaporator) to guarantee an adequate efficiency of the final product. Based on these considerations, a mini-split air-to-water façade-integrated HP for DHW was developed. The design of the outdoor unit was optimised by means of computational fluid-dynamics simulations (CFD) and the overall efficiency evaluated through refrigerant cycle and system simulations. To conclude, the prototype was tested dynamically in a double-room climate chamber with controlled indoor and outdoor temperature conditions.

1. Introduction and state-of-the-art

The European Building Performance Directive (EPBD) 2018/844 [1] stated the commitment of the European Union (EU) to the development of a sustainable, energetically secure and decarbonized energy system, along with a full decarbonization of the building stock by 2050, 35% of which older than 50 years old [2]. The new EPBD indicates also that EU member countries should submit national building renovation strategies within the National Energy and Climate Plans (NECPs) including roadmaps to phase out fossil-based systems supplying heating and cooling by 2040 at the latest. In order to achieve the full decarbonization of the building sector, an improved average yearly renovation rate of 3% is needed (compared to the actual 1%) along with a cost-effective transformation of existing buildings into nearly-zero energy buildings (nZEBs) [3]. Independently from how a carbon neutral energy system will be realized in the future, it is no doubt that HPs will play a crucial role in a sustainable and efficient transformation in the heating, cooling and DHW preparation of buildings [4]. During the renovation of multi-apartment buildings, a complete upgrade or substitution of the existing centralized systems delivering the SH, SC and DHW demands is frequently not possible for techno-economic reasons, among others high investment costs and high degree of invasiveness. The European market offers currently different HP based solutions depending on their construction type [5]:

a) Internal monoblock with integrated hot water storage;

b) Internal monoblock with integrated wall-hanging hot water storage;

c) Split units;

d) DHW HP with integrated or separated hot water storage.

* Corresponding author. Tel.: +43 512 507 63661
E-mail address: william.monteleone@uibk.ac.at.
Split units (air-to-air or air-to-water) are already a standardized product on the market and are offered in all power ranges. A couple of major drawbacks of such system are however the optically unattractive outdoor unit and the high developed sound power level during operation, ranging from 59 to 70 dB(A) for outdoor units and from 43 to 65 dB(A) for the internal module [5,6]. Accordingly, the European market does not yet offer compact, modular and silent split HP solutions with an aesthetically pleasing design of the outdoor unit. Innovative decentral façade-integrated small-scale HP solutions would guarantee a substantial space saving and a high degree of prefabrication, minimizing thus the total investment costs. Additionally, reduced sound emissions should improve their overall acceptance. Within the FFG (Austrian Research Promotion Agency) funded research projects FitNeS and PhaseOut a mini-split air-to-water façade-integrated HP for DHW with a design heating power of 1.5 kW was developed by means of coupled simulation and experimental work to cover an important gap on the wide renovation market and enhance serial renovation in multiple-family buildings. The design and the optimization of the outdoor unit was performed through CFD, refrigerant cycle and system simulations. To supply a proof-of-concept and to verify the efficiency of the developed design, a prototype was tested dynamically with water tapping profiles according to EN 16147 [7] in a double-room climate chamber with controlled indoor and outdoor temperature conditions.

2. Highlight of current research gaps and novelty of developed concept

DHW and SH in renovated buildings are mainly fossil based in continental Europe, with small differences among member countries [8], with more than half of the installed systems relying on either natural gas or oil [9]. New centralized installations are frequently not possible or possible for social, technical or economic reasons, among them high degree of invasiveness, higher investment costs, higher distribution losses and impossibility to provide step-wise renovation. District heating (DH) systems represent a real alternative only if they are already available on site, often not the case especially in densely populated areas. Additionally, the European market does not provide efficient and cost-effective sustainable alternatives to decentral gas-fired or electric boilers that require only minimal construction work. In this paper, a propane-based façade-integrated mini-split HP for the apartment-wise renovation of multiple-family buildings will be presented to tackle the absence of minimally invasive, compact and silent HP solutions on the broad market segment of the refurbishment of buildings. Since the integration takes mainly place within the insulation layer, a deep analysis of the fluid dynamics and the heat transfer is necessary. Firstly, the main boundary conditions of the CFD simulation work will be highlighted and the final design selected based on flow homogeneity, overall pressure drop, sound emissions and electric power consumption of the fans. Secondly, the theoretical performance of the refrigerant cycle will be evaluated under the assumption of uniform flow conditions. Then, the overall performance of the entire system, including the HP, the hot water storage and the fresh water station for the delivery of the DHW demand, will be investigated by means of dynamic system simulation. Lastly, the results of the testing of a prototype of mini-split HP under dynamic conditions will be presented.

3. Methodology

The analysis presented in this work follows a development and optimization approach from the component level up to the system level, as discussed also in [10] where the development of an air-to-air HP for SH is highlighted. The next sections will present the implemented research methodology, starting from the CFD-based design development of the outdoor unit with a brief mention of the criteria used to compare the evaluated designs. Then, the following section will highlight the basic assumptions of a steady-state refrigerant cycle simulation tool developed internally in the MATLAB environment [11] to produce reasonable performance maps of the to-be-developed mini-split HP under the simplifying assumption of uniform airflow. The generated performance maps will be then used as an input in the dynamic system model developed within the Simulink simulation environment [12] to perform a pre-sizing of the optimal size of the DHW storage. Consequently, the primary energy consumption of the entire system supplying the DHW demand will be assessed considering a hot water tapping profile based on the “M” profile according to [7] for a typical household of 2-3 persons. In the last section, the test setup at the University of Innsbruck used to measure the dynamic performance of the prototype will be discussed.

3.1. CFD-based design development and optimization

Several design geometries were simulated in the software ANSYS [13] with the help of the CFX solver in a first phase and pre-selected based on the following criteria:
• Flow homogeneity on the evaporator surface;
• Air-side pressure drop;

The pre-screening included geometrical designs with both axial and radial fans. Crossflow fans were not taken instead into further consideration due to space constraints in façade-integrated installations. Table 1 illustrates the simulated variants based on the geometry of the evaporator, the fan type and the position of the fans related to the evaporator.

Table 1: Overview of simulation cases to assess the optimal geometry of the outdoor unit by means of CFD simulations.

For the simulated variants, the boundary conditions highlighted in Table 2 were assumed throughout the CFD simulations:

Table 2: Boundary conditions in CFD simulations. For the simulations involving axial fans, the rotational speed was also varied between 900 rpm and 1700 rpm.

The k-ε turbulence model was adopted for all simulation models, as it is generally suggested for flows over rotating geometries and baffles, as well as being a robust model with a sufficient accuracy [14]. Additionally, the walls of the fluid domain are assumed to be smooth and the velocity on the model boundaries is equal to zero (no-slip wall condition). To model the fluid interface between stationary and rotating domains, the option “Frozen rotor” was selected.

3.2. Refrigerant cycle simulation model and performance maps generation

In parallel to the selection of the optimal outdoor unit design based on the presented criteria, a refrigerant cycle analysis was executed with the purpose of:

a) Generating physics-based reasonable performance maps to be used in the dynamic system simulation in absence of measurement results;

b) Evaluate the maximum theoretical performance of the refrigerant cycle at varying boundary conditions.

The refrigerant cycle is based on propane (R290), an alternative and more sustainable refrigerant with a global warming potential (GWP) equal to 3 and ozone depletion potential (ODP) equal to zero [15]. However it has the drawback of belonging to the A3 class, thus highly flammable and with a maximum allowed refrigerant charge in Europe equal to 150 g for residential installations [16]. A pre-analysis of the performance of the refrigerant cycle, given the knowledge about the single components, is in this sense crucial. The model itself is built in a modular way, so that each component of the refrigerant cycle has its own equations, which will be highlighted in the following section along with the basic assumptions of the model.

3.2.1. Compressor model

The modelled compressor exhibits the characteristics highlighted in Table 3:

Table 3: Technical features of the compressor modelled within the refrigerant cycle simulation

<table>
<thead>

</tr>
</tbody>
</table>
For the calculation of the isentropic efficiency associated to a certain pressure ratio, a fourth-order, ten-coefficients equation, depending on evaporation and condensation temperatures, was modelled based on manufacturer data:

$$\eta_{is} = f^4(\vartheta_{evap}, \vartheta_{cond}) \quad (1)$$

The refrigerant mass flow supplied by the compressor is calculated from a physical model, as discussed also in [17], described by equation (2):

$$m_{ref} = \eta_{vol} \frac{n_{rpm}}{60} \frac{D_c \rho_{ref,suction}}{\vartheta_{con}} \quad (2)$$

The volumetric efficiency is in turn also deducted from a theoretical model similar to the one described in [18] and [19] depending from the pressure ratio $\tau$ and accounting for any deviation from the ideal gas behavior, as depicted in (3):

$$\eta_{vol} = 0.97 - \left( \left[ \frac{z_s}{z_d} \right] \frac{1}{\tau \vartheta_s} - 1 \right) \vartheta_e - e_v \quad (3)$$

It is noteworthy to mention that the clearance volume of a compressor is usually not included in the technical data supplied by the manufacturer, but reasonably lies between 5 and 15 % of the total displacement [20]. Its value needs thus to be calibrated. The same procedure should be executed for the correction factor $e_v$, since different applications typically exhibit different deviations from the ideal gas behaviour. For the calculation of the electrical power consumption attributed to the compressor, a constant total efficiency of 95% was assumed for sake of simplicity, equal to the product of electrical and mechanical efficiencies.

### 3.2.2. Condenser and Evaporator models

For the sake of pre-analysis and to maintain the simplicity of the model, no detailed calculation of the heat transfer was implemented at the condenser and at the evaporator sides. It was however decided to take into account the heat exchange through the definition of a pinch point temperature difference between the refrigerant cycle and the primary side (air) as well as between the refrigerant cycle and the secondary side (water). No detailed model was introduced within the steady-state model to account for the performance drop under icing conditions. The power laws shown in the equations (4) and (5) were thus implemented, depending on heating and cooling power respectively:

$$\Delta T_{pp,cond} = \Delta T_{pp,cond,0} \left( \frac{\dot{Q}_{cond}}{\dot{Q}_{cond,0}} \right)^{n_{cond}} \quad (4)$$

$$\Delta T_{pp,evap} = \Delta T_{pp,evap,0} \left( \frac{\dot{Q}_{evap}}{\dot{Q}_{evap,0}} \right)^{n_{evap}} \quad (5)$$

The parameters $\Delta T_{pp,cond,0}$, $\dot{Q}_{cond,0}$, $n_{cond}$ as well as $\Delta T_{pp,evap,0}$, $\dot{Q}_{evap,0}$, $n_{evap}$ are subjected to calibration procedure.

### 3.2.3. Expansion valve model

An isenthalpic valve model was adopted for sake of simplicity. For this reason, the condition described in (6) was applied to the model:

$$h_{in,exv} = h_{out,exv} \quad (6)$$

### 3.2.4. Pressure drop and heat losses model

Pressure drop can be taken into account for each component of the refrigerant cycle as a fixed value or through correlations depending on the refrigerant mass flow. The calculation is separated for each phase. Heat losses are solely assigned to the compressor shell and follow the law mentioned in eq. (7):

$$\dot{Q}_{loss} = UA_{compr} (\vartheta_{compr} - \vartheta_{amb}) \quad (7)$$
3.2.5. Basic assumptions about the refrigerant cycle

The following basic assumptions were made for the simulation of the refrigerant cycle:

Table 4: Inputs assumed for the refrigerant cycle simulation regarding superheating, subcooling, air and water volume flows.

<table>
<thead>
<tr>
<th>Property</th>
<th>Value</th>
</tr>
</thead>
<tbody>
<tr>
<td>Superheating</td>
<td>6 K</td>
</tr>
<tr>
<td>Subcooling</td>
<td>6 K</td>
</tr>
<tr>
<td>Air volume flow</td>
<td>350 m³/h</td>
</tr>
<tr>
<td>Water volume flow</td>
<td>4 liter/min</td>
</tr>
</tbody>
</table>

The value of subcooling usually depends, among other factors, on the actual refrigerant charge in operation within the refrigerant cycle. However, since there is actually no implemented model for the calculation of the optimal refrigerant charge, this effect was neglected throughout the refrigerant cycle simulations and a constant value was used as an input instead. Performance maps were thus generated for -15, -7, 2, 7, 10, 20 °C outdoor air temperature, as well as 35, 45, 55 °C supply water temperature.

3.2.6. Calculation assumptions and convergence criteria

The numerical model uses the heating and cooling power as iterated variables to obtain a full characterization of the refrigerant cycle in terms of pressure, enthalpy, entropy and temperature. The convergence of the model is based on the minimization of an error function, defined in equations (8), (9) and (10).

\[ \text{err}_{\text{cond}} = |\dot{Q}_{\text{cond}} + \dot{Q}_{\text{loss}} - \dot{Q}_{\text{evap}} - \dot{Q}_{\text{compr}}| + \text{err}_{\dot{Q}_{\text{evap}}} + \text{err}_{\dot{Q}_{\text{cond}}} \]  

\[ \text{err}_{\dot{Q}_{\text{evap}}} = \left| \frac{m_{\text{ref}}(h_{\text{evap,out}} - h_{\text{evap,in}}) - m_{\text{src}} c_p,\text{src}(s_{\text{src,in}} - s_{\text{src,out}})}{\dot{Q}_{\text{evap}}} \right| \]  

\[ \text{err}_{\dot{Q}_{\text{cond}}} = \left| \frac{m_{\text{ref}}(h_{\text{cond,in}} - h_{\text{cond,out}}) - m_{\text{sink}} c_p,\text{sink}(s_{\text{sink,in}} - s_{\text{sink,out}})}{\dot{Q}_{\text{cond}}} \right| \]  

In the first part of the convergence function, the overall energy balance of the heat pump is checked, while the remaining terms proof the validity of the local energy balances for the evaporator and for the condenser.

3.3. Dynamic system modelling of hot water consumption and performance evaluation

The efficiency of the entire system supplying the DHW demand was evaluated within the simulation environment of MATLAB and Simulink, where the heat pump was modelled using the built-in model already present in the CARNOT Toolbox. The performance data is supplied by the developed refrigerant cycle simulation tool. The dynamic performance of the system was evaluated at the outdoor air temperatures of 10, 15 and 20 °C to be later compared with laboratory measurements. Four different storage tank sizes were simulated, corresponding to 90, 100, 110 and 120 liters. For sake of simplicity, the height of the storage tank was assumed to be constant and equal to 1.1 m, while the diameter of the tank increases with increasing storage volume. The overall heat transfer coefficient of the tank, including insulation, was selected such that for each storage volume it would correspond to the energy efficiency class ErP B [21]. The temperature of the technical room is constant and equal to 20 °C. Figure 1 shows a conceptual drawing of the hydraulic system supplying the DHW demand, as it was modelled within the simulation environment. Along with the HP and the DHW storage, a freshwater station was included in the simulation as well as in the reality to avoid legal and technical constraints due to legionella. The pipe lengths correspond to the lengths in the experimental setup. The simulation time corresponds to 24 hours, of which 14 and a half hours are reserved for tapping.
The entire storage tank is heated to a constant temperature equal to 55 °C. During the start-up phase of the heat pump, the temperature of the water supplied to the storage would be much lower than the actual temperature in the tank. If no additional measures were undertaken, this would result in a disturbance of the stratification of the storage and have a detrimental effect on the system performance. Thus, when the supplied water temperature is lower than 52 °C, controlled by means of the temperature sensor T0 (with an inertia of 5 seconds), the upper and lower mixing valves are closed such that water is recirculated in a loop and its temperature increases. As soon as the setpoint temperature is reached, the storage tank is loaded from above by means of fixed-value control so that a certain reserve volume can be guaranteed for short-term taps. After the reserve volume has been charged, the storage tank is also charged via the intermediate layer, whereby the fixed value control is not used here. Then the lowest part of the hot water storage tank is charged. The control of the temperature in the storage tank is performed based on a hysteresis controller coupled to the temperature sensors T1 and T2. When T2 indicates a temperature equal to the setpoint (55 °C), the heat pump is shut down. On the other hand, when T1 measures a temperature equal to 5 K lower than the setpoint (thus 50 °C), the heat pump is turned on again. On the secondary side, the rotational speed of a PID-controlled inverter-based pump is modulated in order to meet the user water temperature request, in this case 45 °C (temperature sensor T3).

When the desired hot water temperature is reached, the energy control starts counting and tapping continues until the required energy has been supplied.

A tapping profile based on profile “M” according to the standard EN 16147 [7] was taken into consideration for the simulations, in which two major taps (10 liter/min) take place at 07:15 and 21:30 (i.e. shower in the morning and in the evening). Each simulation starts with a completely charged storage. Minimum and maximum operational time intervals of, respectively 5 and 80 minutes are assumed. For air temperatures lower than 7 °C, a 10 minutes stop interval is considered every 80 minutes to take into account for deicing cycles. However, the additional electric power consumption for deicing, for which calculation a dedicated model would be needed, is not taken into account.

The performance of the system is evaluated through the definition of a coefficient of performance (COP) for the entire system as follows:

\[ \text{COP}_{\text{sys}} = \frac{Q_{\text{DHW}}}{Q_{\text{el}}} \] (11)

3.4. Laboratory testing and proof-of-concept

The laboratory infrastructure was used first to compare the electric power consumption and the sound power level of different fan configurations for the outdoor unit and then to test the dynamic performance of a developed prototype of mini-split façade-integrated HP for DHW preparation. To test the electric power consumption as well as the sound power level of the fan configurations, the test rig described in Figure 2 has been set up. The pressure conditions upstream of the fans (1) is imposed by means of a PI controlled ventilation flap. In the same way the pressure difference with the environment downstream of the fans (2) was equal to zero to replicate outflow in the environment by means of a support fan. The rotational speed of the fans is
either controlled by a PWM module for the axial fans and via a 0-10 V control signal for the radial fans. Air volume flow is measured by means of a hot-wire anemometer (3). For acoustical measurements, the channel downstream of the fans must be opened and the sound power level of the fans assessed according to [22] and [23]. On the other hand, to assess the dynamic performance of the split HP, a double room climate chamber was used. The cold room was reserved to the installation of the outdoor unit of the HP, while the ambient room was dedicated to the indoor element. The temperature in each room is controlled by means of brine-to-air and water-to-air heat exchangers. With the current system configuration, it was possible to reach a minimum outdoor air temperature of 10 °C. A conceptual scheme of the test-rig for the assessment of the dynamic performance of the mini-split HP is depicted in Figure 3. Water withdrawal is controlled by means of a magnetic 2-way valve, the withdrawn volume flow being measured by a magnetic flow meter (MFM). Since the cold water temperature cannot be directly controlled, a flush valve is opened intermittently to keep the cold water temperature as constant as possible. A flush valve is also provided on the hot water side to energetically empty the hot water storage and cool it down approximately to cold-water temperature (i.e. for the measurement of the losses attributed to the DHW storage). The temperature in the storage is measured by means of three Pt100 temperature sensors, positioned respectively at 9 cm, 40 and 70 cm from the top cover of the hot water storage. The water supply and return temperatures are also measured and logged. Thus, the prototype of split-type heat pump was tested at outdoor air temperatures of 10, 15, 20 °C under intermittent tapping (M profile, see also [7]). A temperature of 45 °C was considered as minimum comfort condition for the water supplied to the DHW user. In order to allow for longer measurement stints, a hot water storage size of 120 liters was chosen. The total measurement time corresponds to the simulation time where the water withdrawal is different from zero.

## 4. Results and Discussion

### 4.1. CFD-based design development and optimization

The CFD-based pre-analysis yielded the design shown in Figure 4, involving four parallel axial fans (shown in green) and an evaporator tilted of 30° (depicted in red) compared to the inflow direction. The advantage of
axial fans over radial fans was determined with the help of the measurements of the electric power consumption as well as of the sound power level, which will be presented in a later section.

Figure 4: Final design of the outdoor unit featuring four axial fans, flow pattern simulated within the CFD software.

4.2. Refrigerant cycle simulation model and performance maps generation

The refrigerant cycle model presented in section 3.2 produced the performance maps depicted in Figure 5(a) to (d) for a split-type heat pump, with air temperature varying from -15 to 20 ºC and supply water temperature of 35, 45 and 55 ºC:

As it is possible to discern from Figure 5(a), the design heating power of 1.5 kW at the design conditions of 7 ºC air temperature, 55 ºC supply water temperature is theoretically guaranteed. The generated performance
data were thus used as an input for the heat pump model in Simulink/CARNOT to investigate the dynamic performance of the entire system.

4.3. Dynamic system modelling of hot water consumption and performance evaluation

The system was simulated within the Simulink environment for multiple storage sizes at the outdoor air temperatures of 10, 15 and 20 °C. Table 5 reports the results in a concise and more compact way for the different temperatures and a storage size of 90 liters, while Table 6 summarizes the results for a storage size of 120 liters. The results show thus, that considering equal outdoor air temperature conditions, a compact 90 liters storage would be sufficient to fulfill the domestic hot water demand of a small family. The adoption of a larger storage size brings an additional 4 to 7 % performance improvement, due to the reduced switch-on frequency in the larger storage size and therefore to the comparatively lower power consumption.

4.4. Laboratory testing and proof-of-concept

Figure 6(a) and (b) highlight the measured sound power level and the electric power consumption for four axial fans and a single radial fan. The tests show that axial fans might be more favorable than radial one, both in terms of sound emissions and in terms of electric power consumption, if the pressure drop attributed to the inflow geometry and the evaporator can be constrained to values lower than 25 Pa. The measured total pressure drop combination of inflow geometry and evaporator in the prototype at the design airflow rate was of 9.8 Pa, confirming the choice of 4 axial fans in spite of radial fans. Figure 7 shows finally the measurement results of the prototype under dynamic conditions. Generally, it is possible to conclude that the minimum comfort requirement is always guaranteed and the minimum temperature is always supplied to the DHW user. The difference between measured and simulated performance, as highlighted by Table 6 and Table 7, is to be attributed to a higher measured storage heat loss coefficient in the experimental specimen, about 2 to 3 times higher than the simulated one due to improper insulation installation and excessive convection within the indoor unit housing the DHW storage.

Figure 6: (a) Measured sound power levels (A-corrected) on discharge and suction sides for 4 axial fans and 1 radial fan at 350 m³/h air volume flow and (b) measured electric power consumption for 4 axial fans and 1 radial fan at varying pressure drop conditions.

5. Conclusions and outlook

Decentral heat pump solutions could play a major role in the upcoming years on the renovation market. In order to save space and for sake of cost-effectiveness, one alternative and more sustainable solution to decentral gas or electric boilers is a façade-integrated split air-to-water heat pump. This work has focused on the presentation of a general procedure on how to develop efficient small-scale heat pumps in narrow environments and has given proof of the potential of such solutions. A prototype of a propane-based mini-split air-to-water heat pump was thus conceived by means of CFD, refrigerant cycle and system simulations and tested later dynamically under varying tapping conditions. The fluid-dynamics based pre-analysis has highlighted in axial fans a more favorable alternative in compact installations, due also to their lower sound emissions and lower power consumption. Additionally, system simulations have also remarked that a 90 liters storage would be sufficient to satisfy the DHW demand of a small household (2-3 people) and that slight improvements are seen for larger storage sizes. The analysis must be however extended to lower outdoor air temperatures, for which a correct modelling of ice formation and de-icing is necessary. Laboratory measurements have also shown a performance gap between the simulation performance data and the measured ones. This discrepancy was traced back to a higher measured storage heat loss coefficient in the tested HP due to improper insulation installation and excessive convection within the indoor unit. Such drawbacks will require a complete redesign of the indoor unit. Furthermore, the possibility of supplying the SH demand depending on the delivery system will be assessed for a demonstration building. In this case the condenser of the HP would be connected directly with the radiator loop or floor heating.

Abstract

Ground-source heat pump air conditioning systems are more efficient than air-source air conditioning systems in terms of energy consumption. Optimal hybrid utilization of air and ground heat sources has been shown to reduce the heat load on the ground. This study aims to ascertain the performance of hybrid heat pump systems in comparison to the standard air-conditioning system. A field test was conducted for the hybrid air conditioning and air-source systems. For the experiment, two commercial air conditioners were utilized. One of them was set up as a standard air-source air conditioner. Another one was connected with the ground to construct a ground-coupled hybrid air conditioner. The experimental setup was constructed in two small houses, one for each heat pump system. Generally, a hybrid heat pump system performs better over time compared to an air-source system. So, a comparison test between an air-source heat pump and a hybrid heat pump for cooling conditions was conducted to validate this point. The hybrid heat pump system showed an overall higher coefficient of performance (COP) compared to the air source air conditioning system.

1. Introduction

Energy consumption is growing swiftly with the people’s standard of living. The growing demand for renewable energy sources has been driven by the need to reduce greenhouse emissions caused by fossil fuels. Renewable energy technologies research has primarily been focused on solar and wind power because of their ubiquitous and universal applicability [1]. Geothermal energy is also part of renewable energy research and is vitally important for building air-space conditioning. Buildings consume tremendous amounts of energy in a form of heating and cooling. It is estimated that on average a building’s energy consumption accounts for 19% of the total social energy consumption [2].

Conventional heating methods based on fossil fuels emit a massive amount of pollutants, consume a large amount of energy, and waste high-grade energy. So, heat pump technology has been gaining attention because of its energy-efficient, environmentally friendly, and cost-effective applications [3]. Among these heat pump technologies include ground source heat pump (GSHP) which typically yields higher heating and cooling coefficients of performance (COP) compared to the water-source heat pump (WSHP) and air-source heat pump systems (ASHP). A heat pump (HP) is a device capable to transfer thermal energy from the outside using the

E-mail address: 2734001@edu.cc.saga-u.ac.jp.
refrigeration cycle. Heat pumps inject the heat to the ground (GSHP) or release the heat to the ambient air (ASHP) when cooling a building. The decision on the type of HVAC to use depends on the size, reliability, costs, energy efficiency, and maintenance requirements [4][5] The heat pump systems that were investigated in this study were the air-source heat pump (ASHP) and hybrid ground-source heat pump (HBHP). In the case of the HBHP, the heat is transferred from the room and deposited underground during cooling, or heat is transferred from the ground to the indoor space during heating. The air-source heat is the same only that the heat is transferred from the outside air to the indoor space for heating or removed from the indoor space to the outdoor air during cooling.

There have been many studies conducted that compare the performance of ASHP to that of GSHP. Urchueguía et al. (2008) demonstrated that a ground-coupled heat pump (GCHP) saved about 20% more energy compared to the air-source heat pump [6]. Morrone et al. (2014) also showed the economic benefits of using GCHP, particularly in cold climates [7]. Conversely, soil thermal imbalance caused by uneven loads of heating-dominant buildings adversely affects heating capacity and the long-term performance of a GSHP system [8]. This directly affects the initial borehole investment, which hinders the application of GSHP in cold regions.

This work investigates if HBHP is a more energy-efficient and cost-effective option for cooling (or heating) compared to the ASHP. It has been established by many studies that HBHP operates at a relatively higher COP than ASHP resulting in saving on electricity costs and energy consumption. Moreover, this research aims to investigate the role of each component in the overall system COP.

1.1. Study location

The ASHP and HBHP performance testing system was conducted using three prefabricated buildings located at Saga University, Saga prefecture in Japan (see Figure 1).

Figure 1: The map of Japan is on the left (a), The red arrow shows the location of Saga Prefecture (b).
The control room is on the left, the hybrid test room is in the middle, and the test room for the air-heat source system is on the right. The control room is equipped with a data logger for recording instrument values, a pump for water piping, and a monitor for data observation. The hybrid test room and the Air-source heat pump system test room are each equipped with an indoor unit. In the hybrid heat pump system, the PHE, expansion valve, flow meter, and solenoid valve are installed as a single unit in a box on the side of the prefabricated structure above the outdoor unit (hereinafter referred to as "external box"). Similarly, the expansion valve and flow meter are installed in a box in the air-source heat pump system. The experimental site studied is directed north-south and it receives direct sun radiation from east to west. To avoid heat loss an insulated cover was used (see Figure 3 below).

2. Experimental Device

This section describes the air-source and hybrid heat pump systems in detail. Figures 4 and 5 show the external box for the air-source system and hybrid heat pump system respectively in cooling operation mode.
The refrigerant used in the refrigeration cycle is R32 (difluoromethane). The refrigerant (R32) becomes a high-pressure gas refrigerant in the compressor and enters the condenser (outdoor unit). In the condenser, the refrigerant condenses from a high-pressure gas refrigerant to a high-pressure liquid refrigerant in order to dissipate heat into the outside air. The refrigerant then enters an expansion valve, where it is expanded to a low-pressure liquid and enters an evaporator (indoor unit). In the evaporator, the refrigerant removes heat from the room, evaporates, and returns to the compressor as a low-pressure gas. In other words, the cycle of compression, condensation, expansion, evaporation, and compression is repeated. The specifications of the components used are described in the table below:

Table 1: Description of the Components of the heat pump.

</tr>
</tbody>
</table>
The hybrid heat pump system has a plate heat exchanger (PHE) which is installed in series with the air heat exchanger. The PHE is a heat exchanger between the ground heat source and the refrigerant. The pipes connecting the ground heat exchanger (GHE) and the PHE are filled with water. As in air-source systems, the high-pressure gas refrigerant exiting the compressor enters the condenser (outdoor unit). In a hybrid heat pump system, the refrigerant enters the PHE in a two-phase state, i.e., gas and liquid coexist, after the heat is dissipated to the outside air in the condenser, where it is condensed by dissipating heat to water (underground). In other words, the hybrid heat pump system utilizes both air and water. The high-pressure liquid refrigerant enters the expansion valve, where it is expanded to become a low-pressure liquid, which enters the evaporator, and then the gaseous refrigerant enters the compressor and the cycle repeats again. The measuring instruments for the flow of refrigerant and water are summarized in Table 2 below.

Table 2 above shows the measuring instruments used to take data in this study. The accuracy of each device was taken from the manufacturer’s websites. The T-type thermocouple and pressure gauge were used to measure temperature and pressure respectively as the refrigerant enters different components in the refrigeration cycle as seen in Figure 6 and Figure 7. The resistance thermometer was used to measure the temperature of water (see Figure 9). The volumetric flowmeter measures the refrigerant’s flow rate. The solenoid valve is an electromechanically controlled valve that is used to regulate the flow direction of the refrigerant.

2.1. About the experimental apparatus of the Air-source heat pump system

Figure 6 shows the experimental setup for the Air-source heat pump system. The figure shows the cooling operation. T and P in the figure indicate a thermometer (thermocouple) and a pressure gauge, respectively.
In Air-source heat pump systems and Hybrid heat pump systems, pressure gauges and T-type thermocouples are installed at the compressor inlet/outlet, heat exchanger inlet/outlet, and expansion valve inlet/outlet. The T-type thermocouple is soldered to the surface of the copper tube. To calculate the mass flow rate of the refrigerant, a volumetric flowmeter is installed at the inlet of the expansion valve. The mass flow rate is obtained by the product of the volume flow rate and the density. Therefore, it is impossible to measure in a two-phase state where the density is not fixed. Therefore, a volumetric flowmeter was installed at the outlet of the condenser (an inlet of the expansion valve) where the liquid condenses to a pure liquid.

2.2. About the experimental apparatus of the Hybrid heat pump system

The solid line shows the refrigerant piping and the broken line shows the water piping. The control software for remotely operating the compressor speed, expansion valve opening, outdoor unit fan speed, and indoor unit fan speed is also the same as for the Air-source heat pump system. Five solenoid valves are installed in the hybrid heat pump system.

2.3. About Water Piping

The water goes from the pump in the control room to the double U-tube for heat exchange with the ground. After leaving the ground heat exchanger (GHE), the water, which is almost equal to the ground temperature, enters the PHE and exchanges heat with the refrigerant.
The two valves in the diagram above regulate the flow rate of water. As the water moves its temperature changes in the circuit. The changes in temperature were measured by the resistance thermometer (Figure 9). The resistance thermometer measures the temperature by utilizing the fact that the electrical resistance of material changes with temperature. Unlike thermocouples, reference contacts are not required, making temperature measurement relatively easy and accurate (see Table 2). However, the temperature range is lower than that of thermocouples.

The water temperature at the inlet/outlet of the GHE is measured by a K-type thermocouple. The water from the GHE goes to the PHE installed in the external box above the outdoor unit.

3. Methodology

3.1. System modeling procedure

The data collected was represented graphically in T-s and P-h diagrams. The system performance was evaluated by the P-h and T-s diagrams. These diagrams monitor the vapor compression refrigeration cycle as it changes states in different components (from the compressor, condenser, metering device, evaporator, and to the compressor again).
The P-h (a) and T-s (b) diagrams above show the vapor compression refrigerant cycle. The numbers in the diagram indicate the different components which the refrigerant will have to pass through. The movement of the refrigerant through these components will result in a phase change. The refrigerant will move from the compressor (1) after it had be compressed resulting in an increase in its pressure, then it will move to a condenser (2) where the temperature will drop. Position (3) is a metering device (expansion valve) that drops the pressure of the refrigerant as it goes to an evaporator (4) and then it goes to the compressor where the cycle repeats again. The evaporator is where the refrigerant absorbs heat from the room.

3.2. Data Reduction

Firstly, hourly dynamic cooling loads for the ASHP and HBHP were calculated using a Visual Basic for Applications (VBA) program in a CSV file. The experimental data were used to calculate COP and evaluate the system performance. The COP is defined as follows:

\[ COP_{cooling} = \frac{Q_L}{W_{in}} \]  

(1)

Where \( Q_L \) is the available heat at the evaporator and \( W_{in} \) is the amount of energy required for compression. Since \( W_{in} = Q_h - Q_L \), COP could also be expressed as follows:

\[ COP_{cooling} = \frac{Q_L}{(Q_h - Q_L)} \]  

(2)

REFPROP ver. 10 was used to calculate enthalpy and entropy which were automatically plotted in the CSV file. The REFPROP ver. 10 was also used to calculate other important parameters such as the mass flow rate, water mass flow rate, cooling capacity, the amount of GHE, PHE heat exchange rate, pump work, and the COP for both heat pump systems. Out of all the parameters mentioned, the mass flow rate, cooling capacity, and COP were the most important for this research.

The mass flow rate \( \dot{m}_{ref} \) [kg/s] is obtained by the product of the refrigerant volume flow rate \( F_{ref} \) [L/min] and the density \( \rho_{ref} \) [kg/m³]. The density of the refrigerant is calculated from the temperature and pressure using REFPROP. The temperature and pressure are referenced to the measured values at the inlet of the expansion valve, which is the location where the flowmeter is installed. The mass flow rate formula is as below:

\[ \dot{m}_{ref} = F_{ref} \times \rho_{ref} \times \frac{1}{60} \times \frac{1}{1000} \]  

(3)

The cooling capacity \( Q_{cooling} \) [kW] indicates the amount of heat the system can remove from the refrigerated space over time. It is obtained by the product of the mass flow rate \( \dot{m}_{ref} \) [kg/s] of the refrigerant and the specific enthalpy difference \( \Delta h_{eva} \) [kJ/kg] of the indoor unit (evaporator for cooling operation).
\[ Q_{cooling} = \dot{m}_{ref} \times \Delta h_{eva} \] (4)

Enthalpy is defined as the total heat energy of a system and is equal to the sum of internal energy (\( \Delta U \)) and the product of pressure (\( P \)) and volume (\( \Delta V \)). Mathematically, it can be expressed as,

\[ H = \Delta U + P \Delta V \] (5)

The specific enthalpy of the system is defined as the enthalpy per unit mass. It can be expressed as,

\[ h = \frac{H}{m} \]

Where \( h \) is the specific enthalpy, \( H \) is the enthalpy of the system and \( m \) is the mass. Thus, the specific enthalpy (\( h \)) can be defined as the sum of the specific internal energy (\( u \)) and the product of pressure (\( p \)) and specific volume (\( v \)),

\[ h = u + p v \] (6)

So, the specific enthalpy difference \( \Delta h_{eva} \) is the enthalpy difference between the inlet and outlet of the evaporator. The evaporator is where the refrigerant absorbs heat from the room in an isobaric heat addition process (see Figure 10). Using thermodynamic principles, the specific enthalpy can be represented as,

\[ \Delta h_{eva} = c_p \Delta T \] (7)

Where \( c_p \) is the specific heat capacity at constant pressure, and \( \Delta T \) is the temperature difference between the inlet and outlet of the evaporator.

Coefficient of performance commonly known as COP is a measurement of the energy efficiency of a system’s heating or cooling performance. The COP was used to evaluate the performance of an air-conditioner. It is obtained by the quotient of the air-conditioner’s power input \( W_{HP} \) [kW] to the amount of cooled heat \( Q_{cooling} \) [kW]. The \( COP_{AIR} \) [-] for the air-heat source system is shown in the formula below:

\[ COP_{AIR} = \frac{Q_{cooling}}{W_{HP}} \] (8)

The hybrid heat pump system can be obtained by considering, the pump power \( W_{pump} \) [kW]. \( COP_{HP} \) [-] of the hybrid heat pump system is shown in the Equation below:

\[ COP_{HP} = \frac{Q_{cooling}}{W_{HP}+W_{pump}} \] (9)

### 3.3. Data Acquisition

The cooling data was collected from the beginning of August to the first week of October. It was taken in four stages. The data were collected in four stages for both ASHP and HBHP. The data collection steps are summarized below:

- Controlling the compressor speed, expansion valve opening, and outdoor fan in an uninsulated room.
- Automatic air-conditioning (“free mode”) operation in an uninsulated room.
- Controlling the compressor speed, expansion valve opening, and outdoor fan in an insulated room.
- Automatic air-conditioning (“free mode”) operation in an insulated room.

In the first stage; data was collected by controlling the compressor speed, outdoor fan speed, expansion valve, indoor temperature, and PHE. This data was collected to optimize the whole system’s performance by getting desirable values for the COP, cooling capacity, superheat, and air-source percentage ratio (for the hybrid heat pump system). The second stage was collecting data by letting the air-conditioning operate freely as in any building. The changes in a compressor, outdoor fan speed, and expansion value over time were recorded in a
CSV file. Over time, the COP, cooling capacity, and indoor temperature variations were also noted. The third stage involved covering the two experimental rooms with an insulated cover to reduce heat from escaping easily. This was done to mimic how buildings are normally constructed. Buildings in regions with extreme weather like in Japan are built with indoor insulation, so heat doesn’t escape easily unless an air-conditioner is used. This stage was performed exactly like in stage one where we controlled for different system components and observed their influence on the COP, cooling, superheat, or air-source percentage ratio (for the HBHP system). The final stage was the “free mode” where we allow the air-conditioner to run without any interference and changes for compressor speed, outdoor fan speed, and expansion valve were recorded in a CSV file. The air-source percentage ratio was also recorded for the HBHP system. The formula for the air-source percentage ratio is defined below:

\[
ASR = \frac{\Delta h_{Air}}{\Delta h_{Air} + \Delta h_{PHE}}
\]  

(9)

The reason for calculating the ASR for the HB system was to correlate the percentage of air with COP and cooling capacity. This correlation will help us optimize for the correct amount of air-source heat required in the HBHP system to improve the COP and cooling capacity.

4. Results and Discussion

The results focus mainly on comparing the performance (COP), ground heat exchange percentage, cooling capacity, inlet condenser temperature, and percentage of improvement comparison of the two systems.

Figure 11: Cooling capacity for different days.
The two figures above (Figure 11 and Figure 12) compare the hybrid and air source systems. HB stands for the hybrid heat pump system and AIR is for the air-source heat pump system. Figure 11 shows the cooling capacity comparison between HBHP and ASHP for different numbers of days. The HB shows similar cooling capacities for specific days because we controlled each system's specific cooling capacity range. Figure 12 depicts the COP comparison between the two systems. HBHP shows a greater performance overall as compared to the ASHP system.

Table 3 above shows comparison data for the hybrid and air-source systems. Cooling capacity was controlled to a specific range to monitor the COP and outdoor inlet temperature for both systems. The significant metric of comparison is displayed in the last column where a hybrid percentage improvement is shown relative to the air. Higher cooling capacities display a high percentage improvement. A system that is able to remove heat efficiently will have a higher performance improvement. The reason that the hybrid heat pump system shows a higher performance improvement is that it cools the refrigerant coming from a compressor using two main components. The first component is the outdoor unit (condenser) and the second component is the plate heat exchange (PHE) which reduces the refrigerant temperature using the water cycle (See Figure 7 to see the refrigerant and water circuit).

![Figure 13: COP comparison against outdoor unit inlet temperature for different cooling capacities.](image)

Figure 13 above depicts the relationship between COP and the outdoor unit inlet temperature for both systems. The COP for both systems dips slightly as the outdoor inlet temperature increases. Increasing the temperature of the gas requires an increase in work output to condense the refrigerant. So, for the same work output, the temperature of the stream leaving the condenser increases for a fixed input temperature to the condenser, and the heat rejection capacity of the condenser decreases. Thus, the COP for both systems decreased slightly. The hybrid heat pump system shows a higher COP compare to the air-source system in each cooling capacity range.
The hybrid heat pump system has an additional water circuit that exchanges heat with the refrigerant using the PHE. PHE is the main component in our circuit responsible for the improvement of a hybrid heat pump system compared to an air-source system. The ground source heat percentage was also measured to understand the role of the PHE in improving performance. Figure 14 above shows the relationship between the ground heat exchange percentage and the COP for each specific cooling capacity range. Figure 14 can also be correlated to the air-source ratio which demonstrated the percentage of air in the hybrid heat pump system required for optimum performance. Then, the graph shows that increasing the percentage of ground source heat improves the COP. Varying values of ground heat exchange percentage parameters were obtained by changing the compressor speed, outdoor fan speed, and PHE control valve.

</tbody>
</table>

Table 4 shows the COP comparison between HB and AIR source systems. These are average COP values for each cooling capacity range. The HB performed better in every measurement taken for the COP. The highest disparity between the two systems is at higher cooling capacities. This means that hybrid heat pump systems perform better in regions or buildings that require a lot of energy consumption as a requirement to meet air-conditioning needs. The COP percentage comparison was calculated as follows:

\[ COP_{improv} = \left( \frac{COP_{ave\_HP} - COP_{ave\_AIR}}{COP_{ave\_HP}} \right) \times 100 \]
Where,

\[ \text{COP}_{\text{impro}} \] is the COP percentage improvement of HB against AIR source system, \( \text{COP}_{\text{ave,HB}} \) and, \( \text{COP}_{\text{ave,AIR}} \) is the average coefficient of performance for a specified cooling capacity range for the hybrid and air-source system respectively.

5. Conclusion

In this research, a performance comparison between the hybrid and air-source heat pump systems was experimentally investigated. The findings obtained in this research are as follows:

- As a result of the experiment, the hybrid heat pump system's coefficient of performance (COP) is higher than the air-source system. The average COP for the 3.1kW cooling capacity showed the highest COP improvement between the two systems. The Average COP obtained for the HB and AIR was 4.70 and 4.05 respectively. Thus, this resulted in the HBHP performing 13.43% better than the ASHP.

- An increase in outdoor inlet temperature decreased the COP in both systems. This results from the condenser’s inability to reject more heat without affecting the performance of the system. This can be attributed to the higher energy demand by the system to meet the higher cooling requirement.

- The cooling capacity ranges obtained by controlling the compressor speed, expansion valve opening, and outdoor fan speed showed COP values for the two systems that are comparable to other authors. Further research will be focused on system performance comparison for the heating operations. Thereafter, an in-depth component (compressor, condenser, expansion valve, evaporator, and PHE) impact on the overall performance will be fully assessed.

Acknowledgment

Abstract

Critical to decarbonizing gas-fired water heating, typically up to 26 GJ of natural gas consumed per home per year, is advancing heat pump water heaters (HPWHs). This paper provides an overview of the development and experimental demonstration of this novel sorption-type HPWH, using a nested buffer tank/heat exchanger approach driven by an integrated compact steam boiler. Led by a European technology developer with technology support from multiple U.S.-based partners, this fuel-fired HPWH concept is intended for North American homes, with a hybrid design of both up to 2 kW peak output from the sorption modules and up to 12 kW peak auxiliary output from the steam boiler. With an efficiency target of $\geq 1.25$ UEF and a target first hour rating of 284 L of hot water, this paper focuses on several aspects of this product development and testing, including a) the development and testing of a compact steam boiler loop to drive the desorption process, designed for 14 ng NOx/J output and compatible with up to a 30% hydrogen/natural gas blended fuel, b) immersed sorption modules within the buffer storage tank for water heating with a COP\textsubscript{gas} $> 1.40$ using limited moving parts, and c) heat exchange and preliminary system controls, per empirically-calibrated simulation, to meet UEF targets and high usage hot water patterns typical for 4-5 occupant homes. Following this review of testing results, the authors provide an outlook for fuel-fired HPWHs in a rapidly decarbonizing North American market.

1. Introduction

Of the more than four million fuel-fired storage-type residential water heaters sold in the U.S. each year, which outnumber sales of tankless water heaters by about six-to-one, only about 5% of these products have efficiencies greater than the minimum allowable efficiency of a uniform energy factor (UEF) of 0.62 to 0.64 (depending on storage tank volume\textsuperscript{1}). This is despite concerted efforts on the behalf of manufacturers, technology developers, and researchers to introduce higher-efficiency equipment, which includes condensing-level efficiency storage water heaters, hybrid tank/tankless type solutions, and integrated heat pump water heaters (HPWHs). It is the last category that holds the greatest promise to decarbonize the approximately 26 GJ of natural gas consumed per home per year, through increases in efficiency as a critical emerging solution.
to address a market that is challenged by cost-effective energy efficiency with 0.88 UEF storage-type solutions and 0.97 tankless-type solutions available today [1].

While residential electrically-driven HPWHs are mature and available in the U.S. for 10+ years [2], providing multiple options UEF > 2.50 (0.95 on primary energy basis for U.S. average), there are emerging air-source sorption-type HPWHs under development as well that are suitable for direct-fired applications with natural gas, propane, biomethane, and/or hydrogen-based fuels. Sorption-based HPWHs are available for commercial-sized water heating applications but are only now emerging for residential applications. Commercial-sized fuel-fired HPWHs are often able to serve much larger commercial hot water loads than integrated electrically-driven HPWHs (common to have > 3X rated capacity [3]) and have undergone multiple demonstrations in recent years over multiple building types, including hospitality, multifamily buildings, senior care facilities, schools, and restaurants/cafeteria applications [3]. For these commercial-sized products or prototype HPWHs, employing direct-fired vapor absorption cycles (single-effect and GAX-type), units with maximum outputs from 23 kW to 41 kW were operated in conjunction with existing site boilers and/or commercial water heaters as a retrofit for periods of 12 months or more in California, British Columbia, Illinois, Ontario, and Oregon. Results showed a reduction in site fossil gas consumption by 18% to 53% [4–7], with one study using hybrid air/water-source approach to provide supplemental A/C in addition to hot water for two full-service restaurant sites, yielding an additional 14% reduction in electricity demand for A/C in addition to hot water fuel savings, for a net 48% reduction in overall greenhouse gas (GHG) emissions [4].

These residential sorption-type HPWH developments are important, as the regulatory environment in the U.S. is shifting rapidly to accelerate further gains in end-use energy efficiencies. This includes proposed changes to the EnergyStar® specification to have a minimum allowable UEF ≥ 0.86 (original proposal was UEF ≥ 1.0) for gas-fired storage-type water heaters [8] and regional specifications like the Northwest Energy Efficiency Alliance (NEEA) advanced specification creating three performance tiers of minimum allowable UEF from 1.0 to 1.3 [9]. These shifts in performance metrics have often been informed by multiple developments of sorption-type HPWHs, such as one approach based on a single-effect vapor absorption cycle (NH₃/H₂O), which was successfully developed and demonstrated in multiple U.S. field trials to reduce fuel consumption by 50% or greater with a projected UEF of 1.20 (1.08 on a primary energy basis) [1]. Another emerging approach described in this paper is based on a vapor adsorption cycle with enhanced chemisorption, with an NH₃/salt working pair. In this paper, lessons learned from parallel and prior sorption-type HPWH developments are provided and then the authors focus on the latter and review the development of a novel adsorption-type HPWH, using a nested buffer tank/heat exchanger approach driven by an integrated compact steam boiler, a collaboration between technology developers, with a hybrid design approach with 2 kW output sorption module and 12 kW auxiliary steam boiler. Performance goals are ≥1.25 UEF, target first hour rating of 284 L of hot water or greater, and a combustion system with less than 14 ng NOₓ/J output and compatible with 30% hydrogen/natural gas blended fuel, and capacity for typical 4-5 occupant North American homes.

2. Technology Review - Description of Residential Sorption-type HPWHs

For thermally-driven heat pumps (TDHPs) overall, inclusive of not just sorption-type machines but also mechanically-driven vapor compression cycles (e.g. engine-driven) and thermal compression machines (stirling-type, thermoacoustic, etc.), it is sorption-type machines that have the greatest potential be scaled down to sizes appropriate for residential applications (< 25 kW output, often < 5 kW for hot water). This is for many reasons, but for practical concerns, this is primarily due to challenges in cost-effectively scaling down engines for work-activated TDHPs and economies of scale necessary for thermal compression-type machines with commonly high operating pressures (> 50 bar) [3]. Sorption-type TDHPs are commonly used in heating-focused applications, in air-to-water/brine configurations most commonly, as supplements or replacements for water heaters, boilers, and/or furnaces. For these systems, the two primary types of sorption heat pumps are explained as follows:

- **Vapor Absorption** heat pump cycles utilize thermal energy to drive a heat-pump cycle where a refrigerant is cyclically absorbed and desorbed from a secondary fluid (absorbent). While the refrigerant is still compressed by an electro-mechanical pump (solution pump), it is a liquid in solution rather than a vapor – in the case of the predominant vapor compression cycles. Absorption-type heat pumps are an attractive alternative, as lifting the pressure of a liquid versus a vapor requires significantly less energy (1%-2% for standard conditions). Thus, while the job of refrigerant compression is performed by a relatively small, low-power solution pump, the primary input to the process is thermal energy required to drive the refrigerant vapor from its absorbed state in the desorber (or "generator"), taking a low-temperature refrigerant/sorbent mixture and providing a high-temperature, vapor refrigerant. The most common
working fluid pairs are for absorption machines specializing in heating versus cooling, NH₃ (refrigerant) and water (absorbent) for the former and water (refrigerant) and lithium bromide (absorbent) for the latter. For heating applications, regeneration temperatures commonly range from ~115°C (single effect), ~150°C (GAX), to > 175°C (double effect). With significant developments by multiple manufacturers, developments of TDHPs using the vapor absorption cycle were summarized in 2019 by GTI Energy [3].

- **Vapor adsorption** heat pump cycles also referred to as solid sorption cycles, are the adhesion of a gas or vapor (the adsorbate) to form a thin film on a solid surface (adsorbent). Typically, adsorbents are mounted to a heat exchanger that heats and cools the solid. There are many different types of adsorbents, including silicon dioxide, carbon-based compounds, salt matrices, and synthetic compounds such as zeolites. Adsorption is a batch process, a discontinuous process that can continue until a balance between the adsorbent and the adsorbate is achieved. Regeneration temperatures trend lower than vapor absorption overall, depending on cycle and working fluid/sorbent pair, from as low as ~60°C to ~150°C, concerning common open and closed cycle architectures [3]. The adsorption cycle can be applied for multiple end uses, including space conditioning (both heating and cooling) and refrigeration.

As noted, NH₃ is a common refrigerant for sorption-type TDHPs designed for heating applications, used in nearly all of the prototypes and products summarized in the prior section. The table below provides a summary of the broad advantages and disadvantages of TDHPs using NH₃ as a refrigerant, for vapor absorption versus vapor adsorption type cycles. As noted previously and in other efforts [3], the performance advantages of vapor absorption cycles, particularly in heating applications, are well-documented, as are the operational and reliability challenges [10]. TDHPs using the vapor absorption cycle do have a reduced capacity and efficiency but have significant potential for improved reliability.

*This is primarily an improvement over other common adsorption working fluid/sorbent pairs

Before describing the design of the current HPWH, it is useful to review the features and outcomes of the vapor absorption-type HPWH. In this prior effort, a technology developer, GTI Energy, and multiple manufacturers were successful in developing and demonstrating a retrofit-ready GHPWH unit with a target total installed cost of $1,800 and with Ultra Low NOx certification (< 10 ng NOx/J output). The system used an integrated design, with a 3 kW nominal output NH₃/H₂O single effect absorption cycle atop a 227 L to 302 L tank, driven by a custom 2 kW premix gas burner with a nominal 1100 W heater for supplemental high capacity heating. The ~0.5 kg NH₃ was well below the 3 kg limit allowing for indoor installations and, following initial proof-of-concept developments [11-14], successive demonstrations were performed with ~30 units built, roughly half of which were installed in field environments. In the most recent, five-site demonstration in the Los Angeles area between 2019-2020, the per-site energy and GHG emissions reductions were 50% or greater over a 12-month monitoring period as compared to a measured baseline. Operating COP₆, was consistently 1.25-1.60, electric power demand was 0.2% - 2.0% of total output, and end users surveyed indicated satisfaction with the hot water capacity delivered at average temperatures of 52°C [1]. Laboratory testing of the current pre-production generation of GHPWHs demonstrated a path to achieving 1.20 UEF certification. Subsequent analysis and modeling of the potential interactive effects between the GHPWH and the home's HVAC equipment revealed a minimal impact on false loading, substantially less than the impact of eliminating the natural draft baseline water heater product or an electric-type HPWH, and suggestive that a ducted evaporator is neither necessary nor cost-effective [1]. With a photo of a demo unit and the overall field performance compared to baselines in Figure 1, these efforts have aided in demonstrating the technical and market feasibility of sorption-type HPWHs.
In developing this sorption-type HPWH, this team determined the performance criteria necessary to meet the original 1.30 Energy Factor (E.F.) and subsequent 1.20 UEF targets, which were as follows [1, 15]:

- **Average Heat Pump Cycle COP \( \text{COP}_{\text{Gas}} \):** The time-averaged \( \text{COP}_{\text{Gas}} \) of the heat pump cycle needed to exceed 1.65, defined as the ratio of heat recovered from the heat pump cycle (absorber, condenser, flue gas heat recovery) to fuel inputs.

- **Average System COP (COP\(_{\text{System}}\)):** The time-averaged system COP needed to exceed 1.50, defined as the total heat delivered to the storage tank as a ratio of total energy inputs (electricity and fuel inputs). This is often approximately equal to the "recovery efficiency" term as defined in the standard test procedure.

- **Average combustion efficiency \( \geq 95\% \) \( T_{\text{flue gas}} \leq 90 \, ^\circ F \):** This is a time-average of the net combustion efficiency of the process, on a flue-loss calculation basis.

- **Average \( T_{\text{delivered}} \) of hot water \( \geq T_{\text{tank, initial}} \):** To avoid detrimental corrections in the calculation procedure, it is advantageous for time-averaged delivered outlet water temperatures to be at or above the starting average temperature of the storage tank.

- **Standby Heat Losses:** Using the UA term defined in the procedure as a benchmark, a factor of 2.5 Btu/hr-°F or less is prescribed.

- **Power Consumption:** Active and standby power consumption targets were less than 120 W and 10 W respectively.

- **Controls Trigger Early Recovery:** More an artifact of the hot water draw pattern used to yield the UEF metric determination, the product was required to initiate a recovery within the first draw cluster.

While these metrics will not universally apply to all sorption-type HPWHs, nor do they represent the unique set of criteria to meet a 1.20 UEF goal or greater, however, this approach of breaking down these key criteria of HPWH functionality will serve useful in the optimization of the presently described HPWH and others as well.

2.1. Description of the Adsorption-type HPWH Concept

Shown in the diagram and rendering, in both Figures 2 and 4 subsequently, the novel sorption-type HPWH described in this paper embeds a nominal 1 kW output vapor adsorption cycle within a buffer storage tank. The sorption module reactor is driven by a compact steam generator, dubbed a "burner/boiler", which regenerates the sorbate and delivers heat to the buffer storage (via heat recovery). The burner/boiler can also generate hot water directly ("boost" heating). The reactor design uses the \( \text{NH}_3 \)/salt working pair and, as previously developed for space heating applications [16, 17], is modified for this application. The reactor includes calcium chloride, a widely known salt in use in various industrial applications and the adsorption bed uses a shell-and-tube type design as described previously, with the cycling and varying of heat delivery of the batch process evened out by the buffer tank [18]. As shown in the simplified schematic in Figure 2, the heat-driven adsorption HPWH consists of a reactor, a receiver, an evaporator, and a burner-boiler integrated into a 189 L buffer tank. The heat to the buffer tank is delivered either through a sorption cycle or via auxiliary combustion ("boost" heating), which indirectly delivers heat to the potable water. The sorption cycle and
direct-firing can operate both in parallel and in series. In direct-firing mode, the steam generated in the burner-boiler and the remaining heat in the flue gas is recovered to heat the buffer tank directly. The direct-firing mode is utilized during high load periods when the buffer tank temperature drops below set-point during a draw.

In the sorption mode, the heat to the buffer tank is delivered in three different phases: (1) Desorption, (2) Cool-down, and (3) Adsorption. In the desorption phase, the steam generated in the burner-boiler enters the reactor. It condenses in the reactor, releasing heat to the reactor, with the liquid water returning to the boiler. The reactor's temperature increases to a level where ammonia is desorbed from the salt matrix. The desorbed ammonia vapor condenses on the reactor walls and heats the buffer tank with the heat of condensation before returning to the receiver and evaporator through gravity. The communication tube in the buffer tank helps with steam volume expansion. The desorption phase was sized to deliver heat to the buffer tank at 1.5 kW for 20 mins.

In the cool-down phase, the burner-boiler is inactive; the pump circulates water from the buffer tank through the reactor to cool down the salt matrix to the equilibrium pressure. The cool-down phase was designed to last 5 minutes and deliver 0.15 kWh of heat to the buffer tank through sensible heat recovered from the reactor.

In the adsorption phase, similarly, the burner-boiler is inactive. Low-grade heat from the ambient is utilized to heat the ammonia to the gas phase in the evaporator. Ammonia vapor flows through the receiver to the reactor and is absorbed into the salt matrix. The pump circulates water from the buffer tank through the reactor to heat the tank with the heat of adsorption. The adsorption phase was sized to deliver heat to the buffer tank at 0.49 kWh for 95 minutes.

This sorption-type HPWH is sized for residential water heating applications but may be suitably large for space heating, or "combi"-type applications as well. The burner/boiler has a design output of 2-12 kW, sized to regenerate the 3.0 L sorption module and provide excess heating in "boost" operating modes. The system contains approximately 1.2 kg of NH₃, which is sufficiently below the previously noted 3 kg limitation for indoor installations. For this "alpha" prototype, the storage tank is based on a 50-gallon (227 L) platform, however, subsequent versions are expected to be slightly larger to meet the design targets of 2 kW peak output from the sorption module and up to 12 kW peak auxiliary output from the steam boiler. In all cases, the efficiency target is ≥1.25 UEF, with an interim target of the middle tier of 1.15 UEF [9], and in all cases a target first hour rating of 284 L of hot water. To be competitive in all U.S. markets, the product is also targeted to have at least 14 ng NOx/J output emissions and be compatible with up to a 30% hydrogen/natural gas blended fuel.
3. Progress in Novel Adsorption-Type HPWH Development

3.1. HPWH Design and Integration

A first “alpha” prototype with the design described was manufactured for preliminary testing in the second half of 2022. This design is based on several separate subsystem efforts in parallel, with the main focus on design, manufacturing, and showcasing a prototype that has a bill of materials that can meet the set cost targets within the target product category. The system is currently operational with a measured efficiency that is 15%-20% higher than direct-firing with a condensing-level efficiency. To improve on this performance, the authors note that system heat losses need to be better managed, for both direct-firing and heat pumping modes. With subsequent analysis, several pathways to remedy these performance gaps have been identified, including scaling up certain subsystems to optimize capacity versus these thermal losses. At the time of writing, the team continues to address these performance optimization challenges, with completion expected in 2023. Several aspects of this development are described in the subsequent section.

Guiding this design process is the challenging market of residential water heating, where an aggressive cost target is necessary for consumer acceptability [19]. The goal for this system, as a drop-in replacement in North America, would be competing with lower cost, lower performance existing water heaters but also assuring efficiencies well above levels of performance consistent with condensing-level efficiency. In addition to being considered as a replacement or alternative for existing lower efficiency water heaters, the product may also be considered as an alternative to both high-efficiency boilers and electrically-driven heat pump water heaters. With these factors in mind, the system configuration is intended to meet near-term efficiency and decarbonization goals, while retaining end user comfort in standard and extreme loading scenarios, while meeting a mass production manufactured cost of <$1,000 with an even lower cost as a long-term goal. While sizing described previously is for a proof-of-concept version of this sorption-based HPWH approach, designs and product families may evolve with greater/lesser levels of buffer storage, sorption module capacity, and burner/boiler capacity. Ultimately, it is the authors’ sense that the available market for a future product within the category is mainly driven by the cost of the appliance, which drives this optimization process overall, per the simplified representation in Figure 3.

3.2. Burner/Boiler Design and Demonstration

Based on preliminary design exercises, the burner/boiler will need to meet the following basic criteria for performance: greater than 93% overall effectiveness, greater than 83% overall fuel-to-steam efficiency, NOx emissions of less than 14 ng/J output, CO emissions of 100 ppm air-free or below, and suitable modulation over full range over 2-12 kW. During start-up, the burner/boiler should rapidly reach steady-state steam
circulation and the boiler segment should avoid dry-firing in all operational scenarios.

3.2.1. Combustion Design Lessons Learned from Prior Sorption-type HPWH Efforts

Similar to conventional boilers, direct-fired sorption machines commonly employ either "water-tube" or "fire-tube" designs for the desorber, the vessel where the heat source (combustion, typically) drives the boiler of the refrigerant from the sorbent, typically at a peak temperature/pressure for the cycle. In previous work by a subset of the authors in a separate and parallel effort, the aforementioned prototype development of small-scale absorption heat pumps [1] and commercially-available solutions employ "fire-tube" and "water-tube" designs respectively (see figure below). While the heat transfer coefficient of boiling ammonia/water solution differs from what is expected within low-pressure steam generation, by 10-25X, some lessons can be learned, specifically from the "water-tube" desorber design effort, which includes the following as applicable to a custom approach for premixed, modulating combustion within a compact desorber:

- Radial/cylindrical burners were superior in performance and emissions to up-fired approaches in the cylindrical combustion chamber, using a CFD-assisted design approach the ideal dimensions of the combustion chamber and burner were realized, which were a chamber radius approximately equal to the diameter of the burner.

- On downstream quenching, CO emissions, and stability issues, the height of the chamber (distance from the top of the burner, with a blank surface, from transition/exit from the chamber) was found to have a non-linear response. Increasing heights above a certain limit, the simulation suggested a favorable recirculation zone was weakened, leading to poorer heat transfer and flame liftoff. This allowed for an empirically-tuned gradual increase in the chamber height.

- On the burner surface, the impact of vertical distribution was mitigated by internal structures, preventing the "Christmas tree" effect – wherein fuel/air face velocities are greatest at the burner top and lowest at the bottom. The use of conical or parabolic inserts, in addition to revised perforated plate hole patterns, were all shown to improve this impact, further reducing quenching.

- For outdoor installations, several combinations of gas valves, blowers/mixers, and ignition controls were demonstrated to effectively modulate and ignite at down to -20°F, though not all components performed equally.

3.2.2. Burner/Boiler Testing Results

An experimental test stand was designed and built at GTI Energy to perform testing on the burner/boiler component of the novel sorption-type HPWH, as shown in the figure below. A custom-made, cylindrical, radiant-style burner was used in conjunction with off-the-shelf gas train components. The premix burner configuration was assembled using a fuel-air mixer with a nominal output of 27 kW and a turndown ratio of 5:1. During preliminary testing, combustion stability was difficult to maintain, with lean blowoff being the common mode of failure. This may have been caused by insufficient sealing of the burner base and entrainment of secondary combustion air into the burner/boiler, or insufficient drainage of condensate in the flue gas stream leading to abrupt changes in back pressure. Further investigation will be conducted to determine and resolve the flame stability issue.

Despite challenges with maintaining combustion stability, some valuable experimental data was gained from the preliminary testing during stable operation taking place over separate 15 minute and 20 minute
periods. Due to the oversizing of the fuel-air mixer component, the firing rate was set to an average of 14.0 kW with excess air of 170% (air-fuel equivalence ratio of 1.7). Emissions testing results are summarized in Table 2, which indicates NO\textsubscript{x} emissions well below the target but outstanding issues with the CO emissions, slightly above the target. For future testing, a new gas train will be assembled with a more appropriate modulation range that will better match the 2-12 kW operating range of the sorption module. The emissions values will be reassessed at excess air ranging between 140-150%, which is more common for boiler applications.

### 3.3. System Simulation and Projected Performance

The adsorption HPWH model was simulated as a stratified water buffer tank as an indirect Domestic Hot Water (DHW) system coupled with an adsorption heat pump and an internal Heat Exchanger (HX), as illustrated in the Figure 7 schematic. The sensible storage energy balance model were developed in Octave based on stratified sensible thermal storage divided into five volume segment nodes. Each equal volume segment is assumed to be thoroughly mixed. The heat loss capacity rate from the buffer tank to the ambient was specified for the bottom, top and zone as highlighted in Table 3, as heat loss capacity rate \( U_A \). The model constants and buffer tank properties highlighted in Table 3 were based on an off-the-shelf 50-gal indirect storage tank. The buffer tank was discharged (i.e., heating DHW) via the internal heat exchanger. All temperatures in the buffer tank were computed by solving a set of differential equation energy balance for each node given by:

\[
\frac{V_{\text{m,water}} \cdot P_{\text{m,water}} \cdot \delta T_{i,j}}{n_{\text{tank}}} \frac{\delta t}{\delta t} = k_{\text{water}} \frac{A_q}{H_{\text{tank}}} n_{\text{tank}} \left[ \left( T_{i+1,j} - T_{i,j} \right) + \left( T_{i-1,j} - T_{i,j} \right) \right] - \frac{U_{A_{\text{HX}}}}{n_{\text{HX}}} \left( T_{i,j} - T_{i,j,\text{HX}} \right) - \sum U_{A_{\text{loss}}} \left( T_{i,j} - T_{\text{amb}} \right) + P_{\text{heat}} 
\]

Fig. 7. The schematic for stratified water storage tank model with direct heating and internal heat exchanger.
The internal HX heat transfer area is divided into five segment nodes. Each node was thermally coupled to the corresponding volume segments of the tank. The heat transfer coefficient between the heat exchanger and tank was calculated using H. Druck’s correlation for immersed coil heat exchanger [20]. The energy balance for the heat exchanger at each node is given by:

\[
\frac{V_{hx} \rho_{hx} C_{p,hx} \delta T_{i,j}}{n_{hx}} = \dot{m}_{hx} C_{p,hx} (T_{i-1,j} - T_{i,j}) + \frac{UA_{hx}}{n_{hx}} (T_{i,j,tank} - T_{i,j}) - \frac{UA_{hx,loss}}{n_{hx}} (T_{i,j} - T_{amb})
\]  

(2)

The heating of the buffer tank was either performed by sorption phases at fixed-volume nodes, as shown in Figure 7. The internal heating of the buffer tank was modeled like an electric resistance heater controlled by the average tank temperature (i.e., aquastat). The heat loss capacity rate from the buffer tank to the ambient was specified for the bottom, top, and each volume node, as summarized in Table 3.

</tbody>
</table>

As illustrated in Figure 8, the model was validated with experimental data for an indirect DHW storage tank previously collected in the field by GTI Energy. The model’s accuracy was within ± 15% of the experimental data’s tank average temperature. The model’s spatial average temperature was computed by averaging the temperatures of the five nodes. Similarly, the water storage temperature was measured in the field at five equally distributed intervals and averaged.

Energy efficiency standards and labeling metrics (EES&L) for water heaters vary widely among countries [21]. In the USA, the Uniform Energy Factor (UEF) test procedure developed by the U.S. Department of Energy (DOE) is used for the energy efficiency of water heaters [22]. A higher UEF metric means a water...
heater is more energy-efficiency and will cost less to operate compared with other water heaters in the same category.

The UEF test is 24 hours long to simulate the use of a water heater over one day. For the medium draw profile in this work, the UEF consists of numerous water draws organized into three draw groups (series of water draws) at two predefined flow rates (1 and 1.7 GPM). The UEF characterizes the system's energy efficiency based on this characteristic hot water use pattern. The UEF has energy-based corrections for the tank's initial and final conditions and energy-based corrections for the outlet temperature differing from the nominal value.

The COP for the adsorption heat pump during the 24-hour model, the UEF test, was assumed at a constant value of 1.25 based on the UEF test condition requirement of 19.7 ± 0.6°C [20]. The adsorption heat pump operated for a total of 9 hours and 30 minutes, as shown in Figure 9. The heat pump's runtime was divided into two segments, with 3 hours of non-operational period between them. Based on the estimated COP of the adsorption heat pump and the heat loss from the buffer tank, the system achieved a UEF of 1.1 in the model. As illustrated in Figure 9, the tank is vertically stratified, with hotter (lower density) water above cooler (higher density) water, as expected by the model for the stratified tank. Analysis of the tank temperature shows the effect of draws and charging location (i.e., adsorption heating phase) on the stratification.

As illustrated in Figure 10, the buffer tank temperature was set to and maintained at 70°C (158°F), compared to 48.9°C (120°F) in residential storage water heaters. The buffer was held at a higher temperature than the standard due to the indirect design of the DHW. A higher buffer temperature is required to maintain the DHW supply temperature of more than 43.3°C (110°F), accounting for the flow rate and heat transfer limitation on the heat exchanger, as shown in Figure 10 during the UEF testing.

Fig. 10. The effect on DHW supply temperature for the indirect system during the UEF simulation.
4. Conclusions and Next Steps

In this paper, the authors described a novel sorption-type heat pump water heater, sized for residential applications in North America with a hybrid design, of both up to 2 kW peak output from the sorption modules and up to 12 kW peak auxiliary output from the steam boiler, with an efficiency target of ≥1.25 UEF and a target first hour rating of 284 L of hot water. The context of this development is described, in terms of the residential high-efficiency water heating market and the design and performance of sorption-type HPWHs in general. Progress on several aspects of the design and development are described, including a) the development and testing of a compact steam boiler loop to drive the desorption process, designed for 14 ng NOx/J output and compatible with up to a 30% hydrogen/natural gas blended fuel, b) immersed sorption modules within the buffer storage tank for water heating with a COP_{gas} > 1.40 using limited moving parts, and c) heat exchange and preliminary system controls, per empirically-calibrated simulation, to meet UEF targets and high usage hot water patterns typical for 4-5 occupant homes. While these remain performance targets as development and testing are ongoing, a path to reaching these goals is briefly described as are efforts to calibrate a performance model of the novel sorption-type HPWH. In the coming months, the authors anticipate refining system components through successive experimental development, assessing performance in succeeding generations of HPWH prototypes, and if successful in meeting targets, proceeding to initial field trials in the U.S.

Abstract

This paper provides an overview of the most important economic and environmental considerations when deploying very high temperature heat pumps (VHTHPs) in the European region. One of the state-of-the-art heat pumps, a process based on the reversed Stirling cycle, can achieve temperatures of up to 200 °C, and temperature lifts over 150 °C. The coefficient of performance (COP) suffers during such large temperature lifts, and thus the relationship between the price of electricity and alternative fuels becomes a crucial factor when determining the feasibility of replacing existing boilers in industrial settings. The environmental impact is quantified using life cycle assessment and mainly depends on the electricity source used to run the heat pump as well as the construction and decommissioning of the heat pump itself.

It was found that factors such as low electricity prices and/or carbon pricing mechanisms are crucial in order to operate low COP heat pumps profitably. Additionally, it was determined that VHTHPs can significantly reduce the environmental impact of steam generation compared to equivalently sized fossil fuel boilers, provided that renewable sources of electricity are used.

Keywords: VHTHP; Life Cycle Assessment; Europe; Electricity mix

1. Introduction

Very high temperature heat pumps (VHTHPs) capable of delivering temperatures of up to 200 °C (392 °F) are beginning to emerge on the market and offer an alternative process for generating high temperature process heat for industries which have traditionally relied on the combustion of fossil fuels [1]. While there is no generally accepted definition of what constitutes a VHTHP, Arpagaus et al. presents a definition for in Figure 1 which involves operating conditions where sink temperatures exceed 100 °C and/or source temperatures exceed 60 °C. Traditional heat pumps operate with sink temperatures below 80 °C and source temperatures below 40 °C, and high temperature heat pumps occupy the space between traditional heat pumps and VHTHPs [2].

The coefficient of performance (COP) decreases due to the high temperature lifts, and as such the economic feasibility of the technology becomes highly dependent on the price ratio between electricity and fossil fuels, typically natural gas. The environmental benefit of replacing fossil fuels boilers with VHTHPs is also largely dependent on the source of the electricity used to power the heat pump. Countries where electricity grid mixes consist mostly of nuclear power and/or renewable energy sources such as wind, solar, and hydropower produce a significantly smaller environmental footprint when operating VHTHPs compared to grids consisting mostly of fossil fuels. This footprint can be quantified using life cycle assessment (LCA).

In this study, a way to estimate the environmental and economic outcomes associated with installing VHTHPs in different European regions is determined using electricity data from ENTSO-E [3], environmental impact data from ecoinvent v3.8 [4], and real-world data from VHTHPs in industrial settings. Two separate
breweries in Spain utilizing high temperature steam are investigated, and the economic and environmental impacts of replacing existing natural gas boilers with VHTHPs are estimated.

Fig. 1. Temperature operating ranges for heat pumps (HP), high temperature heat pumps (HTHP), and very high temperature heat pumps (VHTHP) [2].

2. Economic considerations

The efficiency of a heat pumps is limited by the theoretical Carnot efficiency, which decreases as the temperature difference between the heat source and the heat sink increases. The VHTHP analyzed in this study, a heat pump based on the reverse Stirling cycle which uses helium as the working medium, can deliver temperature lifts over 150 °C. During these temperature lifts, the COP tends to drop under 2.0 in practice [1, 5]. This means that the price ratio between electricity and fossil fuels, commonly natural gas, becomes a deciding factor when comparing different heating technologies.

Compared to natural gas boilers, industrial VHTHPs are still an emerging technology and therefore tend to have higher upfront costs, as well as potentially higher maintenance costs. Table 1 presents the initial investment and maintenance costs for a natural gas boiler and the VHTHP included in this study. The investment cost of the VHTHP is calculated according to a 1 200 €/kW figure from a product datasheet [6], while the maintenance cost is an internal estimate from the heat pump manufacturer. The values for the reference natural gas boiler are obtained from case study 2 in the EU Commission report Ecodesign preparatory Study on Steam Boilers [7], as it is of roughly appropriate size. The values for the natural gas boiler have been adjusted for inflation to 2022 prices.

All European Union member countries as well as Iceland, Liechtenstein, and Norway are participants in the European Union Emissions Trading System (EU ETS), which is a cap-and-trade scheme in which companies purchase emission allowances for the CO₂ they emit. Depending on the industry, companies get a certain number of allocations by default, and must thereafter either purchase enough allowances to cover their carbon dioxide emissions or reduce their overall emissions [8]. Companies always have an incentive to reduce their emissions, as the allowances can be bought and sold on an open market. Therefore, any reduction in CO₂ emissions can be directly tied to a monetary gain. At the time of writing, allocations were trading at 80 €/ton CO₂ [9].
3. Environmental considerations using LCA

A significant portion of the environmental footprint associated with a VHTHP is tied to the electricity generation used to run the heat pump. The European electricity market consists of a diverse set of energy sources that varies between bidding zones. In order to accurately determine the environmental impact of installing and operating a VHTHP, one needs to know the electricity mix in the region in question along with the environmental footprint associated with each energy source.

3.1. Life Cycle Assessment

LCA allows one to estimate the environmental impact of building, operating, and decommissioning a product at a specific location. The overall impact gets categorized into fifteen or so midpoint categories depending on the methodology used, and includes categories such as land use, carcinogenic substances, and ecotoxicity. These factors can be summarized into wider damage categories covering the impact on human health, ecosystem quality, climate change, and resource usage.

The life cycle impact of the VHTHP in this article has been studied and quantified before and will serve as a basis for further analysis [10].

3.2. Methodology and Impact categories

Depending on what methodology is used, one can group the environmental impact into three or four damage categories. The IMPACT 2002+ V2.15 [11] method was chosen in this analysis, as it separates climate change into its own category alongside human health impact, ecosystem quality, and resource usage. These four damage categories can be normalized in order to compare them against each other, and they can also be combined into a single total environmental impact estimate. This impact is measured in points, which are equal to person years (pers×yr) and represent the average impact associated with a single European citizen per year in a given category.

At the midpoint level, life cycle impacts are typically expressed as kg substance s-eq, which is an equivalent amount of a reference substance s appropriate for the impact category in question. Examples of these reference substances are chloroethylene emissions into the air for the human toxicity category, sulfur dioxide emissions into the air and water sources for terrestrial acidification/nutrification and aquatic acidification, and carbon dioxide emissions for global warming. Other units are used where a reference mass equivalent substance is not appropriate, such as Becquerel carbon-14 into air-eq for the category ionizing radiation.

These emissions are then normalized into the damage category units Disability-Adjusted Life Years (DALY) for human health, Potentially Disappeared Fraction of species over a certain amount of m² during a certain amount of years (PDF×m²×yr), and Mega Joules (MJ) for resource usage. The normalization factors used to further estimate the total environmental impact measured in points are 0.0071 DALY/point for human health, 13 700 PDF×m²×yr/point for ecosystem quality, 9 950 kg CO₂ into air/point for climate change, and 152 000 MJ/point for resource usage [11].

3.3. Environmental impact of different electricity sources

Table 2 contains a summary of the environmental impact associated with the most common electricity generation sources in Europe and the most relevant midpoint categories expressed in damage category units. The inventories for each electricity source were taken from the database ecoinvent v3.8, and the method IMPACT 2002+ V2.15 was used to assess the life cycle impact. The impact of some electricity sources such as solar power differs considerably between regions. The total amount of solar irradiance received is lower in regions further from the equator and the weather conditions may be harsher, resulting in reduced equipment lifespans. As a result, the environmental impact associated with each individual kWh electricity produced over the panel’s lifetime is increased in regions that receive less solar irradiance. The impact of other energy sources such as nuclear power is more consistent across European regions.

The figures in Table 2 are modeled after the “Electricity, source, at power plant/UCTE” modules in ecoinvent v3.8, which represent the average impact across power generation stations across Europe. In reality, these figures vary between power plants, with more modern units being more efficient and producing a smaller environmental footprint for a given amount of electricity.

3.4. European grid mixes

The European electricity market consists of a diverse mix of energy sources that varies greatly between bidding zones. Table 3 contains the average electricity consumption mixes for the year 2022 in some of the largest economies in Europe which were estimated using data from the ENTSO-E transparency platform [6]. The average consumption mix was estimated as the sum of the electricity generated within a region and the consumption mix of any imported electricity. The mix of any exported electricity was excluded in order to only account for the domestic demand. As ENTSO-E provides hourly updates regarding electricity production across the EU, it is possible to create up-to-date predictions regarding the consumption mixes. By combining the consumption mixes in Table 3 with the environmental impact associated with each electricity source in Table 2, one can estimate the environmental impact of operating a VHTHP with a specific COP in any given country. This estimate is performed in chapter 5.

The ENTSO-E transparency platform does not provide additional details regarding the composition of electricity generated from biomass which makes it difficult to estimate the environmental impact. This electricity might be generated by combusting black liquor from pulp production, biogas from silage, biodegradable waste, woodchips, or other sources.

* Data from the year 2020
4. Assessment of two breweries

Two different industrial cases were assessed in this study, and the most important case data presented in Table 4. The first case involved a brewery in Spain utilizing high temperature steam at 170 °C (7 barg). 680 kW of heat was available in the form of ammonia condensation at 26 °C during the winter and 32 °C during the summer, and there were expected to be 6 350 operational hours annually. The COP was estimated to be 1.8, which is 58% of the theoretical maximum Carnot COP of 3.1. The second case involved a different Spanish brewery with steam at 162 °C (5.5 barg) as a heat sink. 425 kW of waste process heat was available at 85 °C. The smaller temperature lift results in a higher COP which was estimated to be 2.3, 41% of the Carnot COP of 5.6.

The COP was estimated based on an internal model provided by the heat pump producer. The performance of the heat pump in several different operating conditions can be viewed in the products datasheet [6]. Electricity was to be available in the form of guarantee of origin solar power priced at 70 €/MWh, the price of natural gas was 27 €/MWh, and the ETS carbon price was 90 €/ton CO₂ at the time. The boiler efficiency was estimated to be 90%.

For the first case, two 750 kW heat pumps utilizing the entire cold heat source and delivering 1 370 kW heat while consuming 760 kW electricity was proposed. The second brewery case had enough waste heat to operate one heat pump delivering 690 kW of high temperature steam while consuming 300 kW electricity.

The reduction in on-site CO₂ emissions from combustion were estimated as follows:

$$m_{CO_2} = \frac{q_{NG}Q}{\eta_{boiler}LHV_{NG}}.$$  

Here $m_{CO_2}$ is the CO₂ mass, $q_{NG}$ is the specific natural gas CO₂ emission factor of 2.75 kgCO₂/kgNG, $Q$ is the heat produced, $\eta_{boiler}$ is the efficiency of the boiler, and $LHV_{NG}$ is the lower heating value of natural gas which is 13.06 kWh/kgNG. Both the economic assessment and the environmental impact assessment assumed a 15-year lifespan.

4.1. Economic assessment

Table 5 presents the estimated annual cost of operating one or multiple VHTHPs in both cases under the conditions described in the previous chapter. It also includes an estimate of the cost of operating the reference natural gas boiler as well as the annual running cost savings if VHTHPs are used in place. The estimated running cost savings were calculated as the cost of natural gas for the boiler, the cost of maintenance, as well as the cost of the ETS allowances needed to cover the CO₂ emissions minus the cost of electricity needed to operate the heat pump as well as maintenance costs.

Table 5. Annual running cost estimates for the two cases

</tr>
</tbody>
</table>
One factor that limits the running cost savings are the relatively few operational hours in both cases, namely 6 350 and 5 200 hours respectively. When estimating the simple payback period as the cost of investment divided by the annual running cost savings, a VHTHP is assumed to have a retail price of 900 000 €, and the natural gas boiler is assumed to cost 76 000 € in accordance with Table 1. With these figures the simple payback periods for both cases are calculated to be 20 years and 13 years respectively.

A sensitivity analysis on the simple payback period provides more insight into how uncertainty in the price of electricity and natural gas affects the economic viability of an installation. One approach is to conduct Monte Carlo simulations which rely on a large number of random samplings of variable values in order to estimate the probability of different outcomes. These simulations were performed with electricity, natural gas, and ETS prices as independent variables. In practice, these variables are not truly independent, as for example grid electricity prices will be affected by changes in natural gas prices if the grid in question partially operates on fossil fuels.

Figure 2 depicts the results of two Monte Carlo simulations, one for each investigated case. 1 000 000 price conditions were simulated with the relative outcome probability on the y-axis. The price of electricity and natural gas was varied with a standard deviation of 10%, while the price of the ETS allowances had a standard deviation of 15%. Outcomes with payback periods longer than 50 years and outcomes with negative payback periods (i.e., unprofitable outcomes) are not included in the figure. These amounted to 13% of the outcomes in the first case and less than 1% of the outcomes in the second case.

Analysis shows that the first case is more sensitive to price changes compared to the second case. This is likely due to the lower COP and, as a result, higher electricity consumption. Overall, 54% of the outcomes in the first case and 93% in the second case end up with a payback period below 20 years, with median values of 19 and 12 years, respectively.

4.2. Environmental impact

Table 6 contains the estimated environmental impact for the proposed solution of two VHTHPs and an equivalently sized natural gas boiler for the first case, and Table 7 contains the results for the second case. The damage categories are presented in bold text while their most impactful constituent midpoint categories are in roman. An estimated total environmental impact is also included.

In both cases, VHTHPs operating under the previously described conditions and utilizing renewable solar energy in Spain show a significantly smaller total environmental footprint, with large reductions in the damage categories climate change and resource usage. The impact on human health shows a slight improvement, while the impact on ecosystems is slightly increased. Case two shows more significant improvements due to the higher COP.

</tbody>
</table>

The 89% and 91% reductions in CO₂e emissions are almost entirely due to the smaller carbon intensity of solar energy compared to natural gas. Spanish solar electricity is modeled as the “Electricity, production mix photovoltaic, at plant/ES” module in ecoinvent 3.8 which has a carbon intensity of roughly 50 g CO₂e per kWh electricity while natural gas is modeled as the “Heat, natural gas, at boiler modulating >100kW” module in ecoinvent 3.8 which has a carbon intensity of roughly 247 g CO₂e per kWh heat.
A network analysis of the LCA results was conducted in order to identify the sources of the emissions. The lessened impact on human health mostly comes down to a reduction of inorganic emissions causing respiratory illnesses as well as reduced carcinogenic emissions. Particulate matter smaller than 2.5 µm in diameter (PM$_{2.5}$) is the reference substance for the midpoint category respiratory inorganics, and in the case of the natural gas boiler, roughly two-thirds of the PM$_{2.5}$ emissions originated from the production and transport of natural gas while most of the remaining one-third occurred during the combustion process. In the VHTHP case, these emissions stemmed from a mix of copper and aluminum refining, glass production, and freight shipping.

The increased impact on ecosystems consists almost entirely of increased terrestrial ecotoxicity. The process of copper extraction and refining accounted for over half the impact on terrestrial ecotoxicity in both heat pump cases.

The use of non-renewable energy resources sees a substantial reduction as no fossil fuel combustion occurs. At the same time, considerably more energy is needed for the extraction of minerals such as copper, nickel, and aluminum. The extraction of copper accounted for roughly half the energy used for mineral extraction in the VHTHP cases.

5. VHTHPs in different electricity grid mixes

In this section the environmental impact of deploying a VHTHP in the different European countries grid mixes listed in Table 3 is investigated. The operating conditions of the VHTHP is modeled to be similar to that of case 2. Electricity generated from biomass is assumed to consist of natural wood chip combustion as no further insight is provided by ENTSO-E, and the category Other is modeled as a mix of waste combustion and biomass, as well as peat in the case of Finland. The Unaccounted imports in the case of Finland consists of Russian electricity. These imports have since halted and have been replaced with imports from the Swedish grid since the 15th of May 2022. Russian electricity production is also not available in ENTSO-E. As a result, the category Unaccounted imports in the case of Finland is modeled after the Swedish electricity mix. The unaccounted imports in the case of Belgium, France, and the Netherlands consist of imports from the United Kingdom, whose production data is not included in the ENTSO-E database for the year 2022. These imports were therefore modeled after the United Kingdom 2020 mix in Table 3.

The total environmental impact of a VHTHP in the second case using grid electricity in the listed countries as well as the total environmental impact of an equivalently sized natural gas boiler is presented in Figure 3, where the red horizontal line indicates the total environmental impact of the natural gas boiler. The four damage categories human health impact, ecosystem impact, climate change, and resource usage have been recalculated into points using the normalization factors in chapter 3.2.

Countries under the red line would see a net environmental benefit by operating a VHTHP instead of a natural gas boiler, while countries over the line would not. The results show that the environmental impact associated with operating a VHTHP across all damage categories is highly dependent on the source of electricity used. In electricity grids reliant on fossil fuels such as Poland or the Czech Republic, the total environmental impact can be greater for a VHTHP compared to an equivalently sized natural gas boiler. This is clearly shown in the damage categories climate change and human health impact, where electricity from the Polish grid results in a significantly larger impact compared to a natural gas boiler. Countries whose grids mostly consist of renewable energy sources, such as Norway or Sweden, would see a significant environmental benefit to installing and operating VHTHPs in place of a natural gas boilers under the conditions described in case 2.
6. Conclusion

This article summarized the most important economic and environmental factors that should be considered when assessing the feasibility of introducing VHTHPs in the European region. A way to quantify the environmental impact using LCA and up-to-date data regarding electricity consumption mixes in distinct regions was presented.

Two cases involving breweries in Spain with a demand for steam at 170 °C and 162 °C respectively were considered, and the economic and environmental impacts of replacing natural gas boilers with one or multiple VHTHPs were investigated. Analysis showed that the running cost savings and payback periods are highly dependent on the price ratio between electricity and natural gas as well as the price of CO₂ emission permits. The first case was estimated to have a simple payback period of 19 years and was shown to be more sensitive to utility price changes compared to the second case which was estimated to have a payback period of 12 years.

It was determined that the first case could operate two VHTHPs with an estimated COP of 1.8 which resulted in an 84% reduction in the total environmental impact over a natural gas boiler if solar power was used as an electricity source. The second case could facilitate a single VHTHP with an estimated COP of 2.3 which would reduce the total environmental impact by 87%. The environmental impact of operating VHTHPs in a number of different European settings using grid electricity was also studied, and it was determined that the environmental benefit of replacing natural gas boiler with VHTHPs is highly dependent on the source of electricity used. VHTHPs operating in electricity grids consisting mostly of renewable energy sources showed a substantial reduction in the total environmental impact compared to natural gas boilers, while VHTHPs operating in grids consisting mostly of fossil fuels showed an increase.

Detecting Leaks of Flammable Refrigerants below the 5% Lower Flammability Limit with a Low-Cost Sensor Platform

Moonis R. Ally*, Stephen Killough

Energy Science and Technology Directorate, Oak Ridge National Laboratory, P.O. Box 20008, Oak Ridge, 37831-6070, USA

Abstract

A new low-cost sensor platform was developed for detecting flammable refrigerant leaks below the 5% lower flammability limit with an intrinsic self-check feature, detection times of under 1 s, no field calibration requirement, and rapid communication with a monitoring station or the fire department using Internet of Things technology. The sensor platform is plug and play and is specifically suitable for environmentally friendly low–global warming potential natural refrigerants, such as propane, that can achieve higher energy efficiency and operate at lower costs compared with hydrofluorocarbons. Because of its flammability, propane is mainly used in secondary and cascade refrigeration systems in supermarkets and chillers. Further adoption and market penetration depends on improved equipment safety because of tight safety standards from regulators and building codes. This sensor platform will provide OEMs and end users with increased safety features and optionality. Adoption of this platform for propane, which has a global warming potential of 3, will help reduce global warming relative to the use of hydrofluorocarbons.

1. Introduction

Phase-out of hydrofluorocarbons (HFCs) and the safe transition to low-GWP hydrocarbon/natural refrigerants are critical global issues[1]. Regulatory, business, and climate impacts are the main drivers of these changes. The 2019 American Innovation and Manufacturing Act and HFC phasedown regulations are requiring original equipment manufacturers (OEMs) and end users to use alternative refrigerants to reduce greenhouse gas emissions. The natural refrigerants market is expected to grow from $1.5 billion in 2020 to $2.45 billion by 2025 at a 12% CAGR [2]. The global market for low-GWP, environmentally friendly refrigerants is estimated at $25.2 billion in 2022 and is forecast to surpass $73.7 billion by 2032, growing at a CAGR of 11.3% from 2022 to 2032 [3]. HFC phasedown and use of low-GWP refrigerants presents an opportunity for a 0.5°C reduction in global warming [4], and to lower energy costs for consumers. HVAC, water heating, and refrigeration systems are the largest energy end uses in buildings, using nearly 50% of all energy in US commercial and residential buildings. DOE is supporting US HFC phasedown efforts that target an 85% reduction by 2035[5], [6] through R&D and testing of low- to zero-GWP technologies.

Propane, with a low GWP of 3, is a strong contender to replace R-134a, which has a much higher GWP of 1,430, in refrigeration equipment. Propane is a natural refrigerant but is also flammable (A3 classification)[7]. Therefore, improving safety features within the equipment is crucial so that propane can be used throughout the heating, refrigeration, and air-conditioning industry in all sectors (residential, commercial, and industrial) of the economy. This paper describes a low-cost plug-and-play sensor platform that is engineered for detecting propane leaks at below the 5% lower flammability limit (LFL) within seconds. The developed sensor platform serves the US Department of Energy’s (DOE’s) maximum daily energy consumption, energy-related greenhouse gas reduction (83% by 2050 from 2005 levels) [8], and climate change (<2°C rise by 2100) targets.

To reduce GWP, OEMs are replacing R-134a with propane; however, better product safety is needed to meet regulatory and building safety requirements. This requires developing propane sensor platforms that enables rapid detection and response at low concentrations.

The sensor platform consists of (1) an electrochemical sensor and (2) associated electronics and specialized software for a self-check feature, propane detection, and communications to a monitoring station or a fire department. The small size is ideal for use in refrigeration and heat pumping equipment. To improve safety, the goal of the sensor platform is to detect leaks in equipment before they can spread to the building or facility level. A microcomputer chip that retails for $0.50 is programmed to self-check the sensor and transmit a signal that indicates the sensor is working with fidelity while simultaneously monitoring any leaks. When a leak is detected, the microcomputer is programmed to transmit a signal to a monitoring station via a LoRa transceiver. LoRa is a wireless modulation technique derived from chirp spread spectrum technology and is used extensively in Internet of Things (IoT). It encodes information on radio waves using chirp pulses. LoRa-modulated transmission is robust against disturbances [9]. In this study, we display the transmitted signal using a terminal emulator (Putty). The sensor output could also be relayed via a satellite signal or telephone lines to a fire station, depending on customer preferences. Packaging these features in a low-cost plug-and-play platform is important for adoption of low–global warming potential (GWP) flammable natural refrigerants.

To optimize the safe use of propane, early detection of leaks is important to reduce flammability risk of propane. In this paper, we discuss four important metrics to reduce risks: (1) the fidelity of the sensor and its ability to self-check, (2) the level of detection, (3) how quickly a leak is detected at a particular concentration level, and (4) data transmission via LoRa.

2. Sensor platform architecture, metrics, and measurements

The sensor platform consists of two main parts. The first is an electrochemical sensor chosen for its rapid reaction with a flammable gas (propane, isobutane, or hydrogen). A small Ni-Cr heating coil heats a sliver of SnO$_2$ on an Al$_2$O$_3$ ceramic substrate to release O$_2$, which is subsequently adsorbed on the ceramic surface. In the absence of flammable gases, the donor electrons on SnO$_2$ are attracted toward the adsorbed O$_2$, preventing current flow. In the presence of flammable gases, the adsorbed O$_2$ is consumed, releasing electrons and allowing current to flow through the sensor. The self-check feature of the sensor ensures that the heating element maintains its integrity for the process to work.

The second part of the sensor is the electronics and associated software that perform the sensor self-check and transmission of signal using chirp spread spectrum technology. The qualification, “sensor platform” refers to the specific use of LoRa, a wireless modulation that is widely used in IoT. It encodes information on radio waves using chirp pulses. LoRa radios use the unlicensed 902-928 MHz band and thus do not require any licensing fees. The monitoring organization would need a receiving unit to watch for alarms, or commercial reception service can be purchased to send messages to the customer through the internet. The radio link range can be several miles thus, a single receiving station can cover several square miles. For shorter range requirements, the transmitter power can be reduced to enable more frequency re-use. A microchip is programmed to communicate with the sensor and the LoRa transmitter. It allows self-checks of the sensor every 5 s, although this can be varied arbitrarily via software modification. We selected an interval of 5 s so that the self-check feature can be witnessed frequently for demonstration in a laboratory setting. A voltage output from the sensor indicates that the sensor is working properly. If this output goes to zero, then the sensor has failed. This inexpensive, robust technology [10] is inexpensive and provides more capability and flexibility relative to other sensors available on the market. It is also plug and play, and the sensor can readily be removed and replaced, if needed.

When flammable gases contact the sensor, via a rubber tube from the calibrated gas cylinder to the sensor head, a current is generated, and a corresponding voltage is displayed on a terminal emulator (Putty, which is freeware). The voltage depends on the concentration of the flammable gas. We tested calibrated gases traceable to the National Institute for Standards Technology (NIST) standards at flammability limits of 47.61% LFL (1% propane + air), 28.57% of LFL (0.6% propane + air), and 4.76% of LFL (0.1% propane + air) with response times of less than 1 s. Representative data with response times are shown in Error! Reference source not found. where the response times are for propane + air concentrations of 47.61% LFL, 28.57% LFL, and 4.76% LFL, with the concentrations traceable to NIST standards provided by the manufacturer. Modules #1, #2 and #3 refer to three sensors from the same manufacturer. The response times of each of the three discrete sensors (same model and manufacturer) is less than 1 s at the 95% confidence interval (C.I.). For the lowest concentration of propane (4.76% LFL, or 0.1% propane in air), the average response time is 0.386 s ± 0.03 s.
Standard statistical methods are used for calculating C.I. These data demonstrate that the level of detection is below 5% LFL and the presence of propane is detected within 0.5 s.

A proprietary software takes readings every 5 s to check the sensor and to check the voltage reading from the sensor above a certain threshold level when no propane is present. This threshold is approximately 0.4 V. As soon as propane is detected, the voltage spikes, which is relayed via a LoRa transmitter to a receiver connected to a laptop and displayed using Putty. Putty is a Secure Shell (SSH) and telnet client and is open source. It is used as a communication vehicle between the host system (e.g., a laptop) and the system command-line interface. The combination of the sensor, transceiver, microprocessor, and software comprising the sensor platform is shown in Fig. 1.

![IoT-based sensor platform with diagnostics and messaging. The size of the module is estimated by comparison to the size of a quarter ($0.25) coin.](image)

The response of the sensor platform to propane at the three distinct concentration levels is shown in Fig. 2. The rapid detections of propane at the three distinct concentration levels are similar, as confirmed by the values in Table 1 and Fig. 2, and the sensor returns to its baseline level of 0.3 V in about 90 s. This pattern of repeated
Propane detection and returning to the baseline case is evident in Fig. 2, demonstrating the sensor’s repeatability and fidelity.

3. Discussion

Many sensors have been evaluated [11][11][11][11] recently to address leak detection of refrigerants, including low-GWP hydrocarbon refrigerants to mitigate global warming and to limit the rise in global
temperature to within 2°C, and preferably to 1.5°C compared with preindustrial levels as per the Paris Agreement adopted by 196 parties on December 12, 2015 and made effective on November 4, 2016.[11]. Refrigerant detectors utilize a variety of sensing principles, including micro-machined membrane, nondispersive infrared, thermal conductivity, metal oxide semiconductor, speed of sound, and electrochemical sensors. We selected the electrochemical sensor because of its rapid response, reliability, ease of operation, and low cost. Tighter regulations and safety standards in the United States and the European Union are anticipated for A3 refrigerants. Propane is approved under the US Environmental Protection Agency’s Significant New Alternatives Policy Program. The sensor platform has the following capabilities: a self-check feature and diagnosis; rapid detection; ability to detect small leakages at less than 5% LFL in less than 1 s; no field calibration requirement; and communication via IoT technology to a monitoring site, which can be adapted in various ways to meet customer demand. In the current version of the platform as described in this paper, the platform transmits a self-check signal and leak detection signal via radio signal to another radio receiver whose output is read on a laptop for remote monitoring. This platform will assist OEMs looking for long-term solutions with equipment life >15 years and in accordance with regulations and safety standards in the United States and the European Union. The properties and performance metrics of the low-cost sensor platform make it attractive for adoption in industry.

Abstract

Large-scale ammonia heat pumps are key technology for enabling sustainable heat supply. Exploiting their potential in integrated systems requires the highest efficiencies and reliability even at varying operating conditions. The varying operating conditions can result from variations in the heat source and sink, such as variations in production processes and sudden changes of weather conditions. The dynamic operating conditions may result in unwanted dynamic effects, risking sub-optimal performance and component damage. This study focuses on the development and validation of dynamic models for the components in an ammonia heat pump system. The various components were assembled in a dynamic model implemented in Dymola and validated against test data from operation of a MW-scale ammonia heat pump. The system responses to sudden changes in the source and sink conditions, compressor speed, and liquid levels in the system were studied. The results from the validation showed that this dynamic model has great potential to be used for developing holistic control strategies and design guidelines in order to further improve the resilience and performance under fluctuating boundary conditions for large-scale heat pumps.

1. Introduction

Large-scale heat pumps are key components for the decarbonization of district heating and industrial heat supply. In line with the efforts to reduce greenhouse gas emissions from the heating sector, the number of installed large-scale and domestic heat pumps is increasing rapidly worldwide [1]. Large-scale heat pumps integrated with ambient heat sources or industrial processes may be required to operate under variable boundary conditions such as rapid changes in the sink or source temperature or flow. These may e.g. occur due to rapid changes in the outdoor air conditions for air-source heat pumps or due to variations related to the type of industrial process the heat pump is supplying heating (and cooling) to. If the systems is not designed to be able to handle such variations, the rapid change in boundary conditions may lead to unwanted dynamic effects, risking sub-optimal performance and component damages [2].

Designing large-scale heat pumps and the respective control systems to operate optimally under expectable and unforeseen variations in the boundary conditions requires studying the dynamic response of the system to such variations. This may be done using validated dynamic models of the system that are based on fundamental physics and thereby applicable to a broad range of operation conditions. Using models to test the dynamic response of the system to different variations in the boundary conditions is expected to reduce costs and time for testing and to reduce the risk of harming the experimental set-up if too extreme variations are tested. Such
models form the basis for tasks such as analysis of system behaviour, system design, model based control design, controller tuning and fault detection and diagnosis [3]. Li et al. provide an extensive overview of the common practices of dynamic modelling of HVAC systems [4-5]. These include component based modelling and the use of the object-oriented programming language Modelica [6] for the implementation, which has been shown to be a suitable approach [7].

This approach has previously been applied to large-scale ammonia heat pumps to assess the ability of large scale heat pumps to supply frequency regulation service to the electricity grid [8]. The same dynamic model was used to assess which components in a two-stage heat pump system have the largest influence on the time constant for changing the load in large-scale heat pumps [9]. Recent studies on large-scale heat pumps used dynamic models to optimize the controller set-points [10] and assess the influence of heat exchanger fouling [11].

The present study aimed to develop and validate a dynamic model for a MW-scale single-stage ammonia heat pump system using a screw compressor and flooded evaporator. The models were developed based on the underlying physics, fitted against design data of the individual components, and validated against measurement data. The available measurement data was obtained from experiments, in which different controller set-points were changed to excite the system. The model was used to analyze the dynamic response of the system to the changes in set-points such as compressors speed, receiver level, sink/source temperature and flow variations. The intended future use of the model is to use it for optimization of both the design and the control of similar large-scale systems to ensure optimal performance during rapidly changing boundary conditions.

2. Methods

2.1. Case description

Fig. 1 shows the overall heat pump cycle layout and control dependencies for the main components as well as the independent input parameters used in the model.

![Heat Pump System Diagram](image)

Fig. 1. Layout of heat pump system, including independent input parameters (written in green).

The heat pump consists of the following main components; screw compressor (C1), plate oil-cooler (HX6), plate condenser (HX3), liquid separators (R1 and R2), plate-and-shell sub-cooler (HX4), plate-and-shell economizer (HX5), plate evaporator (HX1), shell-and-tube superheater (HX2), and expansion valve (V4). The controllers modelled included:

- Receiver (R1) level controlled by main expansion valve (V4).
- Economizer (HX5) liquid level controlled by economizer valve (V3).
- Suction gas superheating (HX2) controlled by valve on the liquid side (V1).
- On/off control valve (V6) and differential pressure valve (V5) for economizer gas flow.
- Inlet temperature of oil to the compressor (C1) controlled by 3-way valve (V7).
To validate the dynamic model and compare it with the operating data from the heat pump, it was necessary to have identical boundary conditions between the model and measured data. For this, various independent parameters were used, which were variable inputs to the heat pump. In Fig. 1 these inputs are highlighted in green and consist of input temperatures and flows on the water side of the sub-cooler, oil-cooler, evaporator, as well as the compressor speed and capacity.

The dynamic model of the heat pump was developed in Dymola [12] with the component library TIL suite [13], based on the object-oriented language Modelica [14]. The basis of the dynamic system model was individual component models, which were first developed, tested, and validated against design data before the component models were assembled in the system model. Both the components and the system were modelled based on a finite volume method [15], consisting of mass, energy and momentum balances supplemented with semi-empirical correlations for describing the component characteristics. The process of preparing the validated dynamic model can be seen in Fig. 2. In step 1 (component modelling) the various component models were first developed by inserting relevant parameters for the available data, e.g. material type and geometry specifications for the heat exchangers. After this, other parameters such as e.g. the heat transfer coefficients and pressure loss coefficients were fitted against data available from standard calculations from e.g. manufacturer component design software, data sheets or experiments. In step 2 (system modelling) the component models were assembled in a system model and the control parameters were defined. Finally, in step 3 (validation) the model was validated by comparing the model results with measurement data from experiments with the heat pump system. The modelling process (step 1 to 3) was iterated where needed. Hence, independent datasets have been used for fitting (component design data) and validation (measurement data from experiments) to develop the final system model.

![Fig. 2. Illustration for the process in relation to the development of the dynamic model.](image)

Coefficients for the different component models from the TIL component library were fitted in relation to, for example, heat transfer, pressure loss, and friction to match the associated design points in the given component. Examples of the component modelling for the heat exchangers and the compressor are given in the following two sections.

### 2.2. Heat Exchangers

The heat pump consisted of six heat exchangers of different types and sizes. The three plate heat exchangers are standard components in the TIL suite component library, while the two plate-and-shell heat exchangers and the one shell-and-tube heat exchanger were modelled to be compatible with TIL suite. For all the heat exchangers, the geometry was known, and the models were based on this information. All the heat exchangers were fitted in relation to a series of different design conditions and compared with the heat transfer rate (HTR), outlet temperatures and pressure drops using TLK’s Modelfitter tool [16]. In addition, pressure loss correlations based on [16,17,18] were used. The fitting procedure used for the evaporator is used as an example of the fitting process.

The model of the evaporator which is a large plate heat exchanger was discretized into 10 cells on the water and ammonia side, respectively. On the water side, a constant heat transfer coefficient was fitted, while on the ammonia side, a heat transfer model was used [20] which was subsequently fitted with a correction factor and a reference heat transfer coefficient. To compare and fit the model against the component design data, a virtual test bench of the component model in Dymola was converted according to the Functional Mock-up Interface standard [21], see Fig. 3, and fitted in TLK’s Modelfitter tool. Here, different various independent parameters (input parameters) for the component were inserted and the dependent parameters for the model and design data were compared. For the heat exchanger, five independent parameters were used: enthalpy, mass flow, and pressure of ammonia, and the flow and temperature of water, see Fig. 3.
Fig. 3. Content of Functional Mock-up Unit for virtual test bench for model of evaporator plate heat exchanger.

Fig. 4 shows three different dependent parameters for nine different steady-state design points from the manufacturer component design software: heat transfer rate, water temperature out and pressure drop on the ammonia side. The difference between model and design points for the evaporator before and after the fit is shown, and it can be seen the R² score was satisfactorily high after fitting.

2.3. Screw Compressor

The model for the screw compressor was based on the compressor base classes from the TIL suite library [13], but some extra functionalities were added to the model in order for it to include the principles of the modelled heat pump. This included among other things an automatically regulating volume ratio within a predefined interval, a capacity slide valve control, and oil cooling. The model was divided in three volumes (inlet, outlet, and economizer volume) and for each volume dynamic mass and energy conservation equations were implemented. Fig. 5 shows how the different control volumes were connected to each other.
Fig. 5. Modelling of screw compressor with injection from economizer port (adapted from [22]).

The energy balance for the suction and discharge volume were influenced by $\dot{Q}_s$ and $\dot{Q}_d$, respectively. For the discharge volume, $\dot{Q}_d$ was calculated based on the friction power, $P_f$, which was a function of the compressor RPM, two empirical friction coefficients, and the torque. Furthermore, oil cooling ($\dot{Q}_{oil}$) was modeled and applied in the discharge volume only and thus also a part of $\dot{Q}_d$. The modeling of the oil cooling was based on a dynamic balance equation and formulated independently of the refrigerant volume. In this way, only heat was exchanged between the oil and the refrigerant. In addition, the liquid oil was assumed incompressible (simplified energy balances).

Several steady-state design data points from the compressor were used to fit the screw compressor, e.g. by varying the friction coefficients and cross-sectional areas for the valve areas determining the flow rates with the use of the Saint-Venant and Wantzel equation [23].

The automatic regulating volume ratio and the oil flow were determined using a polynomial fit based on steady-state design data of the screw compressor and were then used in the model to determine the volume ratio and the oil flow. The design data were generated for all combinations of evaporating temperatures in the range of 20 °C to 45 °C and condensing temperatures in the range 65 °C to 95 °C with a 5 °C resolution at 3600 RPM. Fig. 6 shows a comparison of the design data and the respective fits for oil flow and volume ratio. The oil flow polynomial fit was made as a function of the pressure difference, while the volume ratio polynomial fit was made as a function of the pressure ratio, compressor speed and suction pressure.

Fig. 6. Comparison of model and design data for a) normalized oil flow as function of normalized pressure difference and b) normalized volume ratio as function of normalized pressure ratio for the screw compressor.
As with the various heat exchangers, the screw compressor was fitted in relation to the design data based on a virtual test bench. The screw compressor model was fitted in relation to refrigerant flow, discharge temperature, and compressor power. The result before and after the fit can be seen in Fig. 7.

![Fig. 7. Refrigerant flow, discharge temperature, and compressor power for the model as a function of the design data.](image)

2.4. System modelling and validation

The heat pump system model was aggregated from the various modelled components and PI-controllers. The P and I gains for the different controllers were tuned by comparison with relevant test data from experiments with the heat pump system including controllers. The experiments were conducted in a controlled test environment with several pressure, temperature, flow rate, and level sensors installed. The media on the source and sink side was water, and the heat was exchanged between the source and sink side in a mixing loop.

To validate the behavior of the system model, the independent input parameters for the model (see Fig. 1) were varied based on three different experimental test cases. The cases defined were:

- Case 0: Test period with relatively stable operating conditions.
- Case 1: First dynamic operating case – variation of receiver level set-point.
- Case 2: Second dynamic operating case – with several simultaneous changes being made in the system at the same time, including gradual change of compressor speed as well as changing inlet water temperatures and flows.

The independent input parameters and results from the three validation cases, including further descriptions of the cases are described in the next section. The three cases were chosen because they illustrated a nuanced view of different operating conditions. Case 0 illustrates the steady state error for the various dependent parameters. Case 1 illustrated what happened when one parameter was changed. And finally, case 2 illustrated what happened to the heat pump when multiple changes were made at the same time. The sampling time for the data was 1 second and all three cases were tested without economizer.

3. Results

For the three cases the model was simulated 10,000 seconds before time = 0 s with the independent input parameters from time = 0 s as inputs. This made the results from the model stable before the input parameters from the data processing stated to change at time = 0 s. In a similar manner the tests of the heat pump were kept in steady state for a period before the start of the logging period.

3.1. Case 0: Stable operating conditions

Case 0 was the baseline case which aimed at verifying that energy- and mass balances for model and test data matched in a steady-state case. The case lasted for around 1300 seconds, and the defined independent input parameters can be seen in Fig. 8. From the figure it can be seen that the operating data for the water inlet temperatures to the evaporator (HX1), sub-cooler (HX4), and oil cooler (HX6), respectively, were relatively stable. The inlet temperature to the oil-cooler and sub-cooler were identical. In addition to this, the water flow and compressor were also relatively stable.
Fig. 8. Independent parameters for case 0 – stable operation.

Fig. 9 shows a log($p$)-$h$ diagram and a $T\dot{Q}$ diagram for case 0 at time = 0 s. The log($p$)-$h$ diagram shows the cycle process for both the model and measured data, respectively. The $T\dot{Q}$ diagram shows the normalized heat transfer rate (Norm. HTR) for the different heat exchangers on the water, ammonia, and oil side, in relation to the temperature levels. The heat transfer rate for the data was determined from an energy balance using flow and temperature sensors. The heat transfer rate for the oil cooler (HX6) was in parallel with the heat transfer rate from the sub-cooler and the condenser on the water side.

The temperatures and heat transfer rates were generally in good agreement between model and measured data for case 0. The difference between model and test data for selected values can be seen in Table 1.

Table 1. Difference between model and test data at time = 0 s for selected values.

The dynamic response of some of the key parameters for case 0 can be seen in Fig. 10. Here the discharge pressures (a), evaporation temperature (b), and the oil inlet temperature (c) are shown as a function of time. In this case there were no major differences between measured data and model. It can be seen that for all three parameters the model generally follows the data with an offset of approximately 0.5 bar for the discharge pressure, 0.7 K for the evaporating temperature and 0.1 K for the oil inlet temperature to the compressor (first 700 s).

Fig. 10. Dynamic response for a) discharge pressure, b) evaporating temperature, and c) oil temperature in case 0.

3.2. Case 1: Set-point change for the receiver level

Case 1 was a controlled dynamic test, where the system and hereby the independent parameters were kept in steady state until 412 seconds after the defined start of case 1, as seen in Fig. 11. At that time a single set point change of the high-pressure control valve was made, and the level in the receiver was lowered. The change of level was estimated to correspond to a 7.3 % change of the fraction for the liquid volume in the receiver from 54.5 % down to 47.2 % based on a level measurement in the cylindrical formed receiver with horizontal orientation. After the set-point change in the receiver the other input parameters for e.g. the compressor speed and secondary flows on the sink and source side continued to be almost the same.

Fig. 11. Independent input parameters for case 1 – change in receiver level.
Fig. 12 shows the influence and the dynamic response for the heat pump system with the change in receiver for both the test data and simulation results. In Fig. 12 (a) the filling level is shown, and it can be seen that for both the test data and the dynamic model the value for the filling level was within the neutral zone (±1 % of set-point with deactivated PI controller) for the controller before the set-point change. Immediately after the set-point change the level oscillates similarly outside the neutral zone for both the test data and the model before being within the neutral zone again around 150 seconds after the change. Inside the neutral zone the PI-controller in the model was creating a higher oscillating frequency compared to the test data.

Fig. 12. Comparison of dynamic response in case 1 between data and model for a) the filling level for R1, b) discharge pressure, c) normalized heat transfer rate for the condenser, d) suction temperature, e) temperature for water out of condenser, f) discharge temperature, and g) oil inlet temperature.

Fig. 12 further shows the discharge pressure (b), normalized heat transfer rate for the condenser (c), suction temperature (d), temperature for water outlet of condenser (e), discharge temperature (f), and oil inlet temperature (g) for the dynamic response in case 1. The control of the receiver liquid level has a considerable impact on the dynamic response in the system. The rapid decrease of the set point of the liquid level in R1 immediately caused a small pressure increase on the suction side and subsequently on the discharge side of the compressor. It can be seen that the dynamic response for the outlet pressure was a little slower for the model than for the test data, while the dynamic response for the water outlet temperature from the condenser was a bit faster for the model compared to the test data.

One of the challenges about the system model was to replicate the various controls in the heat pump. For example, the thermostatic valve (V7) in the oil circuit was relatively slow regulating in relation to the set point, which in this case was defined as 73.5 °C, see Fig. 12(g). In the model, this thermostatic valve was modeled with a PI regulator, which then had to reflect the measured data. Another control parameter was the high-pressure control of the liquid level in the receiver. The liquid level was controlled by a PI regulator which was active outside a neutral zone. In order to find the PI gains (proportional gain, k, and the time constant of the integrator block, T) that reflected the measured data, a parameter sweep was made to find the best combination. Fig. 13 shows some of the investigated PI gains. The parameters shown for the red curve were used for further work with the model. For this combination of PI gains, it was possible to control the level within the neutral zone before the set-point change, and it had the same characteristics for the overshoot immediately following the set-point change. In addition, a corresponding settlement time of around 150 seconds occurred before the level again was inside the neutral zone.
3.3. Case 2: Multiple simultaneous changes

Fig. 14 shows multiple dynamic variations of the independent input parameters for case 2. The graph on the left side shows the inlet temperatures to the evaporator and the sub-cooler which were similar to the inlet temperature for the oil-cooler. The graph on the right shows the water flows for the sub-cooler, evaporator, oil-cooler and the compressor speed, respectively. In this case the inlet water temperatures varied by 2 K to 3 K during the 2500 seconds of the case, and the water flows were increased as the compressor speed was gradually increased from 3060 RPM to 3580 RPM.

Although there were several different parameters that were changed at the same time, case 2 still gave a good indication of the ability for the model to predict the dynamic response of the heat pump. Fig. 15 shows the influence and dynamic response of the heat pump system with changes in RPM and inlet water temperatures for both the test data and simulation results.

Fig. 15(a) shows the discharge pressure as a function of time. In addition, the six times with an RPM increase as well as the water inlet temperature to the sub-cooler are highlighted. The model was able to predict a discharge pressure which captures the dynamic fluctuation from the water inlet temperature and changes in RPM. Fig. 15 also shows the dynamic response of normalized heat transfer rate for oil-cooler (b) and condenser (c) as well as the suction temperature (d), water outlet temperature (e) of the condenser, discharge temperature (f), and oil inlet temperature to the compressor (g). In general, there was a good correlation between dynamic patterns in the test data and the model. The model discharge pressure (a) was on average 0.56 bar higher at RPM below 3580, while the average difference at full speed was 0.25 bar. With each RPM change, the pressure level for the test data and the simulation changes. The new pressure levels of the measurements were achieved approximately twice as fast as in the model, but with the same pressure increase. The difference in the normalized heat transfer rate for oil cooling (b) and condensing (c) were on average 1.2 % and 0.7 % lower for the model compared to the measured data. The suction temperature (d) was on average 0.04 °C lower for the model. Here, however, there were a few sudden drops in measured data that the model did not capture. The modelled discharge temperature (d) was on average 2 °C above the measured data, however with a similar dynamic response. The modelled water outlet temperature of the condenser (f) and oil inlet temperature to the compressor were on average 0.2 °C and 0.3 °C above the measured data. For the temperature out of the condenser the dynamic response was similar between the data and simulated values, while for the oil inlet temperature dynamic response also was similar, however with smaller deviation occurring around 1500 seconds.
The dynamic response for the normalized heat transfer rate for the oil cooler was also similar between data and simulated values, however at full load there was an offset of approximately 1.1%.

4. Discussion

The validation of the results from the simulation model compared to the test data showed that the model was able to satisfactorily predict the dynamics seen during operation of the heat pump system. This would not be likely to be captured with only quasi-stationary models as also discussed in [24]. The offset difference between the experimental data and the model in relation to the steady state error can for example be attributed to small differences in the fitted parameters (design data in relation to experimental data), not modeled physical aspects, and/or measurement uncertainties. The difference for the dynamic aspects can for example be attributed to the PI controllers.

The validation showed the importance of suitable parameters used in the controllers. Especially the control of the expansion valve (V7) was sensitive for the system operation. In order to tune and validate the controllers further, more tests are suggested where set-point changes are introduced one at a time. These suggested tests including a test program with ramping the compressor speed up and down, on/off operation with the economizer, changing the capacity glider position, changing the sink and source side flow and temperature, while maintaining all other independent input parameters constant. Since there are several different PI-controllers with different PI-gains and neutral zones which simultaneously influencing each other, future structured tests will further show if additional changes to the PI-controllers in the model are necessary.

In some cases, the dynamic response for the simulation model showed shorter settling times with lower amplitude compared to the measured data. This might be due to neglecting pipe connections between the components and the corresponding heat- and pressure losses. If these connections were taken into account a minor contribution to the dynamic response for the model is expected, however it is also expected that the model will be numerically stiffer and has an accordingly higher computation time [8].

For case 1, in which a change of the liquid level in the receiver was imposed, another source of error could be due to a difference in the interpretation of the value of the experimental data for the height measurement in the horizontal receiver. The measured value in the test data was a relative height measurement, while the used filling level in Dymola was the fraction between the volume of liquid and the total volume. The conversion from the relative height measurement to the filling level was based on approximated values. In future work the exact position of the sensor will be investigated in order to precisely compare the receiver fluid level in the measurements and the simulation.

In some cases, the controllers in the physical heat pump use a varying proportional band depending on the difference between the desired set-point value and the actual value. If the error signal is large and outside the proportional band the controller ramps up quicker, while the controller is slower for low error signals. Further
studies are needed to investigate if this effect needs to be included in the model in order to further minimize errors between the dynamic model and the measured data.

In the present study, the heat pump was modeled without details of the components for the secondary streams, which determined the sink and source inlet water temperatures and flows. These were defined by the test setup, and then used as inputs to the model. This approach is suitable for validation of the heat pump system model. In future studies, it may be favorable to also include the modelling of pumps and valves on the secondary sides when investigating holistic control procedures to accommodate fast changes of external parameters.

Several design points have been used to fit the individual components in the system. For most of the parameters, it was possible to fit the design data very well to the individual components. There was, however, a little difference for the discharge temperature of the screw compressor. In order to make this temperature more accurate, further work can be done to incorporate the oil cooling in the model in more detail.

By making a detailed dynamic model and validating the system in different operating conditions, it was possible to get a thoroughly validated model, which then can be used for more in-depth analyses for many different operating conditions. By having a validated model, these analyses can be done much faster compared to full scale testing of the heat pump system in the laboratory. Hence, the presented validated model in this study allows for relatively quick investigation of different control approaches and development of design guidelines in order to be used as a general development tool for large-scale ammonia heat pumps.

5. Conclusion

A dynamic model of a large-scale one-stage ammonia heat pump with a screw compressor and different types of heat exchangers was implemented in Dymola. The model was validated with three different cases: a case with stable operating conditions, a case with a single set-point change for the receiver level, and a case with multiple simultaneous changes. The validation showed a satisfying agreement between the measured data and the model, both in relation to the offset errors and the dynamic response.

The dynamic model was developed by systematically modelling each individual component in the heat pump system, and fitting it mainly against the component design data, before finally combining the components into an overall system model. The different controllers were set up to match the dynamic response for the measured data in order to be able to validate the system model. The various dynamic responses in the model compared to the measured data were highly dependent on the used gains for the PI controllers, but through parameter sweeps of the PI gains it was possible to find values that led to satisfying agreement between the measured data and the model.

Case 0 showed that the model overall in a steady state scenario performed similar to the performance for the measured data. In case 1 the liquid level in the receiver was changed which subsequently led to a change in pressure for the heat pump system which the model captures. For case 1 it was further shown that the dynamic response overall was in good agreement for all the individual components, however also that for a few components small time differences in the dynamic response were observed, which can be refined in future work. Finally, case 2 showed that model and measured data agree well for changes in the temperatures on the sink and source side as well as for fast changes of the compressor speed.

The results from the validation showed that this dynamic system model has great potential to be used for developing holistic control strategies and design guidelines in order to further improve the resilience and performance under fluctuating boundary conditions for large-scale heat pumps.

Abstract

A detailed methodology is proposed to design and optimise the operation of a ground-source heat pump (GSHP) coupled to a phase-change material (PCM) thermal battery. The objective is to minimise the cost of supplying space heating and hot water to a medium-demand house in the UK during a typical winter day with fluctuating electricity prices. A bespoke 8-kW GSHP is designed and used to optimise the charging schedule of the thermal battery to minimise daily operational costs while meeting the heat demand. If no limit is imposed on the size of the thermal battery, in the best scenario, a 41-kWh thermal battery is required to achieve costs as low as 1.85 £/day. However, large PCM batteries mean high upfront costs and little space restrictions. Therefore, a constraint is imposed on the thermal store capacity to identify the optimal trade-off that can be achieved between PCM battery size and daily power consumption costs. Operational costs strongly depend on the battery size, increasing from 1.85 £/day for a 41-kWh thermal battery to 3.50 £/day for a 6.3-kWh store.

1. Introduction

Delivering near- and long-term international environmental objectives likely requires significant changes in the way heat is supplied to residential buildings [1]. The ambition to phase out the installation of new natural gas boilers in many countries implies remarkable infrastructural and regulatory changes in the upcoming years [2, 3]. Electricity-driven vapour-compression heat pumps are a proven technology [4] associated with a considerably better thermodynamic performance than gas boilers [5]. Although they are widely recognised as a sustainable alternative to conventional heating systems, the share of heat pumps in the market remains low in most countries [6]. This is mainly due to the high investment cost required [7], the high price of electricity when compared to that of natural gas [8] and the low uptake of control mechanisms that can be used to heat homes in a smart and flexible way [9].

Vapour-compression heat pumps involve many possible design options and heat sources [10]. Common types are air-source heat pumps (ASHPs) and ground-source heat pumps (GSHPs). The former uses ambient air as low-temperature heat source, while the latter draws heat from the ground. GSHPs require heat collector tubes to be buried underground. Therefore, they are associated with higher installation costs than ASHPs [4]. However, since the temperature of the ground experiences smaller fluctuations throughout a year compared to the ambient air, GSHPs can often be operated more efficiently on average than ASHPs. Especially in winter, when the demand for domestic hot water (DHW) and space heating (SH) is the highest, GSHPs typically show superior performance.

The cost competitiveness of vapour-compression heat pumps can be potentially improved by using thermal energy stores (TES) in conjunction with smart control strategies [11-16]. TES can be used to decouple demand and supply. Smart controllers can shift some of the electricity consumption from high- to low-electricity-price periods, leading to notable economic savings for homeowners while at the same time benefiting the wider energy system by providing demand-side flexibility [11].

As countries progress in decarbonising their electricity sector, the capacity of intermittent renewable generation sources is increasing significantly in many systems, while firm generation capacity from, e.g., coal- and gas-fired power plants is decreasing. Therefore, it is widely recognised that the value of demand flexibility is ever increasing. The UK aims to install 600,000 heat pumps per year from 2028 and up to 1.7 million heat pumps per year from 2035 [12], for a total of 7 to 11 million heat pumps in 2035 [13]. These heat pumps, if used with conventional controllers, will significantly add to peak electricity demands. However, if coupled with TES and smart controllers, they can potentially provide significant demand flexibility.

Sensible-heat storage in the form of hot-water cylinders is currently the most widely used TES method in residential applications, as it is cheap and safe. However, latent-heat storage systems based on phase-change materials (PCMs) have experienced significant development and have recently entered the market for residential applications [14]. The main advantages of PCM-TES compared to hot-water cylinders are the potential for higher energy densities and the fact that they can work within smaller temperature ranges. This results in potentially lower required hot-water delivery temperatures and thus higher heat pump system efficiencies.

Most of the recent literature on smart operation of domestic heat pumps has focused on ASHPs. Several studies have examined the potential of shifting the operation of heat pumps from high- to low-electricity-price periods. Some of these studies concluded that a very large TES volume can prove beneficial for homeowners. For example, in the work of Arteconi et al. [15] a 500-L hot-water cylinder was shown to minimise the electricity consumption of an ASHP during high-electricity-price afternoon hours in Northern Ireland. Le et al. [16], also focusing on Northern Ireland, showed that hot-water cylinders with volumes in the range of 600 to 1100 L are optimal, depending on the investigated scenario. Furthermore, Kelly et al. [17] concluded that a 1000-L hot-water cylinder or a 500-L PCM thermal store would be required to shift ASHP operation to off-peak periods for a typical UK household. However, since TESs are typically installed within the internal space of houses, such storage volumes are not viable for many households that have limited space.

In addition to the aforementioned studies, Renaldi et al. [18] predicted that smart ASHP operation in a London house can lead to slightly reduced operational cost (by 6%) compared to a gas boiler. Fischer et al. [19] concluded that the use of model predictive control can reduce operating costs for a multi-family home in Germany by more than 10% compared to simple rule-based control methods. In their most recent work, Olympios et al. [20] identified that the operational optimisation of an ASHP for a single-family dwelling in the UK and Germany can lead to operational cost savings higher than 20% compared to simple heat pump control mechanisms based on temperature sensors. In that work, price and demand forecasts were assumed to be known with perfect accuracy.

Less effort has been devoted to optimising the operation of integrated thermal energy storage ground-source heat pump (GSHP-TES) systems. Salpakari et al. [21] studied cost-optimal and rule-based control strategies for buildings with a PV system, a GSHP, a hot-water cylinder, electrical storage and shiftable loads. They showed that, for a low-energy house in Finland, cost-optimal control can lead to 13–25% savings in the yearly electricity bill compared to an inflexible reference control strategy. Yang et al. [22] proposed operation strategies of a hybrid GSHP system with double-cooling towers for a hotel building, but results are not applicable to domestic buildings. Kaiggaard et al. [23] estimated that economical savings achieved by time-shifting the operation of a GSHP heat pump in a typical Danish house can by up to 12%. However, none of the studies focusing on GSHPs considered PCM-TES.

In this work, the operation of an GSHP-TES is optimised for a typical UK household. The novelty lies not only in the development of comprehensive thermodynamic models and their use to perform an operational optimisation of a GSHP system integrated with a PCM-TES for domestic applications, but also in the identification of the optimal trade-off that can be achieved between PCM battery size and daily power costs. The developed heat pump and TES models, as well as the description of the optimisation framework, are presented in Section 2. The results and conclusions are provided in Sections 3 and 4, respectively.

2. Design and operational optimisation of an integrated thermal store ground-source heat pump

An optimisation framework has been developed in-house based on comprehensive first-law thermodynamic and component-costing models with a view to perform simultaneous design and operational optimisation of domestic ground-source heat pumps with integrated thermal energy storage (GSHP-TES). In this paper, we
present a preliminary study aimed at optimising the charging schedule of a phase-change material (PCM) thermal store coupled with a ground-source heat pump to supply both space heating and domestic hot water demands during a typical winter day for a medium-demand house in the UK, as detailed in Figure 1.

![Schematic of a domestic ground-source heat pump with integrated latent-heat thermal energy storage.](Image)

**Fig. 1** - Schematic of a domestic ground-source heat pump with integrated latent-heat thermal energy storage.

Heat demand profiles and time-varying electricity prices used for this case study are presented in Section 2.1. The heat pump is first designed for a set heating capacity and prescribed pinch-point constraints for both condenser and evaporator units, as detailed in Section 2.2, while a simplified model is used to predict the PCM thermal battery performance, as detailed in Section 2.3. The charging schedule of the PCM thermal battery is then optimised for various thermal store sizes (ranging from 7 to 60 kWh), as detailed in Section 2.4.

### 2.1. Case study definition

This study is performed using the hourly heat demand profile of a typical UK household in a typical year. The typical household was identified by applying a kmedoids clustering algorithm to the Cambridge Housing Model dataset [24], which contains a representation of the UK building stock. Since the model only provides annual demand values for SH and DHW, the method developed by Watson et al. [25] was used to determine the hourly SH demand based on the ambient temperature, while the daily DHW demand profile was taken from Herrando et al. [26]. To eliminate any potential bias from choosing a specific year, the weather data was taken from a typical meteorological year, provided by the PVGIS tool [27].

Time-varying electricity tariffs offer end-users an opportunity to shift their electricity usage to low-price periods, which can be achieved with adequate-size thermal batteries coupled to heat pump units. In the current study, we selected the Octopus Agile tariff, which exhibits a high-price period between 4 and 7 pm [28].

Both hourly-defined electricity price and aggregated heat demand profiles for a typical winter day for a medium-demand house in the UK, presented in Figure 2, are used for this study.
2.2. Ground-source heat pump (GSHP) design

The GSHP used to supply both space heating and DHW demands is a standard electricity-driven vapour-compression heat pump (VCHP) made of 4 main components, namely: a compressor, a condenser, an expansion valve, and an evaporator, as shown in Figure 3, operated with R32 as a working fluid, which exhibits a relatively low 100-year global warming potential of 675, as found in the IPCC 4th Assessment Report.

The GSHP is designed to extract heat from a ground-source water stream entering the evaporator unit at a constant $T_g = 12 \, ^\circ\text{C}$ and rejecting heat at $T_h = 60 \, ^\circ\text{C}$, with imposed 5-K pinch-point temperature difference in both the condenser and evaporator units. The return temperature from the PCM thermal store is determined from a heat balance as a function of both the PCM melting temperature, $T_m = 48 \, ^\circ\text{C}$, and the water-to-store heat transfer effectiveness ($\varepsilon = 0.8$), as detailed in Section 2.3. In addition, the compressor is assumed to have a 60-% isentropic efficiency and the expansion valve is set to maintain a constant 6-K superheat at the compressor suction. The working fluid equilibrium and transport properties are obtained using the open-source thermophysical property library Coolprop [29].

The thermodynamic performance of the VCHP unit is assessed with a comprehensive first-law thermodynamic model based on a set of widely accepted assumptions:

- No pressure losses in pipes
- No heat losses
- Zero subcooling at the condenser outlet (which can be achieved with a liquid receiver)
- Dynamic effects are neglected (i.e., cycle assumed to operate under steady conditions)
- Counter-current heat exchangers

![Fig. 3 - Schematic of the domestic vapour-compression heat pump (VCHP) design.](image)
The VCHP cycle and the corresponding performance can then be determined by the condensing pressure, \( P_{\text{cond}} \), and evaporating pressure, \( P_{\text{evap}} \). With the zero-subcooling assumption at the condenser outlet, the thermodynamic state of the working fluid state in point ‘2’ – as defined in Figure 3 – is fully defined and both equilibrium and transport properties are calculated using Coolprop. The saturated liquid leaving the condenser then undergoes an isenthalpic throttling through the expansion valve, which allows us to calculate the vapour quality and properties of the two-phase mixture resulting from the Joule-Thompson expansion, thus fully defining state ‘3’. State ‘4’ is also fully defined from the evaporating pressure, \( P_{\text{evap}} \), and the prescribed 6-K superheat at the evaporator outlet. The compressor discharge (state ‘1’) is obtained from the assumed 60-\% compressor isentropic efficiency, which accounts for various loss mechanisms, including: pressure losses through the intake and exhaust valves, mass leakage through the piston ring and heat transfer.

Finally, both evaporating and condensing pressures are optimised to minimise the power consumption, \( W_c \), to provide a given heating capacity, \( Q_h \), while respecting pinch-point constraints in the condenser and evaporator units. This non-linear problem is solved using the sequential least squares programming (SLSQP) implemented in the Python open-source SciPy library [30]. The coefficient of performance (COP), denoted \( \varphi \), is then defined as the ratio of the heating power to the power input: \( \varphi = Q_h / W_c \).

The design of evaporator and condenser units is then determined using spatially resolved models. Brazed-plate heat exchangers (BPHXs) are used for both units as they offer compact and efficient designs for both water-cooled condensers and water-source evaporators. Heat exchanger units are discretised in equal enthalpy-step nodes and the conjugate heat transfer through the heat exchanger plates are solved for each element to determine the overall required area. Single-phase convective heat transfer is predicted using Bogaert & Boles correlation [31], which is also used to predict the convective-boiling contribution to the heat transfer in the two-phase region of the evaporator unit, while the pool-boiling contribution is estimated with Cooper’s correlation [32]. The fluid-to-wall heat transfer in the two-phase region of the condenser unit is predicted using the model proposed by Thonon & Bontemps [33]. No further detail is provided on these models nor is the choice of these correlations further discussed here, as this study focuses on the operational optimisation of GSHP-TESSs and on the trade-off between the thermal battery size (or capacity) and the daily operational costs. However, interested readers may refer to recent publications where these models are presented in more detail [5, 34]. The following research questions will be addressed in future studies: (i) whether high-spec high-cost heat pumps perform better than low-spec low-cost ones from an economic point of view; or (ii) whether a large heat pump coupled with a small thermal battery outperform a small heat pump with large thermal stores.

For stated assumptions and component performance indicators, an 8-kW heat pump has been designed, and the corresponding geometry and performance characteristics are detailed in Table 1. The stated performance matches that of real-world ground-source heat pump systems, the price and performance of which are detailed in the online technology library proposed by Olympios et al. [35].

Table 1. Detailed characteristics of an 8-kW heat pump (with R32) designed to extract heat from a water stream at \( T_p = 12 \degree \text{C} \) and rejecting heat at \( T_c = 60 \degree \text{C} \), with imposed 5-K pinch-point temperature difference in both the condenser and evaporator units.

2.3. PCM thermal battery design and performance

The latent-heat thermal battery proposed for domestic applications is based on an existing phase-change material, namely the PCM-A48 from PCM Products Ltd., which has a melting temperature $T_m = 48^\circ C$, which is deemed adequate for the mid-size dwelling selected for this investigation and for modern radiators. Further details on the selected PCM are provided in Table 2. Underfloor heating installations with proper insulation would require lower melting temperatures, which would obviously benefit the thermodynamic performance of the heat pump by reducing the source-to-sink temperature lift and using the building thermal mass as an additional thermal storage medium, which is though beyond the scope of this study.

Heat transfer to and from the latent-heat thermal battery is represented using a simple fixed-effectiveness method ($\varepsilon = 0.8$), from which the return temperature to the heat pump unit, $T_{h,r}$, is calculated:

$$T_{h,r} = T_h - \varepsilon(T_h - T_m).$$  \hspace{1cm} (1)

2.4. PCM thermal battery charging schedule optimisation

The charging schedule is defined as a set of on/off times spanned throughout the day to decide when and for how long the heat pump is turned on to charge the thermal battery. Instead of allowing an unlimited number of charges a day, which would be highly computationally expensive, we decided to impose and increase the number of charges a day incrementally until no further improvement is noticed. The optimisation exercise then boils down to decide, for a given number of charges a day, when and for how long should each charge occur to minimise the daily operational expenditure (OPEX). A couple of constraints have been imposed to ensure feasibility and control the size of the thermal battery: (i) the heat demand must always be met; and (ii) the storage capacity of the thermal battery cannot exceed a prescribed value. The latter constraint is first lifted to measure the maximum savings that can be achieved through smart control of the thermal battery charging schedule (results in Section 3.1), while a range of constrained battery sizes are imposed to identify the optimal trade-off between the thermal battery capacity and the daily operational costs (see Section 3.2).

This optimisation problem was formulated in the Python open-source SciPy library [30] and solved using a differential evolution algorithm, which consists of iteratively improving a population of candidate solutions.

3. Results

3.1. Optimised charging schedules without constraint on the thermal battery size

The charging schedule of an unlimited-size thermal battery is first optimised using the 8-kW heat pump designed in Section 2.2. The results are presented in Figure 4, where the optimum charging profiles are shown for 1-to-4 charges per day along the heat demand and electricity prices throughout the typical winter day selected for this investigation, while the associated daily operational costs (i.e., electricity consumption costs) are detailed in Table 3 along with the required battery size for each scenario.

It appears clearly that, for each scenario, low-price periods are favoured to charge the thermal battery, while the peak-price period is avoided. Increasing the number of charges does lead to significant additional savings, with the daily OPEX reducing from 2.01 £/day for a single charge to 1.85 £/day for 3 or more charges per day. It is worth noting that, although the 3-charge-a-day charging schedule differs from that of the 4-charge-a-day scenario, as shown in Figure 4, similar daily costs are achieved. The battery required to achieve the former schedule (46 kWh) is however larger than that needed to deliver the heat demand following the 4-charge-a-day schedule (41 kWh). Increasing the number of charges per day is thus needed to identify a better trade-off between battery size and daily costs, which is explored further in the next section.

Finally, for the unlimited-size battery optimisation exercise, no improvement is noticed when further increasing the number of charges per day.

Corresponding daily operational and required battery sizes are detailed in Table 3.

3.2. Multi-objective optimisation: trade-off between thermal battery size and daily OPEX

Increasing the thermal storage capacity comes at a cost. First, from an economic standpoint, upfront costs for a large-scale thermal battery are very significant, as the specific cost of PCM batteries typically ranges from 200 to 400 £/kWh. Second, space restrictions are to be considered and several end-users simply will not have enough space to fit large-capacity thermal batteries. Therefore, a multi-objective optimisation has been conducted, whereby a constraint is imposed on the thermal store capacity to measure how the potential savings are impacted and identify the optimal trade-off that can be achieved between PCM battery size and daily costs.

The results of this investigation are presented in Figure 5, where the daily operational costs are plotted against required thermal store capacity for a range of optimised charging schedules. These results have been obtained by varying the number of charges per day and the constraint imposed on the battery size to explore the design/operational space. This allows us to identify the optimal trade-off, which is given by the Pareto
frontier plotted in Figure 5. This curve provides the end-user or installer with a direct relationship between how much savings can be expected by fitting a larger thermal battery.

As expected, higher daily power costs are to be paid with smaller thermal stores. The fact that the evening peak demand coincides with the peak electricity prices, as shown in Figures 2 and 4, explains why operational costs so strongly depend on the battery size, with daily OPEX increasing from 1.85 £/day for a 41-kWh thermal battery to 3.5 £/day for a 6.3-kWh thermal store. Indeed, it becomes impossible to avoid charging the battery during the peak-demand/peak-price period with smaller thermal batteries.

Fig. 5 - Daily operational costs (OPEX) plotted against required thermal store capacity and associated Pareto frontier. Each point corresponds to an optimised charging schedule with specific number of charges per day and constraint on the battery size.

4. Conclusions

Quantifying the savings in the yearly electricity bill that can be achieved through smart control strategies of heat pumps integrated with thermal energy storage is key to promote the uptake of clean heating technologies and help heat decarbonisation. In this paper, a detailed methodology is proposed to design and optimise the operation of a ground-source heat pump (GSHP) coupled to a phase-change material (PCM) thermal battery. The objective is to minimise costs of supplying both space heating and hot water to a medium-demand house in the UK during a typical winter day with fluctuating electricity prices.

Time-varying electricity tariffs offer end-users an opportunity to shift their electricity usage to low-price periods, which can be achieved with adequate-size thermal batteries coupled to the heat pump unit. After designing a dedicated 8-kW GSHP fitted with brazed-plate heat exchangers, charging schedules of the thermal battery have been optimised to minimise daily operational costs (OPEX) while meeting the heat demand.

First, no limit was imposed on the size of the thermal battery. By increasing the number of charges allowed per day from 1 to 5, it was found that increasing the number of charges does lead to cost savings, with the daily OPEX reducing from 2.01 £/day for a single charge to 1.85 £/day for 3 or more charges per day. In the best scenario, a 41-kWh thermal battery is required to achieve costs as low as 1.85 £/day.

However, large-scale thermal stores are costly. First, from an economic standpoint, as higher upfront costs are to be paid for larger thermal batteries. Second, space restrictions are to be considered and several end-users do not have enough space to fit large-capacity thermal batteries. Therefore, a multi-objective optimisation has been conducted, whereby a constraint is imposed on the thermal store capacity to measure how the potential savings are impacted and identify the optimal trade-off that can be achieved between PCM battery size and daily power costs. As expected, higher daily power costs are to be paid with smaller thermal stores. Operational costs strongly depend on the battery size, with daily OPEX increasing from 1.85 £/day for a 41-kWh thermal battery to 3.50 £/day for a 6.3-kWh thermal store. This is largely due to the concomitance of the evening peak heat demand and peak electricity prices as it becomes impossible to avoid charging the battery during the peak-demand/peak-price period with smaller thermal batteries.

Three main research pathways are being explored to extend the findings of this investigation.
• Simultaneous design and operational optimisation are being performed, whereby the size and performance of the heat pump system will be optimised along with yearly charging schedules to minimise the levelised cost of heat using ground-source energy systems.

• The assumption made in the current study to impose a constant return temperature from the underground borehole heat exchanger, although acceptable for a daily performance estimation, is no longer valid for yearly operation. A collaboration with a geotechnics research team is currently ongoing to address this limitation and determine year-round temperature variations associated with heat dissipation and accumulation in the ground.

• The omniscient point of view taken in the current study provides us with an upper bound for potential savings through smart control of the thermal battery charging schedule. At best, a real-life smart meter can be fed with inaccurate electricity prices, weather, and heat demand forecasts, which will lead to sub-optimal charging schedules as compared to those presented in this paper. We are currently investigating how close a smart-meter control strategy can approach this upper bound and what & how many data are needed. In other words, how smart does a smart meter need to be?

Abstract

Under the background of carbon neutrality, efficient and low-carbon space heating in distributed areas away from the centralized network is a meaningful topic. In this paper, a gas-fired absorption heat pump was built and tested during winter in Langfang, a city near Beijing. The unit was driven by direct combustion of natural gas, and recovered low-grade heat from the ambient air. In order to increase the energy utilization ratio, solution preheating and intermediate evaporation was introduced. In order to enhance the internal heat recovery under low ambient temperatures, intermediate absorption was adopted. The measured performance showed that the outlet temperature of exhaust gas was lower than 35°C, indicating that both the sensible and latent heat were fully recovered. The average daily primary energy efficiency was over 1.58 and heating capacity was 30 kW, at the ambient temperature of -1.2°C, when supplying 45°C hot water for space heating. It was proven that the designed unit has great application potential in cold winter areas away from the centralized heating network.

Keywords: absorption heat pump; performance analysis; natural gas; distributed heating; exhaust heat recovery

1. Introduction

Under the background of carbon neutrality, the reduction in fossil fuel usage and greenhouse gas emission are urgent and inevitable issues. Over 30% of the worldwide carbon emission is contributed by energy consumption in buildings [1]. Energy consumption for building space heating and cooling accounts for 58% and 41% in the urban and rural areas of China [2]. On the other hand, with the improvement of living standards and the advancement of urbanization in developing countries represented by China, the building area and energy consumption will be further increased [3]. Improving the space heating systems is of vital importance for energy conservation and carbon emission re-duction, and to some extent, is an important step towards achieving carbon neutrality.

In general, space heating can be realized by centralized networks in urban areas. Whereas, the huge initial capital cost for the network construction and the thermal losses along the pipe lines make centralized networks unaffordable in rural areas with low population density [4,5]. In terms of heating methods in areas away from the centralized networks, the wall-mounted gas furnace (GF) [6] and the compression heat pump (CHP) [7] are usually applied. The GF is low-efficient with primary energy efficiency (PEE) lower than 1. Even though the coefficient of performance (COP) of the electrically driven CHP can reach 3 [8], the PEE is still low since thermal power generation with 30-35% efficiency is the major way to generate electricity worldwide [9]. Even worse, these methods of separate heating greatly increase the initial investment of the consumers, and have more carbon emissions during production and operation.

As a result, the decentralized or house-central heating system for areas away from the centralized network has attracted wide attention. The absorption heat pump (AHP) can utilize different kinds of heat sources and provide heating with wide temperature range. For a single-stage system, its heating temperature ranges from...
40°C to nearly 80°C, fitting for the heating demands of most occasions. It should be noted that the absorption system needs two kinds of heat sources: one is high-grade driving heat utilized in the generator, and the other is low-grade heat harvested in the evaporator. For a single-stage absorption system using LiBr-H2O or NH3-H2O as the working fluids, the generation temperature is in the range of 75-170°C [10], which can be easily achieved by natural gas combustion.

Compared with other systems including the GF and CHP, the AHP for district heating has the superiority of high PEE that can reach up to 1.3, due to the ability of utilizing additional low-grade heat through the evaporator. Zhang et al. [11] studied a hot water driven ground-source AHP for the district heating. They showed that the energy utilization efficiency was improved and the power consumption was reduced significantly, compared with those from the electrically-driven heat pump. Moreover, Wu et al. [12] studied a water-source AHP for the low temperature heating. The measured COP was 1.2 when the temperatures of the evaporator inlet, generator inlet and hot water outlet were set to -10°C, 130°C and 45°C, respectively. Moreover, the system could operate at the evaporator inlet temperatures of -18°C. Garrabrant et al. [13] studied a gas-fired NH3-H2O AHP, and the COP was 1.63 when producing 45 °C hot water under the ambient temperature of 20°C. Keinath et al. [14] investigated a gas-fired NH3-H2O AHP. The system achieved a COP of 1.74 when the ambient and water inlet temperatures were 20°C and 32°C, respectively.

The above-mentioned studies were all based on the single-effect system, which means the driving heat only triggered one generation process. Actually, the AHP systems were studied extensively aiming to find out the most suitable system configuration for the residential applications and district heating. Wu et al. [15] reviewed various heating methods based on the AHP technology, and discussed their application and development in different fields. Philip et al. [16] investigated six different configurations, including double-effect, absorber augmented, double-effect regenerated, and generator-absorber heat exchange (GAX), and found that the optimal one is the GAX configuration. Kang et al. [17,18] studied the hybrid GAX system, where a compressor was added between the generator and the condenser to increase the heating temperature of the con-denser. Results showed that the absorber could provide 47°C hot water for district heating, and the condenser could provide hot water up to 100°C for other purposes. However, the GAX system was not suitable for cold regions, because as the ambient temperature decreases, the temperature overlaps between the generator and the absorber decreased or even disappeared, Garimella et al. [19] simulated a GAX system, and found that for the ambient temperature of 5.6°C, the COP reached up to 1.4, while when the ambient temperature decreases to -30°C, the COP reduces sharply to 1.05. In order to improve the performance in cold regions, a double-stage [20] and a compression-assisted [21] AHP were developed.

In this paper, a gas-fired absorption heat pump was built and tested during winter in Langfang, a city near Beijing. The unit was driven by natural gas direct combustion, and recover low-grade heat from the ambient air. In order to increase the energy utilization ratio, solution preheating and intermediate evaporation was introduced. In order to enhance the internal heat recovery under low ambient temperatures, intermediate absorption was adopted.

2. System description

2.1. System Configuration

The schematic diagram of the gas-fired AHP system is shown in Figure 1. The system consists of four branches including the gas, water, solution and refrigerant branch, which are illustrated by the orange, blue, purple and green lines, respectively. Moreover, state points in the four branches are presented as G, W, S and R, separately. For example, W1 presents the return water state point, while G4 presents the flue gas outlet state point.

For the gas branch, the mixture of the natural gas and oxidizing air G1 enters the combustor, and the combustion heat is delivered to the generator. The high temperature flue gas G2 enters the solution preheater, heats the strong solution S1 flowing to the generator, and the temperature is reduced to a medium value. Then the medium temperature flue gas G3 enters the intermediate evaporator and the temperature is further reduced, and finally it is discharged to the ambient.

For the water branch, the return water W1 passes through the condenser, rectifier and absorber subsequently and absorbs the heat generated by each component. The water temperature increases gradually and the supply water W4 is supplied to hot consumers.

For the solution branch, the strong solution S1 is preheated by the flue gas, and after mixing with the reflux solution S0 from the rectifier, enters the generator and flows downward. The strong solution is first heated by
the generated weak solution S2, and generates part of the ammonia vapor. Then the solution is further heated by the gas combustion, and generates large amounts of ammonia vapor. In the meantime, mass transfer occurs between the solution and the vapor, along the packing. The generated weak solution S2 returns back to the generator to undergo the internal heat recovery process, hence its temperature decreases. After the expansion process, the weak solution S4 flows through the intermediate absorber and the absorber, and absorbs the ammonia vapor from the intermediate evaporator and the evaporator respectively. Finally, it turns to the strong solution S7, flowing to the solution tank. After pressurizing by the solution pump, the strong solution S8 enters the intermediate absorber to recover the absorption heat, and then it is further heated by the high temperature flue gas in the solution preheater.

For the refrigerant branch, the ammonia vapor R0 from the generator enters the rectifier. It is partially condensed to the reflux S0, while the remaining enters the condenser and is condensed to the liquid ammonia R2. After the subcooling and expansion process-es, the ammonia refrigerant enters the intermediate evaporator, recovers the waste heat of low temperature flue gas and is partially evaporated. The vapor-liquid mixture R5 enters the separator, where the vapor and liquid are separated. The vapor part R6 enters the intermediate absorber and is absorbed by the weak solution, while the liquid part R7 goes throttling and then enters the evaporator, where it absorbs heat from the ambient and is evaporated completely. After evaporation, the ammonia vapor R9 is superheated in the sub-cooler, and then enters the absorber and is absorbed by the solution.

Except for the above four branches, there exits another branch for defrosting, which is presented with the dotted purple lines in Figure 1. During the defrosting process, the de-frosting valve is opened and part of the intermediate solution S5 enters the evaporator directly, where it absorbs the ammonia refrigerant R8 and releases absorption heat for de-frosting. During this process, the system still operates, however the heating capacity is reduced. The larger the opening of the defrosting valve, the faster the defrosting speed, while the lower the heating capacity.

The main differences between the proposed system and the conventional system are shown in Fig. 2. The P-T diagrams were drawn under the basic working condition of -20°C evaporation temperature and 180°C generation temperature. The main innovation lies in the introduction of the intermediate evaporation and absorption processes. The ammonia condensate from the condenser was firstly throttled to intermediate pressure, and recovered waste heat from the flue gas. In this process, both the sensible and latent heat could be totally recovered by adjusting the intermediate pressure. Furthermore, the ammonia vapor, partially evaporated from the intermediate evaporator, entered the intermediate absorber, and the intermediate absorption heat was used to carry on internal heat recovery.

![Fig. 1. Schematic diagram of the proposed gas-fired AHP system.](image-url)
2.2. AHP unit

The 3D diagram and the photo of the gas-fired AHP unit with 30 kW heating capacity are shown in Figure 3. The unit had a compact design, with the dimension of 1360*1360*2260mm (L*W*H). The built AHP unit was expected to provide space heating for 3-4 families in the north of China in winter. Ammonia-water compare was used as the working fluid, considering that the system operated at low ambient temperatures. Natural gas was burned inside the unit as the driving heat source, and the evaporator could also harvest low-grade heat from the ambient air.

Details of the heat-exchange components of the gas-fired AHP unit are shown in Table 1. The absorber was the shell-and-tube heat exchanger, while the condenser, sub-cooler and intermediate absorber adopted the tube-in-tube type. For the evaporator, intermediate evaporator and solution preheater, plate-fin heat exchangers were used. For the gas-fired generator, its structure is shown in Figure 4. Natural gas and air entered the combustion chamber at the bottom, where the natural gas was burned. The combustion heat was delivered to the ammonia-water solution through the solution jacket, which could also prevent the chamber wall from overheating. High-temperature flue gas from the combustion chamber raised through the gas pipeline, delivering heat to the solution flowing downward along the outer wall of the pipes. In order to enhance the heat and mass transfer inside the generator, the embossed threaded pipes and θ-ring packings were adopted.

Fig. 4. Structure of the gas-fired generator.

3. Methods

Based on the AHP unit, system performance under typical heating conditions was investigated through the environmental tests in Langfang, a city near Beijing. The unit was designed in accordance with the worst operating conditions according to the preliminary simulation results, and all heat exchangers were designed in accordance with the maximum heat transfer capacity during the year-round operation. Therefore, the prototype could adapt to the change of working conditions with part-load operation in some conditions.

The AHP unit has more than 30 temperature measuring positions, 5 pressure measuring positions and 3 flowrate measuring positions, and the system operating conditions can be measured and recorded comprehensively. Details of the measuring components are shown in Table 2.

In the AHP unit, all the components that exchange heat with the surroundings adopted external medium countercurrent heat exchanger. The flowrate, inlet and outlet temperatures of the medium were measured to calculate the heat transfer capacity of each component, as are shown below [11]:

driving heat \[ Q_D = V_{NG} \cdot q_{NG} \] (1)

condensation heat \[ Q_C = m_w \cdot c_w \cdot \Delta T_C = \rho_w \cdot V_w \cdot c_w \cdot (T_{C,out} - T_{C,in}) \] (2)

rectification heat \[ Q_R = m_w \cdot c_w \cdot \Delta T_R = \rho_w \cdot V_w \cdot c_w \cdot (T_{R,out} - T_{R,in}) \] (3)

absorption heat \[ Q_A = m_w \cdot c_w \cdot \Delta T_A = \rho_w \cdot V_w \cdot c_w \cdot (T_{A,out} - T_{A,in}) \] (4)
where \( V_{NG} \) and \( q_{NG} \) are the volume flow rate and calorific value of standard volume of the natural gas; \( m_w, V_w, \) and \( c_w \) are the mass flowrate, volume flow rate, density and specific heat of the water; \( \Delta T, T_i \) and \( T_o \) are the temperature difference, inlet temperature and outlet temperature of each component. The total heating capacity of the AHP unit is the sum of the heat from the condenser, rectifier and absorber:

\[
Q_h = Q_c + Q_k + Q_s
\]

(5)

The heating performance of the AHP unit is presented by the primary energy efficiency \( PEE \), which is the ratio of the heating capacity to the driving heat (i.e., the calorific value of the consumed natural gas):

\[
PEE = \frac{Q_h}{Q_o + \frac{W}{\eta}}
\]

(6)

where \( W \) is the total power consumption of the AHP unit, and \( \eta \) is the power generation efficiency in China, which is about 35% [9].

4. Results and Discussion

4.1. Start-up performance

The startup sequence of the AHP unit followed this order: firstly, the gas combustor started, then the refrigerant valve opened, and finally the water chiller started. The refrigerant valve was closed at first, in order to quickly reach the required generation temperature and pressure. Fig. 5 shows the startup performance of the gas-fired AHP unit. It should be noted that a test run was conducted the day before, and the solution temperature in the generator reduced to about 100°C after overnight cooling.

It is found that a rapid growth in the generation temperature and pressure happened after starting the gas combustor, and the generation pressure reached up to 1.6 MPa within 7 minutes. Meanwhile the refrigerant valve opened, and the generation pressure reduced to 1.2 MPa, while the intermediate pressure raised immediately to 0.8 MPa. It should also be noted that the outlet temperature of flue gas reduced to 37°C after the intermediate evaporation process got involved.

When the solution temperature and pressure reached 90% of the target values, the water chiller started. The generated ammonia vapor was condensed in the rectifier, and then flowed into the solution. This process caused reduction in the solution temperature and pressure at first, and then tended to be stationary. 50 minutes after starting up, the supply water temperature reached the stable value of 43°C, and the AHP unit Began normal operation.
Fig. 5. Start-up performance of the gas-fired AHP unit: (a) Key temperature parameters variation; (b) Key pressure parameters variation.

4.2. Performance under basic working condition

The performance of the gas-fired AHP unit was analyzed in detail under the basic working condition: the evaporation temperature was -1.2°C, the return water temperature was 37.0°C, and the supply water temperature was 45.2°C. Detailed data of key parameters are shown in Table 3. The return water of 37.0°C passed in sequence through the condenser, rectifier and absorber, and its temperature increased to 40.2, 41.3 and 45.1°C, respectively, with flow rate keeping at 3.26 m³/h. It is shown that by introducing the intermediate process, the outlet temperature of flue gas was reduced to 38.6°C, which was lower than its dew point, indicating that the gas-fired AHP unit had ability to fully recover both the sensible and latent heat. It is also shown in Table 3 that the system high pressure, intermediate pressure and low pressure were 1.6 MPa, 0.8-0.9 MPa and 0.2-0.3 MPa, respectively. Moreover, the intermediate absorption pressure was 60 kPa lower than the intermediate evaporation pressure, and the absorption pressure was 70 kPa lower than the evaporation pressure, due to the flow resistance and the obstruction of check valves.

4.3. Influence of the ambient temperature

Figure 5 shows the influence of the ambient temperature on the system performance. It is indicated that as the ambient temperature reduced from 7.2°C to -7.8°C, the primary energy efficiency reduced from 1.82 to 1.38. At the lower ambient temperature, the ammonia evaporation was impeded, and the opening of the electronic expansion valve decreased. As a result, the recovered low-grade ambient heat and the PEE of the AHP unit reduced.

5. Conclusions

In this paper, a gas-fired absorption heat pump was built and tested during winter in Langfang, a city near Beijing. The unit was driven by natural gas direct combustion, and recovered low-grade heat from the ambient air. In order to increase the energy utilization ratio, solution preheating and intermediate evaporation was introduced. In order to enhance the internal heat recovery under low ambient temperatures, intermediate absorption was adopted.

1. The measured performance showed that the exhaust gas outlet temperature was lower than 35°C, indicating that both the sensible and latent heat were fully recovered.
2. The average daily primary energy efficiency was over 1.58 and heating capacity was 30 kW, at the ambient temperature of -1.2°C, when supplying 45°C hot water for space heating.

It was proven that the designed unit has great application potential in cold winter areas away from the centralized heating network.

Abstract

Various faults in components of the refrigeration cycle impact on system efficiency degradation differently. In addition, since sensitive features of each fault are different, the severity of the failures varies according to the operating conditions. Therefore, impacts of residential heat pump faults according to different indoor/outdoor air conditions were analyzed. The test was implemented with R410A residential unitary split heat pump with thermostatic expansion valve (TXV). Six types of common faults were imposed individually: compressor leakage, condenser fouling, evaporator fouling, liquid line restriction, refrigerant undercharge, refrigerant overcharge. Performance parameter model using 2nd order multivariate polynomial was built based on no-fault data. The rate of performance degradation according to the change in operating conditions and the change of fault level was calculated, and the effects of each fault were analyzed. For instance, in case of the temperature difference between indoor and outdoor is small, the refrigerant flow rate increases to handle the cooling load, resulting in a steep decrease in performance at condenser fouling. On the other hand, in this case, the required evaporator capacity was reduced, so the effect of evaporator fouling was small.

1. Introduction

Demand for the air conditioning rapidly grows recently, and it results in increased energy consumption and the CO₂ emissions. In the residential and the commercial building, the heating, ventilating and air conditioning (HVAC) system is the significant source of the energy consumption [1]. According to the OECD/IEA 2018, annual sales of the air conditioners increased about four times from that of 1990. [2] The fault occurrence is one of the main reasons of the energy loss in the HVAC system. And also, such inadequate handling of these problems such as degraded functioning of the components or faulty installation could affect the performance of the system substantially [3]. Fault detection and diagnosis (FDD) of the refrigeration systems is one of key methods to maintain and improve the performance [4].

Recent fault studies for the refrigeration system were focused on improving the accuracy of FDD. Rossi et al. [5] applied the Bayesian classification for the fault detection of rooftop air conditioner operation. Kim et al. [6] proposed the rule-based classifier for the residential heat pump cooling mode, with methodology for boundary direction selection. After 2010s, many studies suggested the application of artificial neural network (ANN) in HVAC systems [7-9].

However, studies about the fault impact on the HVAC system performance have been presented less. Kim et al. [10] selected the seven common faults of heat pump in cooling mode, and conducted the experiments with those faults imposed. Performance change by the single fault level was analyzed by comparing the performance parameters of the no-fault and the fault condition. Later, Kim et al. [11] compared the severity of each fault by comparing the fault levels that degrades 5% of energy efficiency ratio (EER). From the result, since the faults such as evaporator fouling fault (EF) or refrigerant overcharge fault (OC) impacts on the system performance less than other faults, so the fault has to be treated differently in real maintenance situations. Moreover, since the indoor and outdoor temperature conditions are the main parameters in heat pump system, the performance also varies with the operating conditions.

In this study, 40 cases of no-fault steady state experiments and 4 cases of fault tests (combination of indoor temperature conditions of 21.1 and 26.7 °C and outdoor temperature conditions of 27.8 and 37.8 °C) by Kim et al. [10] were analyzed, and the change in system performance of six single faults were observed. Six types of common faults were imposed individually: compressor leakage, condenser fouling, evaporator fouling, liquid line restriction, refrigerant undercharge, refrigerant overcharge. Each performance change at each fault implementation was analyzed using the comparison with the estimated fault-free steady-state reference value.

2. Experimental setup

2.1. System description and fault implementation

The system under the test is R410A 8.8 kW (2.5 ton) residential heat pump system with seasonal energy efficiency ratio (SEER) of 13 [12]. Fig. 1 shows the schematic diagram and the measuring parameters of the system. Constant-speed compressor and a thermostatic expansion valve (TXV) was coupled with indoor and outdoor section heat exchanger units. Detailed information of the test setup and the uncertainties of the measurement can be found in Kim et al. [10].

Six types of common faults in heat pump system and the determination of the artificial fault levels are illustrated on Table 1 [10]. Compressor leakage fault, or the valve leakage fault, was simulated by implementing a hot gas bypass line from the compressor discharge line to the suction line. Condenser fault, which implies improper outdoor air flowrate, was simulated by blocking the finned-heat exchange area. Evaporator fault was imposed by reducing the speed of the nozzle chamber fan at the end of the evaporator duct. Liquid line restriction, which is commonly occur by the pipe clogging, was mocked by controlling the pressure drop between the condenser exit and the evaporator inlet with the metering valve. Refrigerant overcharge and the undercharge were set by controlling the charge level of the system.

2.2. Test conditions

Many studies have been analyzed the impacts of the faults in residential heat pump system, however, indoor and the outdoor temperature was seldom changed since the number of the case becomes large [10, 11, 14, 15, 16]. In order to verify the fault impact in different temperature conditions, experimental data from the Kim’s study [10] was adopted. Heat pump system with six kind of single fault was tested under various conditions: indoor temperatures of 21.1, 26.7°C and outdoor temperatures of 27.8 and 37.8°C. And each faults was tested with various fault levels: CMF (3, 6%), CF (10, 20, 35%), EF (10, 20, 30%), LL (100, 200, 300%), OC (10, 20, 30%), UC (10, 20, 30%).

3. Experimental results

3.1. Performance parameter normalization

Evaporator capacity ($\dot{Q}_{EA}$), condenser capacity ($\dot{Q}_{CA}$) and the coefficient of performance (COP) were selected as performance parameters. Since it is hard to measure the capacities when the refrigerant flows at two-phase state in faulty situations, capacities of the heat exchangers were calculated at air-side. Evaporator air-side capacity was calculated as follows:

$$\dot{Q}_{EA} = \dot{Q}_{EA,sens} + \dot{Q}_{EA, lat}$$ (1)

where the $\dot{Q}_{EA,sens}$ and $\dot{Q}_{EA, lat}$ are the indoor air sensible capacity and the indoor air latent capacity, respectively. Since the measurement of the air flowrate at condenser is hard, condenser air-side capacity was calculated as Eq. (2). And the calculation of the cooling COP was shown in Eq. (3)

$$\dot{Q}_{CA} = \dot{Q}_{EA} + W_{comp}$$ (2)

$$COP = \frac{\dot{Q}_{EA}}{W_{comp} + W_{ID,fan} + W_{trans}}$$ (3)

Fault-free steady-state (FFSS) reference model was presented in order to estimate the reference data in no-fault situation for the performance comparison. The model was developed as a form of 2nd order multivariate polynomial equation shown in Eq. (4), with the key system parameters – indoor temperature ($T_{ID}$), outdoor temperature ($T_{OD}$) and the indoor dew point temperature ($T_{IDP}$) [11]. Reference values of three performance parameters at no-fault situation were approximated with regression model, and the coefficients were listed on Table 2.

$$\phi_1 = a_0 + a_1 T_{ID} + a_2 T_{OD} + a_3 T_{IDP} + a_4 T_{ID}^2 + a_5 T_{ID} T_{OD} + a_6 T_{ID} T_{IDP} + a_7 T_{IDP}^2 + a_8 T_{OD} T_{IDP} + a_9 T_{OD}^2$$ (4)

Performance variation of the system under single faults were indicated with the $r(\phi)$ of the current value and the reference value with FFSS model. The actual difference of the values, $R(\phi)$ was used when the performance variation through residual ratio is vague.

$$r(\phi) = \frac{\phi_{cur} - \phi_{ref}(T_{ID}, T_{OD}, T_{IDP})}{\phi_{ref}(T_{ID}, T_{OD}, T_{IDP})}$$ (5)

$$R(\phi) = \phi_{cur} - \phi_{ref}(T_{ID}, T_{OD}, T_{IDP})$$ (6)
3.2. Performance degradation with single fault imposed

3.2.1. CMF fault (Compressor/valve leakage)

In Fig. 2 performance parameters with temperature conditions change of CMF fault were shown. Since the COP degradation was not significant in CMF fault, the performance change was shown in \( R(\phi) \). According to the Fig. 2 (a), (c), (e), performance decreases as the outdoor temperature increases. Evaporation pressure increases as the indoor temperature increases, which results in the decrease of compression ratio from 3 to 2.2, so the volumetric efficiency increases 8% [13-15]. The specific volume of the refrigerant at compressor suction side decreases 20% as the temperature difference increases. This leads to the increase of mass flowrate at the compressor, according to the Eq. (7) [16].

\[
\dot{m}_{\text{r,comp}} = \eta_e \frac{N_V}{\nu_{\text{comp,suc}}}
\]  

Since the tendency of the volumetric efficiency change is larger than the specific volume change, the mass flow rate changes inversely proportional to the outdoor temperature. Therefore, the degradation of the performance was greater at the outdoor temperature change.

3.2.2. CF fault (Improper outdoor air flow rate)

According to the Fig. 3, performance degradation was little at such low fault level of 10%, and the low temperature difference at fault level of 20%. In case of largest temperature difference \( (T_{\text{ID}} = 21.1 \degree \text{C}, T_{\text{OD}} = 37.8 \degree \text{C}) \) at 20% fault level, the performance drop was large because of the large pressure difference between the condenser and the evaporator. Since the heat exchanger is designed with sufficiently high safety factor, so the performance drop is still tolerable in 20% fault level. But when the fault level reaches 35%, the evaporator and the condenser capacity decrease sharply, which leads in severe performance decrease even at small indoor-outdoor temperature difference.

3.2.3. EF fault (Improper indoor air flow rate)

The decrease of the evaporator air flowrate leads to the decrease of evaporating temperature. According to the Fig. 4, three performance parameter change was less than 8% regardless of the fault level. The evaporator capacity decreases as the fault level gets higher and the condenser capacity decreases similarly. Mass flow rate of the refrigerant decreases with the decreasing evaporating temperature, however the performance of the system increases when the mass flow rate compensated by the increased indoor temperature. Moreover, at high fault level, the refrigerant mass flow rate is too small, so the sufficient system performance could be obtained with little air flow.

3.2.4. LL fault (Liquid line restriction)

LL fault was determined with the pressure difference between the TXV inlet part and discharge part. The flow rate of the refrigerant passing through the evaporator decreases with the fault level increases, so the refrigerant at the rear part of the evaporator superheated, and the opening rate of the TXV increased. At the fault level of 300%, when the temperature difference is smallest, the degradation of the performance was the highest. Condensing pressure was not changed as the operating condition changes, but the evaporating pressure changes drastically. This leads the specific volume of the refrigerant at the compressor suction side increases with the indoor temperature, and the mass flowrate at the compressor gets low. So, the refrigerant flows in two-phase and the performance degradation becomes greater. LL fault shows the largest drop of performance than the other faults.

Table 2. Coefficients of 2\( ^{nd} \) order multivariate polynomial reference model for no-fault performance estimation
Fig. 2. Performance parameters with temperature conditions of CMF fault

Fig. 3. Performance parameters with temperature conditions of CF fault

Fig. 4. Performance parameters with temperature conditions of EF fault

Fig. 5. Performance parameters with temperature conditions of LL fault
3.2.5. OC fault (Refrigerant overcharge)

From the Fig. 6, the system performance degrades a little, at relatively high fault level of 30%. Since the performance of the residential heat pump system is steady even if the amount of refrigerant charge is larger than the normal, performance degradation is not large when the OC fault occurs. In case of 10% fault level, at the refrigerant flowrate gets low when the indoor-outdoor temperature difference is high, the system performance was improved due to the increase of evaporation capacity. However, the OC fault could cause the inflow of liquid refrigerant in compressor, so the fault diagnosis to provide this problem is needed.

3.2.6. UC fault (Refrigerant undercharge)

System performance with the UC fault degrades drastically when the fault level exceeds 20%. As the indoor temperature increases, the mass flowrate increases due to the change of specific volume at the compressor suction side. Therefore, in high indoor temperature condition, required refrigerant is large, so the degree of superheat increased to open TXV. So, the refrigerant flows in two-phase at liquid line and the performance drop exceedingly.

3.3. Comparative evaluation of fault effects in operating temperature conditions

Fig. 8 and 9 shows the COP degradation ratio at four different operating temperature conditions in mild fault level and severe fault level, respectively. As shown in Table 1, each fault level was determined in different point of view, so the first and the last fault level was selected.

According to the Fig. 8 COP degrades greatly at CMF, OC and the UC faults. The performance of the system changes intensely by the operating temperature at EF, LL and OC faults. In highest load condition (T_{ID} = 21.1 °C, T_{OD} = 37.8 °C), the system performance was improved at LL and OC fault. In LL fault, without lowest load condition (T_{ID} = 26.7 °C, T_{OD} = 27.8 °C), system performance was improved rather than the reference value.
In high fault levels, performance drop was severe of maximum 23% at LL fault. In LL fault, the effect of the fault was highlighted at lowest load condition \((T_{ID} = 26.7 \, ^\circ\text{C}, \, T_{OD} = 27.8 \, ^\circ\text{C})\). On the other hand, at highest load condition \((T_{ID} = 21.1 \, ^\circ\text{C}, \, T_{OD} = 37.8 \, ^\circ\text{C})\), system performance was improved. Accordingly, faults that affects the refrigerant mass flow rate such as LL or UC was influenced greatly by the operation temperature.

Fig. 8. COP degradation for each mild fault at four different operating temperature conditions.

Fig. 9. COP degradation for each high fault at four different operating temperature conditions.

4. Conclusion

In this study, impact of single faults on performance of the residential heat pump system was analyzed at different operating temperature conditions. With the no-fault test data and the 2nd order multivariate
polynomial FFSS model, the reference value for the fault test was approximated. By comparing the difference between the reference value and the test data with six single faults imposed, performance difference was observed.

In CMF fault, three selected performance parameters do not fluctuate greatly, but the refrigerant flow backwards at the compressor so that the COP drops less. For CF fault, as the indoor temperature increased, the mass flowrate of the refrigerant increased, so the performance degrades less but the influence of the outdoor temperature is insignificant since the area of outdoor heat exchanger unit is decreased by the fault. At EF fault, as the evaporator air flow rate decreases, the evaporation pressure gets lower and the specific volume of the compressor suction side changes. In LL fault, as the fault level increases, the density of the fluid decreases as the evaporation temperature drops. Therefore, the refrigerant flowrate decreases greatly, and exceeds the capacity of TXV can rise. In OC fault, as charge level of the refrigerant increases the compressor work also increases which leads in COP drop. When the UC fault level gets higher, discharge line of the evaporator is superheated in order to compensate the fault by opening the TXV, which causes the two-phase flow in liquid line and the system performance reduces poorly.

Long term performance analysis of a Dual-Source Heat Pump system by means of the Matlab/Simulink tool ALMABuild

Christian Natale*, Claudia Naldi, Matteo Dongellini, Gian Luca Morini

Department of Industrial Engineering, Alma Mater Studiorum – University of Bologna, Viale del Risorgimento 2, Bologna 40136, Italy

Abstract

In this paper, the performance of a Dual-Source Heat Pump (DSHP), able to exploit energy from both air and ground, has been investigated through the Simulink toolbox ALMABuild. Two different control strategies for the external source selection have been implemented: with the first one, the ambient temperature is compared to a reference value (namely, switching temperature logic); with the second one, the heat pump is forced to operate in air-source mode and ground-source mode during the diurnal and the nocturnal hours, respectively (namely, scheduled times logic). The DSHP has been coupled to a building with unbalanced loads and to a Borehole Heat Exchanger (BHE) field, for which different total lengths of the borefield have been considered. The obtained results show that with undersized BHEs a DSHP achieves better annual performance with respect to Air-Source Heat Pumps (ASHPs) and Ground-Coupled Heat Pumps (GCHPs) coupled to the same borefield. In addition, a DSHP can reduce the ground temperature drift originated by undersized borefield and/or by unbalanced building loads. The paper shows how DSHPs can be selected for the replacement of traditional GCHPs in presence of undersized BHEs.

1. Introduction

In the last decades the global energy demand, and consequently worldwide greenhouse gas emissions, has significantly increased in parallel with a better population wealth. In order to contrast climate change and simultaneously boosting its own energy security, the European Community is strongly promoting low carbon technologies [1-2]. In Italy, buildings account for about 30% of the total energy consumption [3] and, for this reason, the real estate industry must be involved in a systemic refurbishment. With this aim, the Italian government has granted state allowances to improve the building envelope thermal properties and the heating, ventilating and air conditioning (HVAC) systems [4].

Heat pumps are good candidates for this purpose since they strongly reduce the primary energy demand for space heating and cooling of buildings [5-6] if compared to traditional fossil fuel boilers. In fact, heat pumps are able to exploit significant shares of renewable energy from aerothermal, geothermal and hydrothermal energy sources [2]. In recent years, Air-Source Heat Pumps (ASHPs) have been the most sold units in Europe [1] thanks to the extremely wide source availability and low investment costs. However, the air-to-water heat pumps performance is deeply influenced by the external air temperature and, in particular, their efficiency decreases when the ambient temperature drops in winter and rises in summer, in correspondence of the largest building thermal load. Another drawback is related to the defrost cycles, which occur for heating operating mode when the ambient temperature is low and the relative humidity is high. The frost layer accumulated on the heat pump external heat exchanger can be removed with different techniques, such as the adoption of an

* Corresponding author. Tel.: +39-051-209-0467; fax: +39-051-209-0544.
E-mail address: christian.natale3@unibo.it.
electric resistance to melt the ice, the spray of hot water on the evaporator surface or the use of hot refrigerant by-passed from the compressor discharge port. Among defrost methodologies, the most widespread technique, used by commercial reversible heat pumps, is reverse cycle defrosting (RCD). For this reason, RCD has been considered in this paper as defrosting method [7].

On the contrary, Ground-Coupled Heat Pumps (GCHPs) performance is weakly influenced by the external air temperature. Indeed, starting from a depth of about ten meters the ground temperature is almost stable over the year and equal to the mean annual temperature of the locality. This circumstance, combined to a well-sized Borehole Heat Exchanger (BHE) field, guarantees that the GCHP annual efficiency is substantially higher than that of an ASHP [8]. The main drawback of GCHP systems is the high investment cost linked to the installation of BHEs, which requires an accurate analysis to avoid oversized borefields [9-10].

In order to reduce the BHE field length, guaranteeing high values of the heat pump seasonal performance factors, a Dual-Source Heat Pump (DSHP) able to exploit renewable energy from both air and ground can be adopted. In literature several studies have been carried out on multi-source heat pumps; however, they mostly considered multi-generator systems. Many authors [11-12] integrated solar collectors whilst others [13-14] combined photovoltaic/thermal solar panels to heat pump systems. In this work, only one heat generator has been considered, consisting in a multi-source heat pump prototype. This unit can exploit alternatively geothermal energy, by means of a BHEs field, and aerothermal energy, through a conventional finned tube heat exchanger. In this way, the heat pump can work in air-source mode when the ambient temperature is warmer, as during the milder part of the day, and operate in ground-source mode in the most severe part, avoiding the frost deposition and the consequent defrost cycle. Grossi et al. [15] conducted a preliminary analysis on the adoption of a DSHP similar to the one studied in this paper (i.e., a single unit able to exploit, alternately, air or ground as heat sources). In that work, the Authors utilized a commercial software for buildings dynamic simulation (Trnsys) and a single basic control strategy for the heat pump external source selection.

The aim of the present work is to evaluate the energy performance of a DSHP, comparing the overall efficiency achievable with this kind of unit with those of traditional systems, such as a ASHP and a GCHP. Seasonal and annual performance of these systems has been investigated coupling a BHE field having different sizes to the multi-source generator. By using ALMABuild [16-17], an open-source Matlab-Simulink toolbox, seven-year simulations have been performed to take into account the long-term effects of the ground exploitation on the soil temperature drift. Moreover, when the DSHP is considered as heat generator, two control strategies have been implemented to choose the heat pump external source. The former logic selects the operating heat source by comparing a reference temperature, namely the switching temperature, to the external air temperature. The latter logic considers daily scheduled times in which the external source generator system is open, i.e., the source generator is not operating in earth-source mode but in air-source mode when the ambient temperature is warmer, as during the milder part of the day, and operate in ground-source mode in the most severe part, avoiding the frost deposition and the consequent defrost cycle. Grossi et al. [15] conducted a preliminary analysis on the adoption of a DSHP similar to the one studied in this paper (i.e., a single unit able to exploit, alternately, air or ground as heat sources). In that work, the Authors utilized a commercial software for buildings dynamic simulation (Trnsys) and a single basic control strategy for the heat pump external source selection.

The aim of the present work is to evaluate the energy performance of a DSHP, comparing the overall efficiency achievable with this kind of unit with those of traditional systems, such as a ASHP and a GCHP. Seasonal and annual performance of these systems has been investigated coupling a BHE field having different sizes to the multi-source generator. Moreover, when the DSHP is considered as heat generator, two control strategies have been implemented to choose the heat pump external source. The former logic selects the operating heat source by comparing a reference temperature, namely the switching temperature, to the external air temperature. The latter logic considers daily scheduled times in which the external source of the DSHP is pre-defined independent of the climatic conditions. The simulation of two different control strategies for the multi-source generator permits to highlight the benefits of a smart regulation on seasonal and annual performance and, thus, to evaluate the competitiveness of this technology.

2. Building characteristics and climatic data

In order to compare the performance of the different heat pump configurations, a single-storey house [15] has been coupled to the heat pump system. The residential building, located in Bologna (Emilia-Romagna region, Northern Italy, 44°29’N, 11°21’E), has four thermal zones and a non-heated attic. The total net floor area is 111.6 m², the net conditioning volume is 301.5 m³ and the surface to volume ratio is equal to 1.32 m⁻¹. The building main geometrical characteristics are summed up in Table 1, where the external wall surface area, the net floor area and the net volume are indicated for every thermal zone. Moreover, in each thermal zone the infiltration rate has been set to 0.5 vol h⁻¹. In Table 2 the building envelope thermophysical properties are reported.

The insulation level is medium if compared to the current Emilia-Romagna region transmittance limits [18]. The clear components are low-emissivity (equal to 0.1) double glasses (4/12/4) filled with Argon, with a glass transmittance of 1.5 W m\(^{-2}\) K\(^{-1}\). The frame transmittance is 2 W m\(^{-2}\) K\(^{-1}\) and covers 20% of the total window surface. The standards UNI EN ISO 6949 [19] and UNI EN ISO 13370 [20] have been followed to calculate the external opaque components and the slab on grade transmittance values, respectively. Moreover, occupancy and equipment heat gains have not been considered.

The peak heating load is equal to 6.15 kW, whilst the maximum cooling load is 1.66 kW. The heating to cooling load ratio is equal to 3.7, thus, the building loads are strongly unbalanced, with higher values during the winter season. The thermal building loads have been evaluated by means of the ALMABuild tool by setting the indoor set-point temperature equal to 20 °C during winter and to 26 °C during summer. The heating season starts on October 15\(^{th}\) and ends on April 30\(^{th}\) (198 days), while the cooling season goes from June 15\(^{th}\) to August 31\(^{st}\) (77 days). The hourly climatic data included in the Meteonorm database [21] have been used in the dynamic simulations (minimum and maximum outdoor air temperature equal to -7 in winter and 35 °C in summer, respectively).

### 3. HVAC system characteristics

#### 3.1. Sizing of the heat pump

The HVAC system, coupled to the building described above, is based on a single reversible inverter-driven heat pump. No back-up system is present because the heat generator has been sized to cover the maximum heating and cooling loads. To satisfy the building energy demand, three different heat pump systems have been considered: (i) an Air-Source Heat Pump, ASHP (air-to-water); (ii) a Ground-Coupled Heat Pump, GCHP (brine-to-water); (iii) a Dual-Source Heat Pump, DSHP (air/brine-to-water). As mentioned before, the DSHP is able to exploit, alternately, renewable energy from ambient air and soil, depending on the selected control strategy (no parallel exploitation of external sources is possible due to the unit refrigerant circulation). The GCHP and ASHP manufacturer data on thermal power (cooling \(P_c\) and heating capacity \(P_h\)), COP and EER are reported in Figures 1 and 2 for different values of the external source temperature and different inverter frequencies. The curves refer to a load water temperature at the heat pump outlet equal to 10 °C in summer and 40 °C in winter. The DSHP has been modelled by considering the characteristic curves of both the ASHP and the GCHP.

![Fig. 1. (a) Cooling capacity and EER and (b) heating capacity and COP as functions of the outdoor air temperature (air-source mode), for three values of the inverter frequency (30 Hz, 70 Hz, 110 Hz).](image-url)
The selected GCHP and ASHP can satisfy 1.45 and 1.38 times, respectively, the building heating peak load in the most unfavourable conditions (borehole fluid temperature of -5 °C in ground-source mode and external air temperature of -7 °C in air-source mode). Since the building winter energy demand is the most relevant, during summer the heat pump is deeply oversized and this will implicate a large number of on-off cycles.

To model the heat pump cycle inversion due to defrosting occurs when, at the same time and for at least 10 minutes, the outdoor air temperature is lower than 6 °C and the relative humidity is higher than 50%. To model the defrost cycles, three phases have been considered [7]: i) an initial phase τ1 in which the heat pump is switched-off and the inversing valve is turned on; (ii) an intermediate phase τ2 during which the cycle is inverted and the heat pump operates in cooling mode, with power $P_c$ and efficiency $EER_c$; (iii) a final phase τ3 in which the heat pump is switched-off and the inversing valve is reverted again, to return in heating mode. One hour must pass between two consecutive defrost cycles. Table 4 shows the adopted values of $P_c$, $EER_c$, $τ_1$, $τ_2$ and $τ_3$.

![Diagram showing cooling capacity and EER, heating capacity and COP as functions of borehole fluid temperature at heat pump inlet (ground-source mode), for three values of inverter frequency (30 Hz, 70 Hz, 110 Hz).]

### 3.2. Heat pump control system

A PI controller is necessary to regulate the heat pump inverter frequency based on the temperature of the water supplied to the emitters. According to the hysteresis cycle adopted, the heat pump is switched off when the water temperature exceeds/goes under 42.5/7.5 °C and switched on when the water temperature decreases below/increases over 37.5/12.5 °C in winter and summer, respectively. When the minimum inverter frequency (30 Hz) is reached, no further thermal capacity modulation is possible, so the heat pump has to perform on-off cycles to satisfy the building thermal energy demand. In addition, the heat pump in air-source mode has to perform defrost cycles when the outdoor air temperature is low and the relative humidity is high.

In order to evaluate the energy losses linked to on-off and defrost cycles, corrective coefficients of the heat pump performance data have been applied. Concerning the on-off cycles, two coefficients have been used [15]. The first one, $α$, is related to the reduction of the thermal power supplied by the heat pump during the transient start-up of duration $τ_α$. The second one, $β$, is related to the reduction of the electric power requested by the heat pump during the transient start-up of duration $τ_β$. The correct thermal and electric power values have been obtained by multiplying the nominal ones to the corresponding corrective coefficients for the whole transient start-up duration. The values of the penalty coefficients ($α$, $β$) and the transient start-up times ($τ_α$, $τ_β$) are reported in Table 3.

| Table 3. Penalty coefficients and transient start-up time |
|---|---|---|---|
| $α$ | $β$ | $τ_α$ [s] | $τ_β$ [s] |
| 0.69 | 0.96 | 216 | 78 |

|---|---|---|---|
| $P_c$ [kW] | $EER_c$ | $τ_1$ [s] | $τ_2$ [s] |
| -11.4 | 6 | 30 | 360 |

In order to select the most favorable external source (air/ground) when a DSHP is considered, two different control strategies have been analyzed: the switching temperature logic and the scheduled times logic.
former, when the external air temperature exceeds a reference value, called switching temperature, the heat pump operates in air-mode, otherwise it operates in ground-mode. In the latter, two daily scheduled time slots, nocturnal and diurnal, have been considered, taking as time limits the monthly average hours of sunrise and sunset in Bologna [22], reported in Table 5. In the diurnal hours the heat pump exploits the aerothermal energy, whereas in the nocturnal hours it uses the geothermal energy.

Four different case studies have been considered: heat pump system based on a GCHP (case A), heat pump system based on an ASHP (case B), heat pump system based on a DSHP with switching temperature logic (case C), heat pump system based on a DSHP with scheduled times logic (case D).

When the heat pump works in ground-mode (cases A, C, D), another hydronic loop with a single-speed circulation pump connects the heat pump to a BHE field. In Figure 3 a simplified HVAC layout with the multi-source heat pump is shown.

![Fig. 3. Simplified HVAC layout with the multi-source heat pump.](image-url)
The BHE field coupled to the heat pump contains vertical single U-tube boreholes, made of high-density polyethylene pipes in which a mixture of water and 60% Freezium [23] flows. Freezium is a commercial antifreeze borehole fluid, based on organic salts (potassium formate), able to maintain low viscosity and high thermal conductivity in low temperature applications. The gap between U-tubes and ground is filled by a commercial sealant mortar (Termoplast Plus [24]). The main BHE characteristics (borehole diameter \(D_b\), internal pipe diameter \(D_{pi}\), external pipe diameter \(D_{pe}\), grout conductivity \(k_g\), pipe conductivity \(k_p\), shank spacing \(s\), BHE fluid thermal conductivity \(k_f\), kinematic viscosity \(v_f\) and freezing temperature \(T_{ce}\)) are reported in Table 7.

*Property at 0 °C.*

The undisturbed ground temperature has been set equal to 13.2 °C, whilst the ground thermal conductivity and diffusivity have been set as 1.97 W m\(^{-1}\) K\(^{-1}\) and 8.8E-7 m\(^2\) s\(^{-1}\), respectively. The borehole thermal power per unit length, exchanged between BHEs and ground, ranges between 30 and 50 W m\(^{-1}\) [25-26]. The borefield in case A (GCHP) is made of 2 BHEs, each 60 m long. For case C (DSHP with switching temperature logic), 4 different borefield configurations have been considered: 2 boreholes each 60 m long (case C1); 1 borehole 90 m long (case C2); 1 borehole 70 m long (case C3); 1 borehole 60 m long (case C4). In cases C2-C4 the total BHEs length is undersized with respect to the building energy demand. Finally, in case D (DSHP with scheduled times logic) only 1 borehole 60 m long has been considered. Table 8 sums up the different case studies.

The ground thermal response has been modeled by means of the g-functions method, in which dimensionless thermal response functions simulate the ground temperature trend produced by a uniform and constant dimensionless thermal load [27]. By means of g-functions, the BHE fluid outlet temperature has been evaluated at every simulation time step [9], whilst the BHE linear thermal resistance has been calculated with an analytical expression [28].

### 4. Results

The entire system has been modelled in ALMABuild, a homemade tool developed in the Matlab-Simulink environment for the dynamic simulation of coupled building-HVAC plants [16-17]. ALMABuild contains libraries with blocks to model the different building and HVAC components. The considered system, shown in Figure 4, has been modelled by using blocks from both ALMABuild and Carnot, another Simulink library focused on the HVAC system [29].

Yearly and long-term (7 years) simulations have been carried out to investigate the performance of the considered heat pump systems on the basis of the seasonal and annual efficiency indicators reported in Equation (1). In order to limit the computational time of performed simulations with no lack of reliability, a period of 7 years has been considered idoneous to investigate the (eventual) soil temperature drift, since the variation of the ground temperature stabilizes in a few years for all configurations presented in this paper.

\[
SCO_{P_{net}} = \frac{\sum_{j=0}^{T_h} E_{h,j}}{\sum_{j=0}^{T_h} E_{el,j}} \quad SEER = \frac{\sum_{j=0}^{T_c} E_{c,j}}{\sum_{j=0}^{T_c} E_{el,j}} \quad APF_{net} = \frac{\sum_{j=0}^{T_h} E_{h,j} + E_{c,j}}{\sum_{j=0}^{T_h} E_{el,j}}
\]

The net Seasonal Coefficient of Performance (SCOP_{net}) is the winter performance indicator, namely the ratio between the total thermal energy provided by the heat pump during winter \((\sum_{j=0}^{T_h} E_{h,j})\) and the
corresponding electric energy used by the heat pump compressor \( \left( \sum_{j=0}^{7} E_{el,j} \right) \). The Seasonal Energy Efficiency Ratio (SEER) is the summer performance indicator, that is the ratio between the total cooling energy provided by the heat pump during summer \( \left( \sum_{j=0}^{\tau} E_{c,j} \right) \) and the corresponding electric energy used by the heat pump compressor \( \left( \sum_{j=0}^{\tau} E_{el,j} \right) \). The net Annual Performance Factor (APF_{net}) is the annual performance indicator, i.e., the ratio between the total energy supplied by the heat pump during the year \( \left( \sum_{j=0}^{\tau} E_{h,j} + E_{c,j} \right) \) and the corresponding total electric energy used \( \left( \sum_{j=0}^{\tau} E_{el,j} \right) \).

### 4.1. Case A, GCHP

In case A, the GCHP is coupled to the single-storey house and to the BHE field with 2 boreholes, each 60 meters long. The long-term heat pump performance and ground temperature trend have been evaluated. In Table 9 the seasonal and annual performance factors obtained from the first to the 7th year are reported together with the percent variation on the APF_{net} value \( (\Delta_{APF}) \) with respect to the first year, taken as reference.

<td>-3.43</td>
</tr>
</tbody>
</table>

As evident from Table 9, the best efficiency is reached in the cooling season due to an oversized borefield, which allows to keep the maximum BHE fluid temperature at the heat pump inlet below 20 °C. On the contrary, in the heating season the BHE field is well-sized and the seasonal performance (SCOP_{net}) remains quite high over the years, with a maximum value of 3.95 in correspondence of the first year. The APF_{net} index follows the SCOP_{net} trend over the 7-years period because the building loads are strongly unbalanced with predominance of the heating demand. Furthermore, it can be observed that the minimum APF_{net} value, obtained at the last year, is only 3.43% lower than that of the first year. This result is explained by the mean winter temperature values at the BHE-ground interface, which drop only slightly over the years, going from 5.7 °C (first year) to 4.35 °C (seventh year). On the contrary, in presence of both unbalanced building loads and undersized borefield, the ground thermal drift can be significant [27].
4.2. Case B, ASHP

In case B, the ASHP is coupled to the same residential building. Since Meteonorm hourly climatic data refer to a typical reference year, one annual simulation is sufficient to investigate the generator efficiency in the long-term period. In Table 10 the seasonal and annual performance indicators are reported.

<table>
<thead>
<tr>
<th>SEER</th>
<th>SCOPₙₑₙ</th>
<th>APFₙₑₙ</th>
</tr>
</thead>
<tbody>
<tr>
<td>4.06</td>
<td>2.80</td>
<td>2.87</td>
</tr>
</tbody>
</table>

From Table 10 it can be observed that the minimum seasonal efficiency refers to the winter season: the SCOPₙₑₙ value is equal to 2.80, about 31% lower than the SEER value (4.06). This result is due to the high number of heat pump start-ups: 2873 over the year, where 2547 start-ups occur during the winter period and only 326 during the summer one. The large number of winter start-ups mainly depends on the defrost cycles, which are about 9 per day. This aspect becomes even more critical in the coldest and damp months, from December to February, when the daily average number of defrost cycles overcomes 15. In the summer season the heat pump is often switched off (79% of the conditioning period), given that the cooling demand is much lower than the heating one, so that the generator is deeply oversized during this season. Indeed, the maximum compressor frequency does not overcome 39 Hz during the cooling season (the heat pump frequency range goes from 30 to 110 Hz). The APFₙₑₙ value (2.87) is close to the winter coefficient (2.80), due to the unbalanced building loads.

4.3. Cases C1-C4, DSHP with switching temperature logic

In cases C1-C4, the heat pump is a DSHP able to exploit, alternatively, renewable energy from both air and ground. In the heating season, the adopted source control strategy is the switching temperature logic: the controller compares the ambient temperature with a reference value (switching temperature). In particular, when the external air temperature exceeds the switching temperature, the heat pump operates in air-mode, otherwise in ground-mode. In this way the aerothermal energy can be used when the outdoor air temperature is warmer (with consequent higher COP values) and the defrost cycles can be avoided if a switching temperature higher than 6 °C is selected. On the other hand, in the cooling season the heat pump works in ground-mode only in order to partially recharge the ground due to the unbalanced building loads and to exploit a sink with lower temperature values than the external air, with consequent better EER values.

In case studies C1-C4, 4 different BHE sizes have been coupled to the multi-source heat pump. Figure 5 shows the first year APFₙₑₙ trend as a function of the switching temperature, for the different BHE field lengths. It is worth noting that a switching temperature equal to 26 °C (points on the far right in Figure 5) corresponds to ground-source mode only, namely to a conventional GCHP. From Figure 5 it can be observed that the APFₙₑₙ increases, for a fixed switching temperature, ranging from case C4 (BHE length 60 m) to cases C3 (BHE length 70 m), C2 (BHE length 90 m) and C1 (BHE length 120 m). Indeed, the higher the total BHE length, the higher (the lower) the BHE fluid temperature at the heat pump inlet and, consequently, the better the heat pump winter (summer) performance.

Another important obtained outcome is that an optimal switching temperature can be selected, for a fixed BHE length, that maximizes the APFₙₑₙ value. In particular, this optimal value grows as the borefield length rises: in cases C3 and C4 (shorter borefields) the optimal switching temperature is 6 °C, whereas in cases C2 and C1 (longer borefields) it becomes 8 and 14 °C, respectively. This trend is coherent since the ground utilization increases with the switching temperature, and longer BHEs guarantee higher (lower) borehole fluid temperature values, assuring better heating (cooling) performance. By comparing the results of cases C3 and C4 to each other, it is clear that the adoption of an optimized switching temperature allows to achieve, with a shorter borefield, the same APFₙₑₙ value of a conventional GCHP coupled to a longer (and more expensive) field: the APFₙₑₙ value for case C4 (BHE 60 m long) in correspondence of a switching temperature $T_{sw}=6 \, ^\circ C$ is 8% larger than that in correspondence of $T_{sw}=26 \, ^\circ C$ (ground-source mode only) and even slightly larger than that achieved in case C3 (BHE 70 m long) with $T_{sw}=26 \, ^\circ C$ (ground-source mode only). Moreover, adopting a switching temperature of 14 °C even in the well-sized case C1 allows to obtain an APFₙₑₙ slightly greater than that of the traditional GCHP ($T_{sw}=26 \, ^\circ C$). Indeed, with $T_{sw}=14 \, ^\circ C$, the air source is employed when the external air temperature is higher than the ground temperature and this promotes better heat pump performance (compare the heat pump performance data in Figures 1 and 2). Small switching temperature
values can be discarded as they make the heat pump operate for a prolonged time with the aerothermal source even when the ambient temperature is cold and dump.

In order to evaluate the long-term heat pump performance, 7-years simulations have been carried out by coupling the DSHP to the most undersized borefield, namely case C4 (1×60 m). Five switching temperature values (-9, 3, 6, 14, 26 °C) have been selected and the corresponding annual efficiency is reported in Figure 6. It is worth remembering that a switching temperature of 26 °C (red curve in Figure 6) corresponds to simulate a conventional GCHP. It can be observed from Figure 6 that the DSHP APF_{net} with a very low switching temperature \(T_{sw} = -9 \, ^{\circ}C\), green curve) has a steady trend since no ground energy is exploited in winter and, therefore, no ground temperature degradation occurs. Additionally, the thermal energy transferred to the ground in the cooling season is insufficient to markedly increase its temperature over the years, thus no influence on the SEER values has been noticed.

On the other hand, the DSHP APF_{net} with a very high switching temperature \(T_{sw} = 26 \, ^{\circ}C\), red curve) is always higher than that obtained with \(T_{sw} = -9 \, ^{\circ}C\), but the ground temperature degradation negatively influences the annual efficiency, which has a drop of 3.1% after 7 years.

As already mentioned before, the optimal switching temperature for case C4 is 6 °C (orange curve in Figure 6): adopting this control logic, the thermal energy extracted in winter from ground decreases by 40% compared to the GCHP case (red curve). As a consequence, the mean winter temperature of the BHE fluid at the DSHP inlet is from 6.6 °C (1st year) to 7.3 °C (7th year) higher than that reached in the same year by the GCHP and the APF_{net} increases from 8 to 10.4% over the considered period.

Therefore, in accordance with the literature results [15, 30-31], the adoption of a DSHP proves to be competitive: (i) to equilibrate the ground loads when the building loads are strongly unbalanced and/or when the borefield is undersized, avoiding the progressive ground temperature drift; (ii) to reduce the HVAC plant investment cost opting for a total BHE field length reduced with respect to the design one.

4.4. Case D, DSHP with scheduled times logic

In case D, the heat generator is composed of a dual-source heat pump coupled to an undersized (60-meters long) borehole. In the heating season the source control strategy is the scheduled times logic: two daily scheduled time slots, nocturnal and diurnal, are defined taking as time limits the monthly average hours of sunrise and Sunset in Bologna. In the diurnal hours the heat pump exploits aerothermal energy and in the nocturnal ones geothermal energy. With this control logic the number of defrost cycles depends on the temperature and moisture content of the external air in the diurnal hours. On the other hand, in the cooling season the source controller selects only the ground for the same reasons explained for the switching temperature logic (section 4.3). Table 11 shows the results in terms of seasonal and annual performance coefficients over 7 years. As evident from Table 11, the best seasonal efficiency is reached in summer due to a well-sized borefield, with a mean summer BHE fluid temperature at the heat pump inlet which remains below 17.3 °C over the years. On the contrary, in the heating season the BHE field length is halved with respect to the proper design size and the SCOP_{net} values are 48% lower than the SEER ones. Also in this case the APF_{net} index follows the SCOP_{net} trend over the 7-years period because of the higher building loads for heating. Both
the SCOP_{net} and the APF_{net} factors are quite stable over the years, undergoing a weak decrease, due to the mean winter temperature at the BHE-ground interface which drops from 4.7 °C (first year) to 4 °C (seventh year).

#### 4.5. Comparison

The main results in terms of APF_{net} for the investigated cases A-D are summed up in Figure 7.

![Fig. 7. APF_{net} over 7 years of cases A (blue curve), B (red curve), C4 (green curve) and D (grey curve).](image)

According to the plot of Figure 7, the best annual efficiency is reached adopting a traditional GCHP (blue curve in Figure 7) coupled to a well-sized borefield (case A). In this case, the APF_{net} index drops slightly, especially in the first three years, reaching a value of 3.94 after 7 years. The worst performance is obtained by the ASHP (case B, red curve in Figure 7) due to a colder source in winter and to a large number of defrost cycles. The performance of the DSHP coupled to a strongly undersized borefield (1×60 m) is intermediate between that of cases A and B, with the APF_{net} of the C4 configuration with T_w=6 °C (green curve in Figure 7) 4% better than that of the D one (scheduled times logic, grey curve in Figure 7). This result is due to a better exploitation of the renewable sources in case C4: in the scheduled times logic (case D) the number of defrost cycles cannot be controlled because it depends on the temperature and moisture content of the outdoor air in the diurnal hours (when the heat pump operates in air-mode), whereas the switching temperature logic with an optimized T_{sw} (case C4) avoids the inefficient defrost cycles making the heat pump operate in ground-source mode when the external air temperature is below 6 °C. In both cases C4 and D the APF_{net} is quite stable over the seven years thanks to more balanced ground loads with respect to case A. To summarize, the DSHP guarantees an annual efficiency from 17 to 23% larger than that obtained by a conventional ASHP, independently from the logic chosen to select the operating external source. Furthermore, accepting an APF_{net} value only 11% lower with respect to case A, a borefield strongly reduced up to 50% can be coupled to the DSHP, obtaining, in this way, a consistent reduction of the investment cost.

#### 5. Conclusion

In this paper, the homemade Simulink-MATLAB tool ALMABuild has been employed to investigate the performance of different heat pump systems, coupled to the same single-storey house, located in Bologna (North Italy) and characterized by unbalanced seasonal loads. Three heat pump configurations have been considered: a Ground-Coupled Heat Pump (GCHP), an Air-Source Heat Pump (ASHP) and a Dual-Source Heat Pump (DSHP), modelled through the technical data of both the ASHP and the GCHP. In dual-source
mode two different control strategies have been tested: the switching temperature logic and the scheduled times one. In the former, when the external air temperature exceeds a reference value, called switching temperature, the heat pump operates in air-mode, otherwise in ground-mode. In the latter, two daily scheduled time slots, nocturnal and diurnal, have been considered taking as time limits the monthly average hours of sunrise and sunset in Bologna; in the diurnal hours the heat pump exploits aerothermal energy, in the nocturnal hours the heat pump extracts heat from the ground. 

Yearly and long-term (7 years) simulations have been carried out to investigate the different heat pump systems performance. The numerical results demonstrate that, when the borefield is well-sized, the DSHP performance is higher than that of the ASHP and lower than that of the GCHP. Moreover, with the switching temperature logic an optimal value can be adopted to maximize the APF<sub>net</sub>; the optimal switching temperature value rises as the BHE field length increases. Additionally, in presence of undersized BHEs, annual performance factors higher than that of a GCHP can be obtained by a DSHP with an optimized switching temperature, with a consistent reduction of the borefield investment cost. Furthermore, with the scheduled times logic, lower APF<sub>net</sub> values are obtained compared to those of the switching temperature logic due to a worst sources selection. More balanced ground loads are guaranteed by the multi-source heat pump, resulting in more stable APF<sub>net</sub> values than those of the GCHP over the years. The adoption of a DSHP is promising since it allows to reduce the ground temperature drift originated by an undersized borefield and/or unbalanced building loads. As a consequence, DSHPs can be selected for the replacement of conventional GCHPs in presence of BHEs that are undersized (to reduce the investment cost or due to subsequent changes in the building thermal loads).

Abstract

In a power system with an increased share of electricity from intermittent renewable sources heat pumps can act as a large, aggregated flexibility resource. This can help to balance variations in electricity production and to reduce problems with bottlenecks in the power system. In this study a concept based on using the heat pump manufacturers cloud solutions to communicate demand response between an aggregator and individual heat pumps is investigated. The manufacturers cloud solutions were first released about ten years ago, meaning numerous heat pumps installed are ready to be used for flexibility with the missing piece being communication. Possibilities and constrains related to the concept have been investigated in an interview study with nine technical experts from the major heat pump manufacturers in Sweden. A workshop with those experts and additional stakeholder complemented it. Several barriers to solve were identified. Heat pumps are difficult to securely control rapidly and thus communicating flexibility control on beforehand has clear benefits. The transmission system operator normally has high accuracy demands, something many heat pumps today cannot meet as most of them lack electricity meters. Here compromising on accuracy is likely necessary. Alternatives to standardize the communication between the aggregator via the cloud services to the individual heat pumps has been investigated. From a heat pump perspective EEBUS and OpenADR are promising.

1. Introduction

In a power system with an increased share of electricity from intermittent renewable sources such as wind and solar, the need for demand response is foreseen to increase, to help balance the variations in electricity production. Examples of problems that demand response from residential heat pumps can help to solve are, e.g., peak shaving, reduce problems with bottlenecks in the power system and avoid curtailment of renewable energy sources. This is done by load shifting, where the heat pumps electricity consumption is moved from peak hours to off-peak hours. A standardized way to control heat pumps for demand response would make it easier for aggregators and network owners to use the potential of heat pumps to provide flexibility to the power system.
1.1. Scope

The scope of this study is to investigate the technical possibilities and constrains for a concept where residential heat pumps are aggregated and controlled via the manufacturers cloud solution in order to support the power system.

- The focus is on technical aspects, other considerations such as legal, and economical are only briefly described.
- The focus is mainly on conditions and available flexibility products for the Swedish power system.
- The solution evaluated is valid for residential heat pumps with hydronic heating systems, meaning ground source, air-to-water and exhaust air heat pumps, that are connected to a manufacturers cloud service.
- Air-to-air heat pumps are excluded because they are (in Sweden at least) relying on direct electric heating as backup. Turning them off at cold weather will likely cause the electric heaters to turn on contradicting the purpose.
- Comfort issues are not thoroughly investigated as demand response will be voluntary and if comfort is too poor, compared to economic benefit, people will terminate their enrollment. In a demand response system comfort can never be the top priority.
- The focus is on space heating as today’s power system congestion hours are mainly in the wintertime when heating is the major need, and domestic hot water (DHW) has constraints making it difficult to use for flexibility.

1.2. Background

In Sweden, as in the rest of Europe, more and more electricity from weather-dependent intermittent sources is being installed resulting in larger variations in electricity production, see Figure 1 below. In Sweden, there is a political goal that 100% of the electricity should be fossil-free by 2040 [1] [2]. At the same time there is an ongoing electrification of the whole society and several of the roadmaps from “Fossilfritt Sverige”; an initiative to reduce the impact on global warming from different industrial sectors in Sweden, point out an increased electrification as the way forward to reduce the climate impact of the industry [3]. In addition, the Swedish government has published an electrification strategy [4] in order to meet the increasing needs for electricity from renewable sources. The strategy is summarized in twelve points and one of them focus on an increased flexible use of electricity, especially mentioning the need to realize a higher degree of flexible electrical heating. This indicates that an increased load on the power system is to be expected, especially from intermittent sources.

Figure 1. Sources for electricity production in Sweden (left) and EU 28 (right). UK is included, for better readability, in 2020 despite Brexit. Data from Eurostat [5] and the Swedish Energy Agency [6], some data for UK extrapolated in 2020.

Internationally the expected trend with an increasing share of electricity from renewable sources is similar, see Figure 2 below.
In EU's Renewable Energy Directive towards 2030 [11] there is a binding target for the EU for 2030 that at least 32% of the final energy consumption should come from renewable sources, and there are ongoing discussions to increase the target to 40% as part of the European green deal [10]. Child et al. has made a scientific forecast that shows how EU will be able to have an almost completely renewable electricity production by 2050. According to the forecast by 2030 60% of the EU's electricity production needs to come from weather-dependent electricity on an annual basis [8].

1.3. Thermal inertia in buildings

The thermal inertia of a building makes it possible to start or stop the heat production without significant impact on the indoor temperature. The possible duration of the on or off cycle depends highly on the building’s thermal inertia, where heavier building types are more flexible to variable heat production. Weiβ et al. [9] and Le Dréau and Heiselberg [17] have used simulations to investigate the potential with thermal inertia when shifting electrical heating loads in time. Weiβ et al. showed that for residential buildings in Austria, build according to Austrian standards after 1980, at least 50% of domestic heating peak loads could be shifted to off-peak hours during the day, using a comfort band between 19-22°C. The study by Le Dréau and Heiselberg showed that it is possible to shift the heat production in time for a period of 2-5 h in poorly insulated single-family houses in Denmark and still maintain the set comfort conditions. For homes built according to passive house standard it was possible to switch off the heating system for more than 24 h and still fulfil the comfort criteria.

1.4. Potential for demand response from heat pumps

The vast majority of Sweden's installed heat pumps are currently installed in single family buildings, these heat loads are considered to have the greatest potential for demand response in Sweden. As described in chapter 1.3 the thermal inertia of a building allows the heating to be paused for a few hours without any larger impact on the indoor temperature or comfort, which can be used to provide demand response. But this is a returning load, the loads are only shifted in time and one drawback using heat pumps for demand response is that there is a risk for a new load peak when the heating is started again. Note that, depending on the heating- and ventilation system, a building could have short response to the ambient, especially during cold spells.

Around half of the electricity used by single family houses is used for space heating and production of domestic hot water (DHW), and today there are around 1.5 million heat pumps in operation in Sweden of
which 900,000 in hydronic systems, see Figure 4 below. Around 50,000 new hydronic heat pumps are installed every year [13], where many replace older heat pumps.

![Figure 4](image)

Figure 4. Development of heat pump stock in Sweden. The data source is Energimyndigheten [12] with processing from the author.

Earlier studies have estimated the potential for demand response connected to controlling space heating and production of DHW in Sweden to between 1-6 GW [22]. This can be compared with Sweden's total power need at high load situations which today is about 28 GW and is predicted to increase in the future [3]. Already today we estimate the theoretical potential flexibility from heat pumps to several hundred MW in Sweden, with an additional flexibility of approximately 125 MW per year from hydronic heat pumps only, as older heat pumps are replaced with new ones.

### 1.5. Flexibility markets

Using heat pumps for demand response is still in the start-up phase, but there are some potential markets for demand response identified, the most likely are either to deliver ancillary services to the Transmission System Operator (TSO) or flexibility to a local flexibility market. An alternative is to have bilateral agreements with a specific partner to provide flexibility. In this study the aggregator is assumed to be a separate actor, but heat pump manufacturers can in the future possibly take the aggregator role as well. In Sweden all local flexibility markets and all ancillary services from the Swedish TSO, Svenska Kraftnät, the smallest bid size is 0.1 MW or higher [26] [27]. Since each individual heat pump can only deliver a smaller amount of flexibility to the power system, this means that domestic heat pumps must be aggregated and controlled together to accomplish the minimum bid size of 0.1 MW. The aggregator uses its pool of heat pumps to deliver services to the power system.

In the EU Directive 2019/944 [36] there are requirements that flexibility must be an option if it is considered an economically viable alternative to regular options, and there are several local flexibility markets under development in Europe, with partly different purposes. In Sweden, the Netherlands and Germany the markets are primarily used for handle bottlenecks in the grid. In France and UK, the flexibility markets are also used for grid planning. The process to develop a regulatory framework has started in several countries in accordance with the EU directive, but none of the countries identified have finished deploying a full regulatory package on the topic [37]. In Sweden there are a few different local marketplaces for flexibility under development and several of them have run as pilots during the latest years, these include Shlm Flex [19], Coordinet [20] and Effekthandel Väst [21].

One of the main responsibilities of the TSO is to maintain the balance between production and consumption of electricity. To keep the balance the Swedish TSO, Svensk Kraftnät, has a well-established market for ancillary services, see Table 1 for details. The different ancillary services have different requirements and complement each other to cover the required balancing needs [27].
Both a decrease and an increase of power consumption can be of interest for the flexibility buyers. In addition, the time it takes to activate a demand response resource is of high importance. A report from the Swedish Energy Markets Inspectorate (Ei) [30] defines the rules for aggregation to implement the EU legislation. The aggregation accuracy is not yet a part of the Ei mission, meaning the accuracy of aggregation is still undefined [29]. Today the accuracy of delivered flexibility is set to the range of 0.5-5% (for FCR-N, FCR-D, aFRR and mFRR) [23] depending on type of nameplate power and position in the power system, but this is as of now not applicable to aggregation [29]. The sampling interval today is 1-10 s [27], meaning each flexibility resource needs to report power consumption or production this often. If an aggregator will have this high sampling rate is still not decided [29].

2. Method

In this study a concept based on using the heat pump manufacturers cloud and application programming interface (API) solutions to communicate demand response between an aggregator and individual heat pumps are investigated. Possibilities and constrains related to the concept have been discussed in an interview study including nine technical experts from the four major heat pump manufacturers in Sweden. Mainly technical issues are evaluated from different aspects and presented in the results. As a complement input from a digital workshop was used. The workshop included the above-mentioned experts complemented with experts from two grid owners, a grid owners association and the Swedish heat pump and refrigeration association. The purpose with the interviews and the workshop was to understand and discuss their opinions and knowledge in using heat pumps to provide flexibility to the power system and how to communicate flexibility information via their cloud solutions.

To cover other areas related to demand response from heat pumps the authors of the study have had input and discussions with researchers and project leaders within different research areas from the Swedish research institute RISE, e.g., cyber security, electric power systems and smart industrial automation as well as literature within the field.

3. Concept for external heat pump control

To enable a rapid deployment of heat pumps as a flexibility resource this study investigates the possibilities to communicate the load control to the individual heat pumps via the manufacturers already existing cloud and application programming interface (API) solutions. Using the manufacturers cloud and API solutions requires no hardware changes to get an initial flexibility solution up and running. The investment cost to start using the heat pump as a flexibility resource and in the next step reach economical breakeven is lower compared to solutions where new hardware needs to be installed. Other studies, e.g., [25], have shown that a barrier to use flexibility from heat pumps is to find a beneficial business model for all attending parties.

The manufacturers cloud/API solutions have been in use for approximately ten years, meaning many heat pumps installed are ready to be used for flexibility once the communication is in place. In Sweden all the major

Table 1. Overview of requirement of ancillary services in Sweden [27].
Hydronic heat pump manufacturers have the functionality for the owners to control and monitor their heat pumps via an app, by connecting the heat pump to the manufacturer’s clouds solution. This means that many heat pump models can be controlled externally. For example, the heating curve can be altered by the owner via the app, but also automatic planning of the heat and DHW production based on the hourly price of electricity is possible for some heat pump models [31]. Control wise there are still pieces missing to be able to deliver flexibility to the power system via these cloud services, but as the hardware is in place since several years the potential is high. Figure 5 show a schematic overview of the proposed communication flow to deliver flexibility from heat pumps to the power system.

![Diagram of communication flow](image)

Figure 5. Overview of the communication flow for demand response from heat pumps using the manufacturers cloud solution.

Using the concept proposed in this study the aggregator communicates with the individual heat pumps via the manufacturers cloud services. Depending on how the communication is done and how active the heat pump manufacturer wants to be in the control it gives the manufacturer a possibility to either just forward the control signals to the individual heat pumps or to “translate” the signals for each heat pump type or model. In the latter case each individual heat pump can then react to demand response with less risk for decreased comfort to the end user, as the manufacturers have the deepest knowledge about their products and how to control them, meaning they have the best possibilities to make the heat pump react in the way asked for. Furthermore, this approach adds an additional layer to mitigate cybersecurity risks as the manufacturer can ensure that control signals are within a reasonable range.

4. Results, evaluation of the concept

In chapter 4 the concept has been evaluated and discussed from different aspects.

4.1. Communication between aggregator and heat pump

With the necessary communication there are signals and feedback sent directly or indirectly between the heat pump and the aggregator. This means that the aggregator could take informed decisions on which heat pumps, or other flexibility resources, that are available, for how long they are available and what the response will be when reduced or increased power consumption is needed.

In most demand response scenarios, there is a need to verify that the agreed change in power consumption has actually happened and there are several options on how this could be done. The problem is that all these options come with different uncertainties, meaning it is not clear what the real outcome of a demand response will be. Domestic heat pumps seldom have dedicated power meters, giving a high degree of uncertainty just there. Examples of functions that can increase the difficulty to calculate the baseline are smart price adaption functionality, meaning the heat pump adapts to the price of electricity or functions to lower the buildings power peaks. Calculating the baseline is thus not trivial. Should it be done before or after the price adaption is set? Huang [28] evaluates seven different methods for baseline calculations with a focus on demand response products currently in use in Sweden.
4.1.1. Placement of logic

There are several options when it comes to where in the information chain different types of logic can be situated. The three main options are:

- The logic is integrated in the heat pump, and the heat pump sends information regarding its availability via the cloud to the aggregator.
- The logic regarding heat pump availability is integrated in the manufacturers cloud.
- The logic is integrated in the aggregator solutions and information is relayed to and from the heat pump via the cloud to the aggregator.

Depending on where the logic is situated the information sent between the heat pump, the cloud and the aggregator will be different. However, the information needed could be the same in all cases. It is assumed that the control logic of the normal heat pump operation for space heating and production of domestic hot water is handled locally in the heat pump or in the heat pump cloud service.

There are several different alternative protocols for standardizing the communication between an aggregator and a heat pump to achieve in-home flexibility. A recent study listed several renown protocols, such as OpenADR, EEBUS, EFI, and OCPP [32]. OpenADR was found possible to use alone or in combination with OCPP [33], and EEBUS [34]. From a heat pump perspective EEBUS and OpenADR are promising and are both open access and license free, in opposite to the international standard for communication in the power system, IEC 61850, meaning the hurdle to start using them is much lower.

EEBUS is a European initiative, while OpenADR has its origin in USA, is sprung from the 2002 electricity crisis in California. While the geographical heritage could have relevance to the choice in different regions, cooperation between the two initiatives is seen. None of the initiatives seems to fulfil all needs from an aggregator to individual heat pumps, but hopefully this will emerge from the cooperation. One complete solution, possible to use worldwide would benefit the heat pump industry.

It is worth noting that IEC 61850 is extended with WAN communication and security [35] and should not be ruled out, since if one or more TSOs point out IEC 61850 as their choice the heat pump industry must adapt and offer solutions based on it.

4.2. Technical possibilities and constraints of heat pumps used for flexibility in the power system

The results in chapter 4.2 is based on interviews with the four major Swedish heat pump manufacturers.

4.2.1. The speed of increased or decreased power consumption

The manufacturers have common ground in how fast their heat pumps can be controlled to decrease or increase power consumption. The auxiliary electric heater can be controlled within a second, both for decreased and increased power consumption, but most likely they will need new software to be used as a flexibility resource. In normal operation the use of the auxiliary heater is minimized, to keep performance up. Clear economic incentives are needed if the auxiliary heater should be used as flexibility resource, this in order to compensate for the much lower performance factor and thus higher power consumption.

On/off compressors can also be turned off within a second, but most of them need the brine pump to start before the compressor is allowed to start. This will delay the start with up to a minute. If anti-freeze brine is used the start delay can likely be removed, but this will need reprogramming of the control systems to be operational. Other technical aspect, for example preheating of compressor sump, could delay startup as well.

The last ten years variable speed drive (VSD) heat pumps have taken a larger and larger share of the market, today more than 50% of the ground source heat pumps (GSHP) sales in Sweden are VSD [13]. These heat pumps are significantly slower to control compared to on/off heat pumps. From turned off to the wanted correct speed it will take several minutes, often the same is true when turning off the compressor. Control wise improvements can likely be done to speed up the process of starting and stopping, but some technical aspects will still limit what is possible.

4.2.2. Measurement on decrease or increase of power consumption

To measure the power consumption of today’s heat pumps is difficult, as they normally lack electricity meters and installing it afterwards is expensive and need skilled personnel. VSD heat pumps may have the possibility to measure the power consumption within the inverter controlling the speed of the compressor, while on/off compressors have no technical possibility built in to measure power consumption. The
manufacturers estimate that the uncertainty of the power consumption of VSD heat pumps is ±2-10%, but this is partly estimated and needs further investigations before conclusions can be drawn.

For on/off heat pumps the manufacturers state the uncertainty from under ±10% to ±20%, meaning much lower accuracy than Svenska krafträtts requirements today. This is due to the lack of electricity measurement, the power consumption is calculated from the operating temperatures of the compressor and known compressor equations. Note that the legislative accuracy demand for aggregation is not yet defined, see chapter 1.5.

The uncertainty of the auxiliary electric heater is stated to ±0.5-5% if the voltage is known (as it usually is with VSD heat pumps), else the accuracy is lower as voltage will vary in the power system. For high accuracy on electricity measurement of the entire heat pump the power consumption of fans and circulation pumps needs to be monitored as well. It is not clear if these are part of the measurements/calculations the manufacturers do.

The question on accuracy increase with aggregation was not asked in the interviews with the manufacturers, but according to one manufacturer the accuracy would increase significantly with larger number of heat pumps. Further studies on the accuracy increase are needed, especially to understand how to validate the accuracy anticipated.

The necessary measurement interval was not discussed with the manufacturers, but likely a sampling time of 1-10 s as stated today for Svenska krafträtts ancillary services [27] could be too frequent for today used control system or using the buildings electrical meter. A possible solution is extrapolation or other ways of producing a high frequency of sampling data. As the data management of an aggregator is still pending it is unclear if the sampling interval will be this short or not [29].

4.2.3. Communication to the TSO (Svenska krafträtts) or an aggregator and what product will be possible to fulfill

There are no clear thoughts among the heat pump manufacturers on how to communicate to the TSO (Svenska krafträtts) or to an aggregator. API and ModBus were mentioned. One of the manufacturers states that they have no interest in taking the aggregator roll itself, which could be a possibility, as they don’t want that responsibility. Svenska krafträtts has a number of ancillary services to control disturbances in the power system, see Table 1. The possibilities to fulfill the requirements for these services was discussed with the manufacturers.

One manufacturer claims that FFR, the ancillary service with the shortest activation time (0.7-1.3 s), is possible with limited load change, the others have no answer or answers that “it is difficult”. All manufacturers but one (where we lack an answer) claims that FCR-N is feasible and for FCR-D, which requires an activation time of 50% within 5 s, all claims that it is possible to fulfill the requirements from a technical point of view. For aFRR and mFRR there are few answers from the manufacturers since this was not discussed in detail in the interviews, but due to the longer activation time compared to FCR-N and FCR-D, it will likely be possible for heat pumps to fulfill the requirements also for these two services.

The answers should not be interpreted that solutions are ready, which might well be the case, but rather that they are technically feasible to solve.

4.2.4. Comfort disturbance at decreased heat production

It was stated by one of the manufacturers that when the heat is turned off the thermal comfort risk to decrease as the temperature in the heating system decrease fast and thus not compensates for cold surfaces (i.e. windows) in the property. Depending on the building envelope this will have different impact on the comfort. How the thermal comfort was before the heat was turned off and how sensitive for variations in temperature the persons living there are also important aspects. Earlier studies based on simulations, see chapter 1.3, indicates that it should be possible to shift heating loads in time and keep a good comfort.

One manufacturer stressed that heat production turned off for one hour could be problematic and that domestic hot water (DHW) is the limiting factor. With a small DHW tank or a high usage, the DHW temperature risk to drop fast, and if the heat pump is blocked new DHW will not be produced.

It was highlighted that underfloor heating (in concrete slab, authors note) should be able to be turned off without any or small comfort impact, even in the winter, as the thermal inertia is very high compared to other types of heating systems.

Concern regarding dimensioning of the heat pump system was raised, meaning at very cold weather the heat pump could not regain the heat in the building without using the electric backup heater after decreased heat production due to lack of heating capacity. According to the manufacturers this problem is low as newer heat pumps generally have spare capacity even at cold spells.
4.2.5. Comfort disturbance at increased heat production

The question on comfort disturbances at increased heat production was asked generally, we didn’t get any feedback there. Temporarily and unnecessarily high heat production could be of interest in the future, for example to buffer heat in a property during the night to skip heating at later morning congestion hours in the power system. This needs further discussions to understand what problems could occur. On days with excess electricity production, for example due to windy conditions, buildings with heat pumps could act as heat sinks, meaning wind turbines could keep producing and not being curtailed. To some extent DHW could also be used to store energy, but due to legislative limits on temperature the potential is normally low at least without temperature regulation added to the outlet. From a technical point of view the auxiliary electric heater could be used more freely, meaning it could be used without the compressor running. In this way the heat pump could use more electricity during periods when the power system is in need. Higher electricity consumption, which will be the consequence, will only work at very low electricity prices or other compensations for this aid from the heat pump to the power system. The heat pump manufacturers control systems don’t have this functionality to run the auxiliary electric heater today, it needs reprogramming to work.

4.3. Risks related to cybersecurity

To enable flexibility the heat pumps being part of a large-scale flexibility systems need to be remotely controllable, which as of now means controllable over the internet. This opens for cybersecurity risks, as for all internet connected devices. The heat pump industry historically has mainly been a mechanical business, with only the necessary electronics for the fundamental control functionality. Thus, there is most probably a need to raise the awareness and extend the organizations and solutions to cover cyber security sufficiently.

A few potential ways to recruit (hack) connected heat pumps are:

- **Cloud service** – could have insufficient isolation between users, be misconfigured, have insufficient physical protection
- **Communication** – could be unencrypted, contain safety holes, or have become outdated due to the lifetime of the product
- **Device** – could expose services by mistake, contain weak or hardcoded passwords, have unsecure software update
- **Employees** – needs to be protected against leakage of sensitive information, either by mistake or by extortion

It has been shown that high-wattage IoT devices can cause significant impact to the power system [15], [24]. If large amounts of e.g., heat pumps are hacked or otherwise manipulated to operate in a non-favorable way, for the power system, this could lead to disturbances in the power system even causing safety mechanism to trigger. Saleh et.al. [15] has shown the impact on the Polish power system when simulating IoT attacks via air conditioners and heaters. As heat pumps may require similar or higher power, there is a need to work on rising the awareness of cybersecurity in the heat pump industry and evaluate the system architecture including the communication between individual heat pumps and the server solution. One of the more challenging effects of cyber security is related to the longevity of the systems. While end- customers traditionally expect a heat pump to last for 15-20 years, new vulnerabilities may require software and hardware updates. This is an additional cost due to the Internet connectivity that must be motivated and provide an additional value. Furthermore, as high-wattage IoT devices start offering flexibility services to the electricity grid, they become a critical part of the electricity infrastructure. This also includes all involved companies in the supply chain. Hence heat pump manufacturers will face a new set of challenges.

5. Discussion

The focus in the study is on technical aspects of the heat pumps with less focus on thermal comfort in the heated buildings, business models or to get the concept attractive for the heat pump owners. Some stakeholders were not included in the interviews (e.g., TSO and heat pump owners) and the study is theoretical and not based on tests or field measurements.

The benefits with the flexibility concept evaluated in the study is that all hardware needed to control the heat pump for demand response is already in place and several older heat pumps models have had the hardware for several years. This mean the investment costs to use heat pumps as a flexibility resource will be lower compared to the alternatives. It could make the potential for demand response from today’s heat pumps more rapidly accessible for aggregators. Additional hardware to control the heat pump or meters to measure the
electricity consumption will require larger revenues for short enough payback time and will slow the process significantly. But even if the hardware is in place, there are still several barriers to overcome before the system efficiently can be up and running. Standardization is important, to have the communication standardized will make it easier for the parties involved. The aggregators will know better what is possible to achieve and how to control their heat pump pool and the manufacturers will know what to implement in their control systems. In the longer run an international standard would be optimal, avoid developing different solutions in different countries.

To use many small units aggregated as a flexibility resource is new compared to what historically has been used, when balance services mainly were delivered by large electrical producers and large industrial units. Thus, the requirements need to be adopted to these new flexibility resources to give high enough functionality. One typical example is the low accuracy of electricity metering in heat pumps, meaning the measurement of delivered flexibility risk to be low. Today no villa heat pump identified has a dedicated electric meter factory installed. The first alternative method is to estimate the power consumption through the heat pumps inverter or with help from the operating temperatures, this is in the study shown to have low accuracy. The second alternative is to use the electricity meter of the building, but as it is metering the entire building it could have even lower accuracy than the estimations in the heat pump. High accuracy demand will thus be difficult to fulfill and if it later becomes mandatory it will likely erase older heat pumps as a flexibility resource, as it is costly and time consuming to add meters. Possibly aggregating large number of heat pumps could statistically increase accuracy, but that has not been investigated in the project nor how to validate that accuracy.

Heat pumps are distributed over the grid and can also be used to balance the power system locally. New local flexibility markets might be able to adapt their accuracy requirements more easily as they are under development and their needs are different. One example is the activation time, where the local markets have no frequency control need and the activation could thus be slower or even planned in advance. This means heat pumps could both deliver flexibility and at the same time decrease the risk of too low comfort.

Delivering flexibility to the power system is a new area for the heat pump industry and these new functions are outside their core business today. It is still open how the heat pump manufacturers are going to handle this new opportunity and how an aggregator can communicate through the heat pump ecosystem. Will any manufacturer see the benefit in taking the roll as aggregator themselves? It could mean more accurate control of the heat pumps as the manufacturer has superior knowledge on their different control strategies and heat pump types compared to any other player. Likely at least some manufacturers will distance themselves from controlling their heat pumps in non-comfort optimized way, which any demand response or flexibility solution will do, and simply let another company take the risk. Saving money and at the same time giving the heat pump owners lower comfort level is a delicate path to walk and could risk that company’s reputation.

The actual monetary incentive is still unclear with flexible heat pumps aiding the power system. Smart price adaption, meaning producing more heat at low-cost hours is not considered a real direct aid to the power system, but is still a clear and easily understandable way to save money. In Sweden this today normally means producing heat during the night and stopping or running the heat pumps at lower speed at least during the peak hours in the morning and early evening.

Giving the power system, on national level, help to manage congestions or loss of power production is already controlled with the products from Svenska kraftnät (the Swedish TSO), but economic model to distribute the income gained is still not fully mature. On local or regional level, the market is even more immature, there are a few research projects ongoing in Sweden.

6. Conclusion

The study has through expert interviews and literature review investigated the technical possibilities and constrains for a concept where residential heat pumps are aggregated and controlled via the manufacturers cloud solution to support the power system with flexibility. Depending on how the communication is done and how active the heat pump manufacturer wants to be, it gives the manufacturer a possibility to either forward the control signals to the individual heat pumps or to “translate” the control signals for the individual heat pump models. The manufacturers have the deepest knowledge about their products and how to control them, meaning they have the best possibilities to make the heat pumps react in the way asked for with lower risk for decreased comfort.

Technical experts from the four major heat pump manufacturers in Sweden have been interviewed in order to understand and discuss their opinions and knowledge in using heat pumps to provide flexibility to the power system and how to communicate flexibility information via their cloud solutions. The manufacturers are all on somewhat different levels or have different opinions in parts of the discussions, while there is consensus in
other parts. As a complement a lively digital workshop with the above-mentioned experts, experts from two grid owners, a grid owners association and the Swedish heat pump and refrigeration association was performed to get consensus on the needed solution and the obstacles still not overcome.

The experts from the heat pump manufacturers have common ground in how fast their heat pumps can be controlled to decrease or increase power consumption. The auxiliary electric heater can be controlled within a second, both for decreased and increased power consumption, but most likely they will need updated software to be used as a flexibility resource. On/off compressors can also be turned off within a second, but most of them need the brine pump to start before the compressor is allowed to start. This will delay the start with up to a minute. Variable speed heat pumps are significantly slower to control. From turned off to the wanted correct speed it will take several minutes, often the same is true when turning off the compressor. From a technical point of view the manufacturers claims that the requirements for the ancillary services FCR-N and FCR-D, where FCR-D has an activation time of 50% within 5 s, is possible for heat pumps to fulfill. While the requirements for FFR, with an activation time of 0.7-1.3 s, seems difficult.

Today’s heat pumps lack electricity meters, giving low accuracy to measurements of demand response delivered. VSD heat pumps normally have the possibility to measure the power consumption within the inverter controlling the speed of the compressor, while on/off compressors have no technical possibility built in to measure power consumption. The manufacturers estimate that the uncertainty of the power consumption of VSD heat pumps is ±2-10%. For on/off heat pumps the manufacturers state the uncertainty around ±10-20%. The uncertainty of the auxiliary electric heater is stated to ±0.5-5% if the voltage is known (as it usually is with VSD heat pumps), else the accuracy is lower.

Alternatives to standardize the communication between the aggregator via the heat pump manufacturers cloud services to individual heat pumps has been investigated. From a heat pump perspective EEBUS and OpenADR are promising. They are possible to use alone or in combination and are both open access and license free. To enable flexibility the heat pumps need to be remotely controllable, which as of now means controllable over the internet. This opens for cybersecurity risks, as for all internet connected devices. It is worth noting that cybersecurity cannot be addressed lightly in the heat pump industry as hacked heat pumps could, at least in the future, cause severe problems to the power system. This means heat pumps risk being used in cyber warfare. After the renewed Russian attack on Ukraine in February 2022 thousands of wind turbines in Germany were attacked and left offline [16], hence the threat is real and should not be underestimated.

Abstract

To reach the goal of decarbonization, the thermal loads of buildings are being electrified with the use of heat pumps in replacement of traditional fossil fuel boilers. In the European project HAPPENING, a cascade heat pump system has been designed for the renovation of a building originally heated by a gas boiler. Air-to-water heat pumps provide heat to a water-loop which is the source for a water-to-water heat pump used to produce domestic hot water and for different water-to-air heat pumps, located in the apartments, that cover the heating and cooling loads. The system is controlled with a model predictive control which aim is the optimization of renewable energy consumption. The performance characterization of the heat pumps and the system is crucial for the definition of such advanced control. In the “Heat Pumps Lab” of Eurac research, the system has been characterized in two phases. In this paper we present the first step which includes the investigation of the operational limits, the definition of a performance map and the calculation of the system performance. The second step is the dynamic whole system test where the system is installed in three climatic chambers: one for the external unit, one for the water-loop and one for the internal units.

1. Introduction

The decarbonization of the thermal load of building is a key factor to achieve the energy and climate targets since the heating and cooling demands cover near the 50% of the heat demand [1]. The heat pumps cover an important role in the transition of the electrification of the thermal load of the buildings and in the decarbonization process [1–3].

The proper design of the heat pump is important for the performance and therefore for the operational costs, confirmed by the evaluation of the monitored data [4]. For example, Li et al. [5] evaluated the impact of the storage volume identifying in 30–40 l/kW the optimal solution. Also, heat pumps are used in a hybrid system with gas boilers [6], thermal or electrical storages, and are coupled with solar energy (solar thermal or photovoltaic) [7,8]. In all these mentioned cases the proper control of the system is crucial for performance. Advanced control strategies can improve the COP in a range of 5 to 20% [9–13].

Introducing the heat pump system in a new building is simpler than in the renovation of a building since the design of the new building is integrated: the thermal loads are minimized, the space of the technical room is dedicated to the system, the distribution circuit is at low temperature and can be supply both heating and cooling loads, and so on. In this case one single stage heat pump can work with a good coefficient of performance. Instead, in the renovation of a building there are several barriers to overcome. A single stage heat pump could not satisfy all the requirements of the renovation.

In literature different cascade heat pump systems are presented where the refrigerant of the first stage exchanges heat directly with the refrigerant of the second stage through an intermediate heat exchanger. The
main advantage of a cascade heat pump is the possibility to reach high temperatures, with the downside that at low or medium temperatures a single stage heat pump can reach higher COP than a cascade heat pump [14–17]. The system design and control are important for the performance; for example, Le et al [17] show that despite a nominal COP 2.5 at 7/80 the system can perform with a SCOP of 1.4 using a storage, 2.1 with direct heating, and 1.9 with price-based control. In renovation of the building, cascade heat pump systems are able to cover the heating loads thanks to the high temperature.

The cascade heat pump system with intermediate water-loop has been developed in the H2020 project HAPPENING. The system is presented in the Section 2. The proposed system presents different advantages for building renovation:

- i) the distribution temperature is neutral minimizing the thermal losses of heat distribution; in addition, the efficiency is higher than the high-temperature cascade systems.
- ii) the distribution system is not replaced (reducing the renovation investment) with adding the possibility of covering the cooling loads independently for each room. Otherwise, a medium temperature terminal would require the replacement of distribution piping (due to a different nominal flowrate) or the change of distribution layout (with a three-pipes or four-pipes distribution).
- iii) in summer the domestic hot water demand can be balanced with the space cooling demand.
- iv) the source heat pump can be decoupled to the heat pumps that cover the loads.
- v) the storage can be managed to guaranty flexibility.

The advanced controllers can improve the system performance acting in these last two points. On the other hand, such systems require a higher investment cost. Therefore, the performance and those features should be guaranteed to justify the cost of such systems.

In the HAPPENING project, the system is installed in case studies and this paper presents the laboratory characterization of the same system in a smaller scale. This activity is used to validate the model used to develop the model predictive control [18]. The methodology for the laboratory characterization is presented in Section 3 while the results of the test on the heat pumps are presented in Section 4.

2. Description of HAPPENING cascade heat pump system

The cascade heat pump system developed with the HAPPENING project has been designed for the renovation of buildings originally heated by a gas boiler. The distribution system of the building is maintained while the generation system and the heat emission terminals are replaced by heat pumps. The system includes air-to-water, water-to-water and the water-to-air prototypes developed by Innova within the project. The heat pumps have different refrigerants: the air-to-water and the water-to-water have R32, while the water-to-air R290. The selection of refrigerants followed the phase down foreseen by EU F-Gas Regulation. In the Heat Pumps Lab of Eurac Research, the HAPPENING system has been reproduced in a smaller scale than the system designed for the demo case. The system considers the same units of the demo case except for the air-to-water that is a commercial unit with R410a already available in the laboratory. The results described in this paper refer to the commercial air-to-water unit and to the prototypes of water-to-water and water-to-air heat pumps.

Figure 1 shows the layout of the system installed in the laboratory. An air-to-water heat pump delivers heat at low-temperature to the water-loop through thermal energy storage. The temperature of the water-loop is controlled by a three-way valve connected to a collector that is the source for booster heat pumps. A water-to-water heat pump is used to produce domestic hot water charging a thermal energy storage while two water-to-air heat pumps control the air temperature covering the heating and cooling loads. The two water-to-air heat pumps are of a different size: the larger one is called WL400 while the other is called WL200.

In Figure 1 there are also identified the hydraulic modules (called energy hubs EH) that the laboratory uses to reproduce the control of the system. The figure reports only the used functionalities of those modules showing with a blue dotted line the control logic. Specifically, the EH7 controls the water-loop temperature, the EH8, EH9 and EH10 control the flow rate of the heat pumps. The EH2 on the secondary circuit simulates the DHW tapping, while in the primary circuit can be configured with different controls: P2 always running or running when there is a tapping, and V2 fully open or controlling the supply temperature.

Differently from the system proposed in Figure 1, the demo case has 15 dwelling and therefore the system presents three air-to-water heat pumps connected in parallel, higher capacities of the buffer and thermal energy storage, and the water-to-air heat pumps are installed in each room of the dwellings.
The whole system is tested according to two control strategies: one traditional and a model predictive control. The traditional control is obtained using the heat pumps set point: the air-to-water heat pump controls the return temperature (according to the blue-dotted-line of Figure 1); the water-to-water heat pump controls the storage temperature while the water-to-air heat pumps control the ambient temperature. From the validation of the system model, the model predictive control is developed to optimize renewable energy consumption [18]; then the model predictive control will be implemented in laboratory to control the system. Finally, the system with the model predictive control will be tested.

3. Method

The characterization of the cascade heat pump system was done in two phases:
- Test at component level
- Test at system level

The test at component levels was performed on each unit. The first aim of this activity is the definition of a performance map as a function of the compressor frequency, source temperature and flow rate, and load temperature. Another aim is the comparison of the measurements performed by the laboratory with the internal measurements of the unit in order to validate the algorithms developed by Innova for controlling the performance of the units. Finally, the operational limits of the units are investigated since the demo case can present some boundary conditions out of the nominal and design conditions.

3.1. Test at component level

The heat pumps have been configured according to the instruction of the manufacturer and the compressor frequency has been controlled with different levels.

Table 1 reports the different combinations of test boundaries for the test of the single heat pumps. The boundary conditions considered in the table investigate all the possible operating conditions in order to understand the limits of the units. The choice of the flow rate is explained in the following section for each heat pump.
Table 1. Test boundary conditions at component level.

Fig. 2. Installation in laboratory. a) Water-to-air heat pump WL200. b) water-to-water heat pump.

3.1.1. Water-to-air heat pumps

The water-to-air units have a different nominal flow rate corresponding to 480 l/h for the unit WL400 while 240 l/h for the unit WL200. The flow rates indicated in Table 1 are different to the nominal since the demo case is not able to satisfy the nominal flow rate of the unit WL400.

In addition to the points of Table 1, at source temperature of 25 °C and air temperature of 19 °C, the laboratory tested both units at 480 l/h and investigated the minimum flow rate accepted by the unit before presenting faults, warnings, or alarms.

The laboratory has measured the source water inlet and outlet temperatures, the water flow, the internal differential pressure of the source loop, air temperature and humidity, electric consumption and has record the internal registered read by ModBus connection.

In the laboratory installation we recreated a barrier to avoid air recirculation (bypass).
3.1.2. Air-to-water heat pump

The air-to-water heat pump was tested with the nominal flow rate defined according to the EN 14511-3:2018 [19] considering a fixed flow control and nominal condition 7/35 (1.95 m3/h). In addition, some the air temperatures of -15 °C and -7 °C were tested at the minimum speed of the circulator (1.4 m3/h) with the same hydraulic circuit. To measure the different capacities the frequency of the compressor has been limited acting on the internal registers of the unit.

The laboratory has measured the air temperature and humidity, load water inlet and outlet temperatures, the water flow, the internal differential pressure of the load loop, electric consumption.

3.1.3. Water-to-water heat pump

The test of the water-to-water heat pump has been performed with the nominal flow rate defined according to the EN 14511-3:2018. The load temperature indicated in Table 1 is the supply water temperature where the value at 58 °C has been defined to reach the maximum before presenting faults, warnings, or alarms.

The laboratory has measured the source and load water inlet and outlet temperatures, the water flows, the internal differential pressures, air temperature, electric consumption and has record the internal registered read by ModBus connection.

3.2. Theoretical performance of a cascade system

The equivalent COP of the system composed by two heat pumps connected in cascade, in the hypothetical absence of thermal losses between the exchange from one to the other, can be calculated according to the equation (1). The first heat pump has the subscript “1” while the second heat pump has the subscript “2”; Q is the useful heat, W the electric consumption and COP the coefficient of performance.

\[
COP_{\text{syst}} = \frac{Q_2}{W_1 + W_2}
\]  

(1)

Elaborating the equation (1), the system COP can be described as a function of the COP of the two heat pumps by expressing with energy balances Q and W as a function of COP and source heat.

\[
COP_{\text{syst}} = \frac{COP_1 \cdot COP_2}{(COP_1 + COP_2 - 1)}
\]

(2)

The equation (2) is used to evaluate the theoretical performance of the cascade system starting from the COP of the single heat pumps.

3.3. Test at system level

The performance of the cascade heat pump system will be performed with the whole system test procedure PLPE developed by Eurac [20]. The external unit of the air-to-water heat pump is installed in a climatic chamber that reproduces a six-day sequence representative of the year while the hydraulic circuits are installed in another climatic chamber conditioned at internal ambient temperature reproducing the technical room. The water-to-air heat pumps are installed in a calorimeter that reproduces the space heating and cooling loads.

Figure 3 shows the installation prepared in laboratory: in the left part there is the external unit of the air-to-water heat pump; in the middle there are all the components that are installed in the technical room as the internal unit of the air-to-water heat pump, the buffer and the thermal energy storage, hydraulic modules; in the right part there are the two water-to-air heat pumps WL200 and WL400 with the relative pumping hydraulic modules.
4. Results

4.1. Test at component level

4.1.1. Water-to-air heat pumps

In order to evaluate the operational limits in terms of source flow rate, in the first stage the two units were installed switching the supply and return piping and in a second moment the installation was corrected. With the wrong installation, the minimum flow rate was varying between 230 l/h and 260 l/h depending to the boundary conditions, while with the correct installation, the minimum flow rate was below 160 l/h.

The request for the demo case is that the unit can work between 200 l/h and 300 l/h even if the nominal flow rate of the unit WL400 is 480 l/h. To verify the effect of the flow rate, a specific test was performed with the water temperature of 25 °C and the air temperature 19 °C controlling the unit according three different capacity levels. Figure 4 shows that the effect of the flow rate is negligible if compared to the effect of varying the compressor speed, but the unit performs better with the nominal flow rate: indeed, the nominal flow rate is higher, and this means a lower temperature difference of the water circuit and therefore a better heat exchange in the evaporator of the heat pump.
The Figure 5 presents all the test points of the unit WL400 while the Figure 6 presents all the test points of the unit WL200. The figures are divided in four diagrams: in the top-left figure it is presented the heating capacity while in the top-right the COP; in the bottom-left figure it is presented the cooling capacity while in the bottom-right the EER. The performance factors are indicated as a function of the source temperature for different series of flow rates and air temperatures. In the capacity graphs it is indicated the frequency of the compressor of one of the four data series.

The operational limits of the units were investigated also in terms of source temperature. The source temperature of 40 °C in space heating as the source temperature of 10 °C in space cooling are not relevant application temperature for a water-to-air heat pump but this test allowed to investigate a wider possibility of the temperature control of the water loop. The COP and EER obtained in those conditions are really high thanks to the very favourable boundary conditions.
4.1.2. **Air-to-water heat pump**

The performance of the air-to-water heat pump presented in Figure 7 shows the heating capacity and the COP according to different compressor frequencies. The limits of the compressor frequency are indicated in one series of the graph. The cooling capacity has been defined only at nominal capacity.

The figure shows the compressor’s working range: below 2 °C the compressor does not reach the minimum frequency (since the capacity would be too low) and at 12 °C the compressor is at the top limited due to the high source temperature.

---

Fig. 6. Performance of water-to-air heat pump WL200.
4.1.3. Water-to-water heat pump

The water-to-water heat pump was tested at two load temperatures at supply temperature 45 °C and 58 °C, that was the maximum temperature identified during the test. This limit is higher than the declared maximum temperature.

Usually, the commercial heat pumps for domestic hot water do not provide a modulation in the preparation of the hot water even if the unit has an inverter (that is used during space heating). In the logic of controlling the system with the model predictive control, the water-to-water heat pump was tested with PLR of 50 %, 75% and 100%.

4.1.4. Cascade performance

Table 2 presents the COP calculation of the cascade heat pump system (COPsys) calculated from the COP of the air-to-water heat pump (COPa2w) as source and water-to-air (COPw2a) for the space heating load and water-to-water (COPw2w) for the domestic hot water according to the equation (2). The COPa2w is defined...
with the air temperature (Tair) and water temperature (Twater loop) corresponding as source/load boundary conditions. The COPw2a is defined from the water temperature to the ambient air of 22 °C. At the same time, the COPw2w is defined considering the temperature of the water loop as source and supply hot temperature 45 °C. The last column presents the COP of the air-to-to-water heat pump used as single-stage (COPa2w sg) to reach the 45 °C considered as supply temperature for the space heating and the domestic hot water; in this case the COP is not dependent from the water loop temperature. The supply temperature of 45 °C for the space heating is to represent a fan coil as heat emission device to have a similar installation of the water-to-air heat pump.

In the calculation of Table 2 we considered two temperatures of the water loop.

In space heating, the cascade heat pump system performs better than the air-to-water heat pump in single stage for air temperatures up to 7 °C; the only exception is at 12 °C. One consideration is that the second stage works with a lower condensing temperature since the second heat pump works with 22 °C of the air while the air-to-water single stage was supposed to work with fan-coils.

The differences between the cascade heat pump system and the single stage heat pump decreases for the domestic hot water. The motivation is that the boundary conditions are the same since both systems have to heat domestic hot water.

The COP presented in Table 2 are defined at full load and the performance of the cascade system can improve at part load conditions. This motivates the necessity of further investigate on the model predictive controller and the necessity of test in laboratory.

Table 2. Calculation of cascade COP and comparison with a single stage air-to-water heat pump.

5. Conclusions

The performance characterization of a cascade heat pumps system has been performed in the “Heat Pumps Lab” of Eurac research.

The system has been characterized in two phases; the first phase presented in this paper, we investigated the operational limits and have defined a performance map of each heat pump. With this data, we calculated the performance of the cascade heat pump system with intermediate loop and compared the system with a
single stage air-to-water heat pump. The results of the detailed performance map obtained in the first phases provided the possibility to the manufacturer to further optimize the units’ controllers. The part load performance has been improved to optimize the SCOP; in the water-to-air unit, the manufacturer improved the management of the ventilation and the supply temperature.

The second step of the laboratory characterization will be the dynamic whole system test where the cascade heat pump system is installed in three climatic chambers. In this test we will evaluate a traditional control strategy and the model predictive control developed with the HAPPENING project.

The performance of the cascade system is comparable to the single stage heat pump. Despite the higher cost needed for the installation and similar performance, the cascade system presents several advantages that are optimized with the implementation of the predictive controller: the domestic hot water can be balanced with the space heating during the summer season; the generation part can be decoupled to the loads; the management of the storages (thermal and electrical) guarantees flexibility and renewable energy utilization.

Feasibility Analysis for the Use of Retrofitted Air-Conditioners Using Thermal Energy Storage (TES) for High Ambient Temperature (HAT) Countries

Al-Hussain Othmana, Vikrant Autea, Daniel Bacellara

*aCenter for Environmental Energy Engineering, Department of Mechanical Engineering, University of Maryland, 3151 Glenn L. Martin Hall Building, College Park, MD 20742, United States

Abstract

In high ambient temperature (HAT) countries, summer temperatures exceed 35°C, degrading the performance of air-conditioning systems and straining power grids. In this paper, a feasibility analysis was conducted to investigate potential savings during the peak using latent Thermal Energy Storage (TES) at near room phase-change temperatures, replacing condensers, thus, minimizing temperature lifts. Weather data, building loads, and baseline air-conditioning systems data were gathered for Dubai. A transient vapor-compression model in Modelica was used to compare the COP, total power input and cooling capacity of the air-conditioner at peak hours when ambient temperatures range between 35 – 45 °C versus the TES-Phase-Change Material (PCM) melting temperatures from 22 – 28°C. The results indicate that the TES-PCM can enhance the system COP at the peak by a factor 1.4 and 2 for during for outdoor temperatures of 35 – 40°C, and 40 – 45°C, respectively. Lower melting temperature PCMs were able to reduce the required power input by 30-50%, with more savings occurring at higher temperature days. On the other hand, higher temperature PCMs enhancements were minimal especially at outdoor ambient temperatures ranging between 35 – 40°C. Improvements to the cooling capacity range from 8 – 18 % for the outdoor temperature range of 35 – 45 °C. An economic analysis was conducted to find the potential saving in utility costs for 30%, 60%, and 90% of the space cooling demands of Dubai, and find the trade-off points between utility savings and cost of PCM-TES implementation. If the peak loads are to be shifted by 6 hours daily, the percentage utility savings for the city is 18%. Using estimated costs of the PCM-TES, ranging from $200-500/kWh, the daily load shifting hours were estimated to range from 4 hours at the lowest cost systems to 2.5 hours at the highest costs.

1. Introduction

Globally, space cooling already consumes 20% of the total electricity to buildings [1]. In high ambient temperature (HAT) countries, challenges in providing sustainable cooling arise in residential and commercial buildings. Gulf Cooperation Council (GCC) countries are characterized as HAT given their extreme conditions during the summer as temperatures exceed 45°C during the day [2-3]. With such hot conditions, more power input is required by compressors to meet cooling demands, and reject heat to such extreme ambient heat sinks. This degrades the COP of air-conditioning equipment that can range from 10 to 30% depending on the refrigerant and cooling system installed [4-5]. Increases in power requirements, maximizes the strain on power grids, specifically during the peak, with air-conditioning being a major contributor to the power demand. For example, around 50% of the annual electricity demand in Dubai is consumed on air-conditioning [6]. With the continuous population growth and urban development, these demands will only grow, increasing carbon dioxide emissions as more powerplants will be required just to meet peak demands.

Thermal energy storage (TES) systems fitted with phase-change materials (PCMs) provide an opportunity to maximize the COP at peak conditions and shift the electrical demand on the grid during the day. There are several applications on retrofitted air-conditioning systems and buildings with PCM-TES systems. Chaivat & Kiatsiriroat [7] placed a thermal storage heat exchanger in return air duct precooling it prior to ventilation air mixing in Thailand. Using paraffin waxes that melt at around 20°C, the PCM was discharged at peak hours when the return temperatures are above 25°C, and recharged with cool air directly at the evaporator exit. Annual electrical cost savings of 9.1% were reported. Real et al., [8] connected PCM tanks to an experimental air-conditioning system through the means of secondary water loops for cooling. On the condenser side, the heat is rejected to the low-than-ambient PCM melting conditions (T_{melt} = 27°C) during the peak, increasing the COP by 36%. Implementations of solar photovoltaics to power the compressor in the vapor-compression were also added along the thermal energy storage tanks [7, 8].

In many studies conducted the TES-PCM systems were incorporated into a heat pump through the means of a hydronic secondary loop [9–11], whether on the indoor or outdoor heat exchanger. With the exception of Maaraoui et al., [14], where the authors proposed an air-refrigerant-PCM heat exchanger for heat pumps for heating residential buildings. The configuration of the retrofitted heat pump is to have the PCM tank charge at off-peak hours with low heat load, and only the PCM storage discharge the heat at peak conditions. The limiting factor of this design was the lower thermal conductivity of PCMs, resulting in a large HX. On the other hand, the PCM storage tank did last up to 2 hours during the discharge period, which can contribute to improving the annual seasonal performance.

In this paper, the authors propose the inclusion of the TES-PCM storage in the vapor-compression cycle, with the storage tank is both heated (discharged) and cooled (charged) directly with a refrigerant-PCM heat exchanger. For a 17.5-kW (5-tons) R-410A air-conditioning unit, the ability of several PCMs with near-room melting temperatures ranging between 22-31°C were assessed as replacements for the condenser during the peak for Dubai, UAE. The TES-PCM storage will operate as the condenser for 4-hours during the peak. Using a commercial building prototype, building load data were obtained and a transient model on Modelica was used to predict real-time electrical loads. Using the retrofitted vapor compression cycle, the potential electric savings during the peak hours were assessed, along with their corresponding increases in COP and cooling capacities. Furthermore, the load shifting effect of re-charging the TES-PCM tanks were assessed, and city-level economic analysis was conducted.

2. Methodology

2.1. System Description

In this system, there are two configurations that are shown in Fig. 1. The first configuration (Fig. 1(a)) operation is twofold. The first is the conventional vapor compression cycle, that is running at off-peak conditions, with the TES system (represented as the thermal battery) is fully charged or charging. In this case, the air-conditioning system can provide cooling when lower building loads are there, not requiring excessive electrical demands, thus, not straining the electrical grid. The second operation of configuration 1 occurs when the PCM is partially or fully melted, the conventional cycle can be used to recharge the battery. This can typically occur when the indoor load at low, or no indoor cooling is required. In the second configuration shown in Fig. 1(b), the refrigerant flow to the condenser is eliminated and the high-pressure refrigerant is directed to the thermal battery. This occurs during the peak-hours when the outdoor ambient conditions are extreme 35°C or higher, or when the system COP drops. Given that the thermal battery consists of PCM with melting temperatures that are lower in temperatures than ambient conditions, there is potential to reduce the required power input from the compressor increasing the COP during these hours.

---

2
2.2. System Modeling

The TES-AC integrated cycle consisted of a variable-speed compressor, header microchannel heat exchangers for the evaporator and condenser, and an electronic expansion valve (EXV). The thermal battery model was adapted from the Modelica Standard Library [15], CEEE Modelica Library (CML) [16], Dhumane et al. [17], and Cao & Faghri [18]. The thermal battery model, was a conjugate heat transfer model, between the refrigerant and the PCM material through a material wall (CML [16]). The refrigerant heat transfer and pressure drops are already determined using the control volume available in CML [16]. The PCM transient model [17] considers the solid, two-phase and liquid region to obtain an equivalent specific heat \( (c) \), from the enthalpy of fusion \( (H_{sl}) \), solid \( (C_s) \) and liquid \( (C_l) \) specific heats. The equivalent specific heat in the mushy zone considers the average solid and liquid specific heats along with the enthalpy of fusion as per Cao & Faghri [18]. The melting range is assumed to be \((2 \times \Delta T)\), and \( T_m \) is the midpoint melting point in the melting range. An additional term \( s \) is a correction to the temperature difference to account for any additional changes during the melting and solidification process. Finally, the thermal energy release is predicted depending on the change in enthalpy \((dh/dt)\), and required PCM mass (Equation (1)).

\[
T^* = T_{pcm} - T_m
\]
\[
h = c(T^* + s)
\]
\[
c = \begin{cases} 
    C_s, & \text{if } T^* < -\Delta T \\
    C_s + C_l + \frac{H_{sl}}{2\Delta T}, & \text{if } -\Delta T < T^* < \Delta T \\
    C_l, & \text{if } T^* > \Delta T
\end{cases}
\]
\[
s = \begin{cases} 
    \Delta T, & \text{if } T^* < \Delta T \\
    C_l \Delta T + \frac{H_{sl}}{C_l}, & \text{if } T^* > \Delta T
\end{cases}
\]
\[
Q = \frac{dh}{dt} M_{PCM}
\]

To meet the required thermal battery loads of 17.5-kW for 4 hours, the total required loads were summed for the entire time period, over the material density and enthalpy of fusion for the PCM (Equation (2)). For salt-hydrate PCMs, the material densities, range between 1.2 to 2 g/cm³, with enthalpies of fusion ranging between 100-250 kJ/kg for room temperature PCMs [19]. The reason for selecting salt hydrates as opposed to paraffin waxes, is their higher energy density [19]. To ensure that the heat transfer loads are met at with PCM-TES in place, the overall UA’s is in the range of 3000-5000 W/K. In this paper, the following assumptions were made:

1. The PCM-TES UA was 3000 W/K given that this is most likely the least expensive design.
2. The PCM heat transfer coefficient was assumed to be around 10 W/m²K.
3. The enthalpy of fusion was 200 kJ/kg.
4. The initial PCM temperatures was 15°C, with the refrigerant pressure was around 2-MPa
5. The initial conditions in the indoor coil: pressure was 1-MPa, and temperature was 9.5°C
6. The initial conditions in the outdoor coil: pressure was 2.8-MPa, and temperature was 45°C

\[
V_{PCM} = \frac{\int_0^{4h} \dot{Q} dt}{\rho_{PCM} \cdot H_{sl}}
\]

The variable speed compressor model, consists of multiple 10-coefficient maps each corresponding to a frequency level. The model switched between the maps based on the required cooling capacity from the building load. Similarly, the EXV model consists of a variable opening orifice, that is adjusted by the manufacturers pulse-capacity curves and degrees of superheat. The dimensions and properties of the microchannel evaporator and condenser were inputted in the CML [16] MCHX models.

Each configuration in Fig. 1 was modeled in a separate cycle, and the cycles were operating based on the required air mass flow rates for the evaporator (indoor coil) and condenser side (outdoor coil) (Fig. 2). When
the required cycles are off, the indoor and outdoor mass flow rates are set to near-zero amounts, according to a time schedule set by the building loads. During the day, the indoor mass flow rates are included based on the corresponding building load, and the outdoor mass flow rate is determined by the manufacturers' fan curves at the operating conditions. The remaining outdoor and indoor boundary conditions (temperatures and humidity ratios), were obtained from the weather data sets [20] and prototype commercial building models [21], respectively. When the thermal battery is discharging during peak hours, the only boundary conditions to the cycle are the indoor air temperature, humidity and mass flow rate (Fig. 3(a)), and during the charging stage the outdoor weather data, along with the operating air mass flow rate are the only boundary conditions (Fig. 3(b)). The prototype building model, in EnergyPlus [22], consists of a small office building with 4 office rooms and one corridor, with building loads around 15-18 kW. Using this building prototype EnergyPlus files [21-22] for Dubai along with the locations corresponding weather data, the required boundary conditions were obtained on the indoor coil of the Modelica model.

![Fig. 2: Conventional air-conditioning model](image)

![Fig. 3: Thermal battery cycle in (a) discharging mode during the peak, and (b) recharging mode during off-peak conditions](image)

2.3. Selection of Days and PCM Melting Temperatures

For the summer months, between May and September, the weather data [20] obtained was analysed to see the peak temperatures per day. From Fig. 4, the peak temperatures can be divided into two ranges: 35-40°C and 40-45°C. While there are other impacts on the building cooling demands, including indoor thermal demands, and outdoor humidity and incoming sun radiation, in this paper, the focus will be more towards the outdoor temperature, as the sole objective of the PCM-TES is to lower the temperature/and pressure lift in the air-conditioning cycle, thus reducing the compressor power during the peak. Three days were selected for each peak range.

In this study, three mid-point melting temperatures were selected (a) 22°C, (b) 25°C, and (c) 28°C. The outputs from each day was averaged for its corresponding peak temperature. According to the Government of
Dubai, the peak hours occur between 12:00 PM and 6:00 PM during the summer [23]. As the first step, the conventional air-conditioning model (Fig. 2) to assess the COPs during the 6-hour peak period. Based on the lowest COPs for these 6-hours, a 4-hour period was selected, and the thermal battery discharging model operation times were set (Fig. 3). Having the TES operate for 4-hour rather than the complete 6-hour period is due to the excessive mass of the TES system. As mention is section 2.2, enthalpies of fusion ranging between 100-250 kJ/kg, the mass of the PCM can range from 1,000-1,200 kg at 4-hours to at 1800-2,000 kg at 6-hours. That increase in mass can pose installation challenges along with the current lack of economic benefits over the entire 6-hours shown in Section 3.3.

3. Results and Discussion

3.1. Effect of the PCM temperatures on the conventional system

For a day with the peak temperatures ranging between 35-40°C (Fig. 5a), it can be seen that near room PCM temperatures have provided a significant increase in COP at the peak, from 15% at $T_{PCM} = 28^\circ$C to 51% at $T_{PCM} = 22^\circ$C. However, the improvements in COP for higher ambient temperature days (40-45°C) are significantly higher, shown in Fig. 5(b), with factors ranging from 1.6 to 2 of original system when the PCM melting temperatures are 28°C and 22°C, respectively. This increase in COP can provide an excellent opportunity to reduce the strain on the grid and provide a higher cooling capacity, especially during the peak hours at high ambient temperatures.

Fig. 5: Improvement in system COP for during the peak hours resulting from the thermal battery for PCM melting temperatures ranging from 22 – 28°C during the peak, when daily maximum outdoor temperatures are between (a) 35 – 40°C and (b) 40 – 45°C

Fig. 6 compares the reduction in the total power demand required by the air-conditioner for the two ambient temperature ranges. This power demand is the total compressor power input from the grid with the outdoor and indoor fans. In Fig. 6(a), the power demand increases from 9 to 11 a.m., given the increase of the building load, therefore increasing the compressor power. Given that at higher outdoor temperatures, the compressor requires higher power input to accommodate the required temperature and pressure lifts just to meet the
required cooling demands. As of such, the reduction in the total power during the peak hours (Fig. 6(b)) are significantly higher when the temperatures are 40-45°C compared to the lower ambient temperature cases. Furthermore, the reduction in the total is lower with the melting temperatures are higher. Another benefit of the retrofitted PCM-TES, is the elimination of the outdoor fan, therefore, eliminating the fan power consumed during the peak. Table 2 shows the percentage savings for each PCM melting temperature. For the higher ambient temperatures, one can see that the potential for power consumption during the peak is between 30 – 45 % of the conventional A/C system. This can be beneficial to high ambient temperature countries, given that such reductions can potentially eliminate plans of building more powerplants, just to meet the electrical loads during the peak hours.

Another reason for the COP improvements during the peak hours for the retrofitted cycle was the increase in the cooling capacity of the system (Table 1). The cooling capacity of the system ranges from 17-18.5 kW. This occurs as the pressure lift decreases, and the PCM thermal battery dissipating almost the same amount of heat at the condenser at a lower pressure, the refrigerant is entering the evaporator at a lower vapor mass fraction (0.15-0.19) than the conventional system (0.22). This has resulted in increases in the cooling capacity ranging from 8% to 18%. The highest increases in the cooling capacity occurs during the with the PCM melting temperature being 22°C, given that at these conditions the lowest pressure and temperature lifts are obtained. Furthermore, the percentage increase in outdoor temperature ranges of 40 – 45°C, given that the pressure and temperature lift drops are the higher in these cases as compared to the 35 – 40°C peak outdoor ambient temperatures. Therefore, the inclusion of thermal battery can provide another advantage as there is a lower need to oversize the air-conditioning system, especially at the summer peak conditions which can in turn have potential savings on the electrical grid.

3.2. Energy Required for Load Shifting

In this section, an assessment of the electrical load required to recharge or (solidify) the thermal battery during nighttime was conducted. This is important to quantify the estimated saving during the peak to the energy required to recharge the battery. Table 2 shows the required power consumption by the air-conditioning
system in kWh. The reduction in power input with higher PCM melting temperatures is due to the lower temperature difference between them and the outdoor ambient temperatures which are typically between 25°C and 30°C, along with the minor reduction in charging time between the different temperature PCMs (<400 seconds). The selection of PCM appropriate melting temperature relies mostly on the available savings that can be achieved during the peak, without having excessive recharge costs. While the cooling capacity for the three PCMs are close (17-17.5 kW), the choice of the PCM temperature effects mostly how much can be alleviated from the grid during the peak, without excessive energy when recharging. Looking at the saving of the PCM melting at 22°C, the savings along with the recharge power, it is acceptable to recharge that PCM with this power.

3.3. Economic Analysis

An economic analysis was conducted to assess to the potential savings for Dubai during the peak hours. This analysis can help predicting the expected savings from increases in meeting the city building more powerplants, just to meet the required cooling demands. According to the Dubai Electricity and Water Authority (DEWA), the peak electrical demand in 2021 was 9,204 MW occurring in August, when the outdoor ambient temperatures exceed 40°C. So far, the city of Dubai can generate 13,417 MW, with 89% of the power is generated through steam and gas turbines, and 11% is generated by solar photovoltaics [23].

Currently, air-conditioning is responsible for 50% of all the electricity consumed [6]. The thermal battery will consist of the PCM material and heat exchangers. However, even with the low cost PCM ($3-30/kWh [19]), current commercially available thermal battery technologies put their cost between $200-500/kWh [24], given heat exchanger material cost and assembly requirements. In this analysis, the objective was to identify the number of hours for the thermal battery to operate during the peak that can be used to reduce the demand cost for 30%, 60%, and 90% of the city, against the amount the estimated city cost of the thermal battery to meet that required demands.

Dubai has several powerplants (Table 3), with investments up to 6.6 Billion USD [26]–[29]. During the peak, it is assumed that all the powerplants are operating at full capacity, bringing the estimated cost during the peak at $0.49/kWh. According to DEWA [23], Dubai has a single utility rate per kWh, depending on the amount of electricity consumed per month. Fig. 7, and Error! Reference source not found., shows the estimated cost savings for 30%, 60%, and 90% of the city using the electrical space cooling demands of 2021.

For a PCM with a melting temperature of 22°C, Table 1 provides us with potential energy savings of a retrofitted air-conditioner with TES at two maximum outdoor temperature ranges. Using the meteorological data in TMY3, it was observed that on average during the summer the outdoor temperature exceeds 40°C for one hour during the day. For limited operation, the energy savings were calculated for this one-hour using the corresponding percentage reduction of 51%. For longer operating periods the total savings were calculated by a weighted average corresponding to the number of hours per year in the different temperature ranges. From this, we obtain the overall utility reduction estimate of 18% for the entire 6 hours, shown in Fig. 7 and Fig. 8. This brings the total savings electricity costs to $0.59 and $1.78 billion for 30% to 90% of Dubai’s space cooling demand reduction, respectively. That percentage saving is due to the single utility rate per kWh used, rather than having variable rate depending on the peak hours or non-peak hours. In all scenarios, 30% to 90%, the are annual cost savings that increase with more peak hour loads alleviated by the TES, that corresponds to electrical savings at the peak.

Fig. 7: Predict savings in the utility cost when using TES at against cost of $200/kWh of thermal energy storage per operating hours daily for 30%-90% of the AC requirements
Fig. 8: Predict savings in the utility cost when using TES against cost of $500/kWh of thermal energy storage per operating hours daily for 30%-90% of the AC requirements

The key challenge is to identify the point which is the trade-off between the cost of the PCM-TES and the number of hours the can be altered. Thus, the cost of TES/kWh is an important factor, and that lower cost TES systems are required, to increase the number of hours that can be used to load shift. For the lower bound of $200/kWh, it is logical to provide TES for 4 hours during the peak, which is the assumed number of TES hours in this study. More hours, will result in higher investment costs than the potential savings. At the higher cost of TES rates, the number of peak load hours shift will reduce to 2.4 hours and if an investment is done at this cost, the operation of TES should only be there at the highest temperature hours of the year. If a cost of $15/kWh of TES is achieved [30] the city of Dubai can provide TES for the entire 6-hour peak for 90% of its citizens at a $1.1 billion, giving a payback period of 2 years only, and not 10 years (TES cost $200/kWh).

3.4. Challenges with the retrofitted TES-PCM air-conditioning system

While the cost of PCM materials are quite low, there still remains challenges in designing and assembling a TES, especially for large applications. This is due to PCMs being constrained by their material properties. PCMs have low thermal conductivities, and a finite energy storage (~100 – 250 kJ/kg for salt hydrates) [19]. To get more thermal energy stored, more PCM is needed, however, the compactness of the TES system must not be affected, not to degrade the heat transfer. Increasing the PCM volumes and heat transfer surface areas, will result in increasing the internal volumes on the refrigerant side, therefore increasing refrigerant charge in the cycle, which is problematic for higher-GWP refrigerants and flammable alternatives. All these challenges can drive the cost of TES systems to increase. Nonetheless, with more research in the design, assembly, and demand for enhanced PCM-TES systems, the cost will start to decrease.

Retrofitting the air-conditioning system with the TES storage has several challenges. Firstly, if the available system has a single-speed compressor, designed for higher temperature lifts, reducing that temperature lift with the TES can potentially degrade the isentropic efficiency of that compressor, degrading the potential savings that can be achieved during the peak. Thus, a variable speed compressor may be used to operate at lower compressor RPMs to meet the building loads at lower temperature lifts, without degrading the isentropic efficiency. Secondly, explicit controls are required to ensure that the cycle can achieve a set point superheat and subcooling when operating with the TES, as lower the pressure and temperature lifts presents hurdles on both the condenser and evaporator obtaining subcooling and superheating. Finally, the air-conditioning refrigerant cycle will require a number of on/off valves to switch refrigerant flows between the outdoor condenser and the TES during peak hours, along with adequate controls to ensure that this switch can occur smoothly, without damaging any cycle component.

4. Conclusions

In this paper, a proposed retrofitted air-conditioning system with near to room temperatures PCM-TES feasibility was investigated for a city in a HAT country (Dubai). A transient model in Modelica was built and used to assess the potential power savings during the peak for a 17.5-kW R-410A air-conditioning unit, and the electrical loads required to recharge the PCM-TES. Using the typical meteorological year data, two types
of days were analyzed, days with peak temperatures ranging between 35 – 40°C, and others with peak temperatures above 40°C. For each outdoor temperature ranges, the COP, total power input and cooling capacity was assessed. For higher ambient temperature days, a PCM-melting point of 22°C, can result in COPs almost doubling, reduction in the power consumption during the peak by up to 50%, and increases in cooling capacities by 18% during the peak hours. As the PCM melting temperatures increase, the enhancements to the cycle during the peak hours reduces, especially when outdoor temperatures are below 40°C. From an economic standpoint, given the higher costs of PCM-TES/kWh, the number of hours for feasible application of PCMs can range between 2.5-hours per day ($500/kWh), to 4-hours a day ($200/kWh) for an entire year with capital investments ranging from $4 – 12 billion depending on the range of the city cooling load to be met (30% – 90%). With more research in the design and assembly of PCM-TES, its cost can further drop, reducing the capital investments into the system to a fraction of the current costs.

Cold Climate Field Demonstration of Variable Refrigerant Flow (VRF) Heat Pump and Variable-Air-Volume (VAV) System

Patricia F. Rowleya*, Alex Fridlyand, PhDa, David J. Schroeder, PhDb, Shawn Scotta

Abstract

Heat pump variable refrigerant flow (VRF) systems are increasingly used in U.S. small commercial buildings to provide cost-effective efficient heating and cooling for multi-zone applications. The complexity and customized design of VRF systems for specific buildings make it difficult to predict energy savings relative to other HVAC systems. Due to limited VRF field data, especially in colder climates, energy savings are often based on energy modeling or laboratory data obtained under controlled conditions. A field demonstration at Naval Station Great Lakes (NSGL) in Illinois offered a unique opportunity to directly compare measured performance data for a VRF system to the baseline variable-air-volume (VAV) system for the same building. The objective of this demonstration was to evaluate the performance of two VRF systems: an electric cold climate heat pump and a natural gas engine-driven heat pump in a side-by-side installation for a small office building compared to the existing VAV system. This paper will focus on the benefits and limitations of the electric CCHP VRF system compared to the baseline VAV system for cold climate applications. The VRF system paired with a dedicated outdoor air system (DOAS) significantly reduced the facility peak electric demand, greenhouse gas emissions, and energy costs compared to a conventional VAV system.

1. Introduction

GTI Energy conducted a field demonstration of two side-by-side heat pump technologies with variable refrigerant flow (VRF) at a small office building at Naval Station Great Lakes (NSGL). This demonstration compared the installed performance of an electric cold climate heat pump (CCHP) VRF system and a natural gas engine-driven heat pump (GHP) VRF system relative to the baseline performance of an existing variable-air-volume (VAV) system for the same building. The objective was to quantify the energy use, economics, and qualitative benefits of each technology for cold climate DoD applications. Parameters evaluated included natural gas and electric consumption, peak electric demand, primary energy, full-fuel-cycle emissions, lifecycle costs, and simple payback. Additional details on this demonstration are available on the Environmental Security Technology Certification Program (ESTCP) website. [1] This paper will focus on the benefits and limitations of the electric CCHP VRF system compared to the baseline VAV system for cold climate applications.

2. Cold Climate VRF Heat Pumps and DOAS

The selected demonstrated site was a multi-zone office building, a common application for VRF technologies. Heat pump VRF technologies are well suited for multi-zone building types including schools, retail, hospitals, and hotels. VRF systems are often paired with dedicated outside air systems (DOAS) that provide ventilation directly to the conditioned space. For this configuration, DOAS capacity and air flow are sized to meet the ventilation requirements for each zone and to deliver supply air at space neutral conditions. VRF fan coils are used in place of the VAV-boxes to meet the remaining internal and skin loads of the building providing heating and cooling to meet the thermostat setpoints for each individual zone.

Electric VRF heat pumps are a mature technology with several U.S. manufacturers offering products, but have yet to achieve the 30%-50% market share they currently have in Asia and Europe. VRF systems are increasingly used for multi-zone commercial buildings, driven by the potential for energy savings, economic benefits, and improved comfort with zoned temperature control. Studies report energy savings up to 30% compared to conventional HVAC systems [2]; however, energy savings are typically based on manufacturer data and modeled building energy use. Due to the custom nature of VRF installations, direct comparisons of energy use and economics can be difficult to quantify. In addition, the performance of all air source heat pumps varies significantly with ambient temperatures, so performance and energy savings for one climate will not be the same as a different climate.

VRFs are typically installed in warm climates that benefit from their high cooling efficiency. In colder climates, VRFs are often installed in heated mechanical rooms or with backup electric resistance heaters increasing installed costs and reducing energy savings. [4, 5]. Recently manufacturers have introduced cold climate versions of electric VRF systems without supplemental heating. Additional field studies are needed to validate modeled energy savings for VRF systems, especially in colder climates.

3. VRF and DOAS Field Demonstration

This demonstration provided detailed field data on the installed cold climate performance for both the baseline VAV system and an electric CCHP VRF system. A full calendar year of baseline data was used to characterize the performance of an existing VAV system across the full range of heating and cooling loads. The VRF systems were then installed at the field site and monitored from October 2017 to May 2019. These datasets provided a direct comparison between the VRF systems and the baseline equipment to quantify their relative energy savings and site-specific life cycle costs (LCC). Qualitative benefits, such as reliability and comfort, were also addressed.

3.1. Field Site

NSGL, located in northern Illinois in ASHRAE Climate Zone 5, was selected for this cold climate demonstration with cold and moderately long winters averaging 131 days/year below freezing and -5°F design temperature. Based on NOAA 30-year normals, this location averages 1078 cooling degree days per year (CDD55) and 4362 heating degree days per year (HDD60) [3]. Shown in Figure 1, the field site was a single-story multi-zone office building with an existing conventional VAV system. The north wing, circled in red, was selected for the demonstration due to symmetric zones and higher heating loads. The north wing was divided into two equivalent sections with similar zones and thermal loads. One section was served by the electric CCHP VRF while the other was served by an equivalent GHP VRF system.

The baseline HVAC system was a ground-mounted VAV system with 500 MBH modulating gas heating (80% Te) and 30-tons electric cooling (9.5 EER). The system included 19 VAV-boxes with electric resistance reheat to provide zone temperature control. Historic utility data for the total building indicated the system capacity was about twice the typical heating and cooling load.

Two 2-pipe heat pump VRF systems were specified as retrofit equipment for this application. A total of twenty cassette-style VRF fan coil units were installed above the ceiling panels throughout the building. The VRF systems were paired with a conventional DOAS to provide ventilation with gas-fired heating (80%Te) and electric DX cooling (11.3 EER) sized to match the baseline ventilation rate (800 cfm). For cold climates, gas heating is needed to meet the required temperature rise for conditioning 100%OA. The DOAS delivered conditioned air at 64°F (17.8°C) directly to each zone via ceiling diffusers. The DOAS was able to use the existing ductwork which significantly reduced installation costs for this site.
Fig. 1. (a) A multi-zone office building selected for the cold climate demonstration site. (b) The demonstration VRF/DOAS replaced a VAV system serving the north wing, circled in red.

To ensure proper sizing, the design engineering firm developed load calculations based on code-required minimums taking into account a range of DOAS setpoints based on a 60°F (15.6°C) supply temperature to address outdoor latent loads during the cooling season and a neutral 70°F (21.1°C) during the heating season. A 10% safety factor was added to both heating and cooling capacities. Due to its reduced capacity at lower ambient temperatures, the electric CCHP outdoor unit was oversized to meet the heating load at the coldest design conditions. A 12-ton CCHP outdoor unit was paired with approximately 8-ton VRF indoor fan coil capacity.

3.2. Measurement and Verification Approach

3.2.1. Baseline HVAC Monitoring
Gas and electric consumption of the existing VAV system was monitored for a full calendar year. Outdoor air, return air, and supply air temperatures were also measured. Room temperatures and relative humidity were monitored in each conditioned zone to quantify any significant changes in comfort.

3.2.2. Demonstration Monitoring
The CCHP VRF was instrumented with gas and electric meters to measure energy use. One compact watt meter monitored total electric consumption at the outdoor condensing unit; a second watt meter measured the total energy use for the indoor fan coils. DOAS air temperatures, gas and electric consumption were also monitored. The efficiency of the VRF system was calculated by the ratio of total energy (heating and cooling) delivered to total energy consumed for a given period. Due to the design of the cassette-style VRF fan coil units, it was challenging to accurately measure the supply and return air to calculate the total energy delivered by the individual fan coil units to the conditioned space. An alternative approach was used to monitor the total heating and cooling delivered by the VRF system by measuring changes in enthalpy at the refrigerant lines, as shown below in Figure 2.

A Coriolis flow meter was installed in the liquid refrigerant piping to measure the mass flow rate of the refrigerant delivered to/from the indoor fan coils. Thermocouples and pressure sensors were installed in the refrigerant lines adjacent to the outdoor unit. Enthalpy of the liquid and vapor refrigerant was calculated based on R410A properties using the National Institute of Standards and Technology Reference Fluid Thermodynamic and Transport Properties Database [6]. Heating or cooling delivered was calculated based on the enthalpy change between the vapor and liquid refrigerant lines. In previous studies, this method of measurement was successfully validated through comparison of measured field data to laboratory data at similar conditions. This approach improved accuracy and reduced M&V costs compared to air side measurements at each fan coil unit.

3.3. Data Analysis
Data was recorded at 5-minute intervals and downloaded remotely via a cellular modem to provide real time access to performance data. Measured performance data was collected for a calendar year for both the baseline and VRF performance and then normalized based on heating and cooling degree days and the total measured space conditioning load.
3.3.1. Baseline Performance

Measured energy use for the baseline VAV system was highly correlated to heating and cooling degree days. As shown by the graph on the left in Figure 3, cooling energy use was linear with respect to cooling degree days, base temperature 60°F (15.6°C). For heating, natural gas and electric consumption was also linear with respect to heating degree days, base temperature 55°F (12.8°C).

During heating operation, energy use for the VAV-boxes was higher than expected. Electric resistance heating provided by the VAV-boxes is designed to provide only trim heating and to adjust temperatures between zones. Baseline data shown in Figure 4 shows the VAV-boxes at peak electric heating (orange) while the outdoor unit’s modulating gas burner (blue) operated at low fire. Per the manufacturer, a building automation system (BAS) is required to integrate the controls for the gas burner and the VAV-boxes reheat elements. Without a BAS, the outdoor unit and VAV-boxes operate independently resulting in excess electric resistance heating and higher peak electric demand. This may be typical operation for smaller buildings or sites without a central BAS.

Fig. 2. (a) Pressure and temperature sensors in the refrigerant lines (circled in red) were used to calculate total heating/cooling delivered. (b) Coriolis meters (circled in yellow) measured the mass flow rate of the liquid refrigerant.

Fig. 3. Graphs show the baseline VAV measured energy use correlated with (a) cooling degree days and (b) heating degree days. VAV electric reheat consumption was higher than expected during heating (shown in gray).
3.3.2. VRF Cooling Performance

In addition to offering higher cooling efficiency, VRF provides zoned cooling eliminating the over-cooling and reheat energy used by VAV systems. Figure 5 shows the measured energy use of the CCHP VRF and DOAS with respect to cooling degree days. Performance was based on a limited dataset due to unrelated component issues and operational outages. Daily average cooling efficiency ranged from 13 to 25 EER, exceeding the specified 12.3 EER rating for 95°F (35°C) due to milder ambient temperatures during this period. Cooling efficiencies decreased with lower part load. Part load for this assessment was calculated as the ratio of measured cooling delivered relative to the rated total capacity. Since the CCHP outdoor unit for this demonstration was oversized to meet peak heating capacity, the system operated at very low part loads (15% to 25%) during cooling. In addition, the DOAS operated with a 64°F set point year-round which reduced the building cooling load.

3.3.1. VRF Heating Performance

Figure 6 shows the measured energy use of the CCHP VRF and DOAS during heating correlated with respect to heating degree days. Daily average heating efficiency ranged from 0.5 to 4.0 COP, compared to manufacturer specifications of 4.1 COP at 47°F and 2.3 COP at 17°F.
Ambient temperatures had a larger impact on heating COP than part load operation (Figure 7). For this assessment part load was calculated as the ratio of measured heating delivered relative to the rated total capacity. Heating capacity and efficiency of all air source heat pumps decrease with lower ambient temperatures. For this demonstration, the CCHP did not meet the heating load for seven days at daily average temperatures at or below 16°F, shown circled in the graphs in Figure 7. This indicates the need for supplemental heating for this climate zone. The manufacturer-rated minimum temperature for this CCHP model is -4°F. For this region, the ASHRAE 99% design temperature is -5°F; however, during the demonstration ambient temperatures reached historic lows dropping down to -23°F due to the Polar Vortex in January 2019.

3.4. Energy Savings

To estimate annual energy and cost savings, measured energy use data was normalized to published Typical Meteorological Year version 3 (TMY3) cooling and heating degree days based on the National Centers for Environmental Information National Oceanic and Atmospheric Administration Annual Climate 30-year Normals (1981 to 2010) for Waukegan National Airport [3]. Energy use for the CCHP VRF system was normalized with respect to the total building load. Energy savings for the VRF/DOAS were calculated with respect to the baseline VAV system. Primary energy and full-fuel-cycle GHG emissions were calculated based on estimated annual energy use. Primary energy and full-fuel-cycle emissions takes into account all upstream energy used to generate power or to supply fuel to the building meter. Primary energy is a more comprehensive approach to evaluate energy use and may be more relevant to energy security for DoD facilities than the energy metered at the site. A growing number of codes and standards are adopting full-fuel-cycle metrics to quantify the environmental impact of different energy sources and appliances.
A summary of the results is presented in Table 1. The VRF/DOAS system had lower natural gas and electricity use compared to the baseline VAV, reducing primary energy use by 68% and full-fuel-cycle CO2e emissions by 70%. Modeled annual savings for VRF relative to VAV systems range from 20% to 60% for various climates [7]. These results are at the high end of the range due to higher than expected baseline energy use for the VAV system. The VRF/DOAS reduced summer peak electric demand from 43.2 kW to 14.5 kW. The VRF system provides very high efficiency cooling and eliminates the need for electric reheat used in the VAV-boxes. For heating, the baseline VAV peak electric demand (65.4 kW) is higher than expected due to the lack of integrated controls, as previously discussed; however, VRF/DOAS heating operation resulted in a high winter peak electric demand (36.8 kW), exceeding the facility summer peak demand. The peak electric demand in buildings is typically driven by electric cooling, but the use of electric heating creates a secondary winter peak. With the growing use of electric heat pumps, the winter heating peak demand is likely to exceed the summer cooling peak especially in cold climates.

3.5. Economic Assessment

Table 2 presents a comparison of annual O&M costs for the baseline VAV system and the CCHP VRF/DOAS. Total energy costs were reduced by 51%. Energy costs per square foot of the facility dropped from the baseline $2.21/sqft ($23.79/sqm) to $1.08/sqft ($11.63/sqm) for the VRF/DOAS. These energy and cost savings may be higher than typical cold climate applications due to higher than expected electric resistance heating for the baseline VAV system. Energy prices were based on incremental composite rates provided by the field site ($0.0559/kWh; $10.3037/kW; $0.49/therm). Utility demand charges and rate structures can vary widely from state to state. Demand charges for the field site were calculated from the highest hourly peak kW during the past 12 months, whether summer or winter. For this demonstration, the highest peak electric demand occurred during the heating season for both the baseline VAV system (65.4 kW) and demonstration VRF/DOAS (36.8 kW).

<td>$9,120</td>
</tr>
</tbody>
</table>

Assumptions: $0.0559/kWh; $10.3037/kW; $0.49/therm
Maintenance tasks for CCHP VRF systems differ from more central systems such as VAV. Some sources predict VRF/DOAS have higher maintenance costs than conventional equipment [2], while other publications expect similar or lower maintenance costs [8]. Increasing the number of fan coil units can significantly increase maintenance costs; however, the design for this field site included twenty VRF fan coil units which was similar to the baseline nineteen VAV-boxes. Maintenance for the baseline VAV included annual economizer and terminal unit maintenance, while VRF maintenance included biannual condensate system cleaning and filter changes for the fan coil units [2]. Based on conversations with the manufacturer and facility staff, it was assumed no other repairs or refrigerant replacement are needed over the 15-year equipment lifetime. For the economic assessment, maintenance costs were assumed to be similar for both systems.

Table 3 presents the incremental costs, LCC and simple paybacks for the CCHP VRF compared to the baseline VAV system. VAV installed costs were based on published estimates of $20/sqft ($215/sqm) [13]; a similar range of installed costs were found using R.S. Means. CCHP VRF equipment costs ($2.6K per ton) were based on invoices from the demonstration. VRF installation costs were based on mature market estimate ($6K/ton) plus a $20K engineering design. DOAS installed cost ($1.3K/ton) were based on 2016 R.S. Means. VRF/DOAS installed cost of $22.7/sqft ($454/sqm) and incremental cost of $2.73/sqft ($29.38/sqm) aligns with previous studies [2,7]. Note this includes the additional costs for oversizing the CCHP VRF system for a cold climate which is offset by recent reductions in VRF equipment prices. Based on this assessment, replacing a conventional VAV system with a VRF/DOAS in a cold climate has potential to reduce LCC by about $84,660 (25%) with a simple payback of 3 years. This does not include any equipment or energy use for supplemental heating.

4. Conclusion

This field study offered a unique assessment of the cold climate performance of an electric cold climate heat pump VRF/DOAS system for a multi-zone office building. Detailed measured field data allowed a direct comparison of the VRF/DOAS system with the baseline conventional VAV system to quantify their relative energy savings and economic benefits. These results can also be used to validate energy savings and cost savings predicted by energy modeling and simulation tools. Based on this demonstration, VRF/DOAS systems can reduce O&M costs and primary energy use (up to 50%) in cold climates. Several factors contribute to the VRF/DOAS energy savings. VRF with ductless fan coils eliminates duct losses associated with forced air HVAC systems. In addition to higher cooling efficiency, VRF can provide zoned cooling eliminating the need for over-cooling and reheat energy use. During heating operation, VRF trim heating is more efficient than electric resistance heating used in VAV-boxes. Likewise, the use of DOAS has multiple energy-saving benefits including more effective humidity control, less over-ventilation, and lower fan energy [9]. These savings may be higher than some sites due to the higher than expected energy use for the baseline VAV system when operated without a building management system.

This demonstration also identified some limitations for electric CCHP VRF systems. Despite the cold climate design and oversizing to meet the heating load, the electric CCHP required supplemental heating to maintain heating capacity for ASHRAE Climate Zone 5. Although the VRF/DOAS system reduced the summer peak electric demand at the field site, VRF/DOAS operation significantly increased the winter peak electric demand, much higher than the summer peak. For typical buildings, the peak electric demand occurs during the summer cooling operation due to electric air conditioning, but the use of electric heating can create
a secondary winter peak demand. With growing use of electric heat pumps, the winter peak demand is likely to exceed the summer cooling peak especially in cold climates.

Future research will focus on more efficient and cost-effective approaches to use supplemental gas-fired heating to enable electric CCHP VRF systems to operate in cold climates and to minimize the impact and energy costs of increasing winter peak electric demand.

Abstract

To reach the climate targets set for 2040, it is necessary to increase the efficiency of the building stock and foster the electrification of the buildings’ heating system. In this framework, heat pumps will play an important role, in the process of phasing-out fossils. Nevertheless, to enable the efficient operation of a heat pump for heating purposes, low supply temperatures are required. This means that the building should be renovated (i.e. to reduce the heating demand) and the emission system should allow for low supply temperature operation.

In this work, an overview of the development of energy policies in Europe is provided to show the requirements in terms of heating demand. In addition, the effect of the renovation deepness on the heating demand and heating load is shown using a reference multifamily building located in Potsdam (DE). For each renovation scenario, the room-wise heating load is calculated and the effect of the heating load reduction due to renovation in combination with different hypotheses for the sizing of the radiators on the design supply temperature and heat pump performances is described.

1. Introduction

1.1. Energy-efficient buildings - development of requirements

The European Union (EU) aim at limiting the environmental impact of buildings through specific policies ([1] presents a good overview of the history of European standardisation, while in [2] the overview is extended to standardisation in China and the USA). A clear example is the recast of the Energy Performance of Buildings Directive (EPBD) [3]. According to the EPBD recast, all new buildings must be nearly zero energy buildings (nZEB) by the end of 2020. Nevertheless, the definition of nZEB is up to each Member State. However, the common aspect is to achieve very high energy efficiency and to use as much as possible on-site (or nearby) renewable energy to meet the remaining low energy demand of the buildings. In addition, Member States should develop a methodology for cost optimality. The history of the definition of nZEBs in the European context is shown in Fig. 1.

The national nZEB definitions are quite different and hardly comparable [4] and in both Germany and Austria the current level of the requirements fail to achieve the goal of significantly improving energy efficiency in the building sector and thus reducing primary energy consumption and CO\textsubscript{2} emissions. Technical development would allow achieving the Passive House standard already 30 years ago demonstrating that the implementation of energy-efficient buildings does not present any technical hurdles. Calculated over the life cycle, such buildings are also more economical than buildings realised according to the current level of requirements [5]. Fig. 1 shows the development of energy efficiency requirements for buildings in Germany and Austria compared to the Passive House Standard. The heating demand was calculated based on a terraced...
house (Passive House Kranichstein). The first German standard dates to 1977, in which the maximum U-value of the individual building components was defined. This was followed by the Heat Conservation Ordinance (WSchV 95) that introduced the calculation of the energy balance and a maximum value for the annual heating demand.

If the tightening of the requirements had continued at the same pace, the maximum heating demand (HD) would have reached the passive house standard already in 2013.

The first Energy Saving Ordinance (EnEV) came into force in 2002 and replaced the annual heating demand as a criterion with the primary energy demand of the building compared to a reference building. In addition, non-renewable primary energy factors were defined.

In Austria, the development towards energy-efficient buildings took place somewhat later: based on the Energy Performance Certificate Act (EAVG) in 2006, the guideline OIB-6:2007 imposed a limit on the HD. The level was then tightened in 2010 and 2011. In 2014, the National Plan for the definition of nZEBs in Austria was published (the review took place in 2018). Since the introduction of the guideline OIB-6:2015, the so-called dual path (see Fig. 1 fgee and EEB) has been defined in Austria. With the new version of the OIB guideline, non-renewable primary energy is used as an indicator and excludes household electricity in residential buildings.

The requirements for the thermal quality of the building envelope have remained essentially unchanged since OIB-6:2007 (external wall max. U = 0.35 W/(m² K)).

Fig. 1: Heating demand according to the German legal framework compared to the passive house standard [6] and history of nearly zero energy buildings - nZEBs (Directive 2010/31/EC) [7].

In the United Kingdom the Energy Performance of Buildings (England and Wales) Regulations 2012 set the Energy Performance Certificates (EPCs) as a requirement whenever a building is built, sold or rented and, in some circumstances, refurbished. With the Energy Efficiency Regulations 2015, it will be illegal to lease buildings with a EPC rating of F or G [8], [9].

In Spain, the procedure for the calculation of the EPC are defined by Royal Decree 235/2013 [10]. The Royal Decree-Law 14/2022 foresee a wide range of energy saving measures (e.g. limitation of the heating and cooling set points to 19°C and 27°C respectively, encouraging electrifications and penetration of renewables, etc.).

In Italy, the EPBD 2002 was implemented with Decreto Legislativo 192/2005, which introduces the criteria and method for the calculation of the EPC. The DM 26/06/2015 define new rules for the calculation of the EPC and the minimum energy requisite for new and renovated buildings [11].

In Sweden, the Energy Performance Certification Act (Sw. Lag (2006:985) om energideklaration för byggnader) makes the EPC mandatory for certain building categories. A minimum standard (i.e. from A to G) is introduced for buildings classified after 1/1/2014. In 2020, the PBF and the BBR were revised tightening
also the requirements for energy performance for buildings. The Act (2006:985) on energy performance certificates for buildings as well as Boverket’s BED was updated in March 2021, regarding inspections [12].

As non-EU-country, Switzerland is not obliged to implement the EPDB, nevertheless Switzerland as member of CEN, agreed to adopt all EU standards [13]. The MuKEn 2014 define the sample regulation used as a reference for the application of the energy regulation in the different cantons.

In Belgium, the first EPB ordinance was defined in 2007. In 2015 a new ordinance (COBRACE) came into force, which transposes the EPBD 2010 [14].

A deep comparison of the nZEB implementation in different European countries is also presented in [4], [15] and [16].

1.2. Plus, zero or near-zero energy building

Various definitions of highly efficient buildings (i.e. good quality of the building envelope) in combination with a high share of renewable energy (usually PV) are in use with the aim of achieving zero, almost zero or plus energy. These definitions sometimes differ significantly with regard to the boundary of the energy balance (space heating, domestic hot water, auxiliary energy, household electricity) and the type of balancing. Plus, usually refers to net-plus, i.e. annual balance. This is possible in very efficient buildings such as the Passive House with a PV system of about 5 kWp; in multi-storey residential buildings, net-zero is usually no longer possible from about 4 storeys upwards if household electricity is also taken into account. It is important to pinpoint that a net-zero building still requires a considerable amount of energy from the grid in winter. According to [17], an NZEB could theoretically be a building with relatively high U-values and consequently a high heating demand having a correspondingly large photovoltaic (PV) system. Such an NZEB would generate a large PV surplus in summer while still having a high grid load during the heating period (so called ”winter gap”).

The final energy demand and primary energy demand of different building concepts and energy standards are shown in Fig. 2 [18]. In terms of primary energy demand for heating and domestic hot water (DHW), the Solar Active House with a specific limit value (based on the net floor area) of 15 kWh/(m² a) is slightly below that of the Passive House (i.e. 18.5 kWh/(m² a)), this considering that the building is supplied with a heat pump (HP) characterized by an annual performance factor of 2.4 (for heating and DWH purposes and including the losses of the storage and distribution system [19]).

![Graph showing energy demand comparison](image)

**Fig. 2:** Final energy demand (top) and primary energy demand (bottom) of different building concepts. The results are normalized with a reference area of 140 m². The following inputs are used for generating the results of the figure: domestic hot water (DHW) 25 l/d/P at 60 °C and 4 persons, no heat losses through distribution and storage; household electricity demand: 3500 kWh/a [18].

Passive House Institute set the limit on the primary energy to 120 kWh/(m² energy reference area a) for heating, domestic hot water, technical and household electricity requirements (incl. ventilation and auxiliary power). In addition, since 2015, the Passive House Standard is assessed with the indicator PER (Primary Energy Renewable)[20].
1.3. Role of Heat Pump

As highlighted in [21], heat pumps are the driving technology for the decarbonization of the heating in the building sector and it is foreseen that the number of heat pumps installed globally will rise from 180 million to 600 million in 2030. This in combination with the renovation of the building stock will enable the transition towards a higher share of renewable energy in the electricity grid (see also [22]). Heat pump is a very flexible and efficient technology that as exhaustively reported in [23] can work with different sources, can be applied at different levels (i.e. district, centrally building or block-wise, decentral flat-wise) and can be used for different services (i.e. heating, domestic hot water, cooling, mechanical ventilation in combination with an exhaust or extract air heat pump).

Nevertheless, some challenges have to be overcome to enhance the application of heat pumps. According to [21] the main challenges are: high upfront, operating cost and emission depending on the electricity mix, space restrictions, heating distribution system, low efficiency of heat pump in combination with high-temperature radiators, permission to install the external unit due to visual and sound reasons, social acceptance.

New heat pumps, with adapted refrigerants might help to improve the performances at higher supply temperatures [24]. Nevertheless, the COP will inevitably and drastically decrease as the temperature lift increases (see [25], Figure 58 for a comparison of performances at low and medium temperature level of heat pumps using different refrigerant fluids). In addition it is important to highlight that the performances of the heat pumps under real operating conditions are typically lower compared to the declared performances of the manufacturer [19].

2. Methodology

2.1. Reference Building

The reference building is a typical Austrian multi-family house composed by 3 floors and six flats of 56.8 m². The total net floor area of the building is 340.8 m² while the total energy reference area is 364.5 m². Within this work, the results will be presented using the net floor area as a reference. The walls of the building are made with hollow brick construction, while the roof and floor core construction are based on concrete concave boards.

In Fig. 3 the floor plans and one picture of this building are reported.

With regards to the weather data, the Test Reference Year (TRY) of Potsdam (generated using Meteonorm v8.1 [26]) is used for the analysis within this work (see Fig. 4).
2.2. Renovations

The renovation deepness is very heterogeneous in existing buildings, in fact step wise renovation are often performed. In [27] (see Figures 14-16) an analysis of the average U-values of walls, roof and windows for 45 buildings built between 1979 and 2005 is presented. From this analysis it can be seen that buildings built in the same period can be renovated with very different insulation levels. For this reason in this work, different renovation scenarios are considered for the envelope of the reference building and an overview is provided in Table 1, where the U-values of the building envelope are reported as well as the average U-value (i.e. Ht') considering an envelope area of 779.2 m² and the equivalent ventilation rate (which is reduced when a mechanical ventilation system with heat recovery is applied).

![Figure 4: Monthly average ambient temperature (black line) and monthly horizontal solar irradiation (red columns) for the TRY of Potsdam.](image)

</table>

The yellow marked cells of Table 1 highlight the changes made in one renovation case compared to the previous one to facilitate readability. The first case corresponds to a completely non-insulated building, the second case introduces a few centimetres of insulation material in all the structures and double-pane windows. In all the following cases other improvements to part of the envelope and/or the ventilation system are introduced leading to an always more efficient building. The only exception is between cases 6 and 7 where the envelope is improved but the ventilation system has no heat recovery. The set point temperature is considered to be 20°C.

2.3. Heating and Domestic Hot Water demand and Load calculations

For each renovation scenario, the building envelope is designed and the heating demand (HD) and load (HL) for the whole building and flatwise are calculated using the Passive House Planning Package PHPP [28]. In addition, the whole building is evaluated by means of dynamic simulation using the carnotUIB toolbox [29] developed in Matlab/Simulink to assess the dynamic heating demand (on 10 min basis) of the building throughout the whole year.

---

1. $H_t = \sum_{i=1}^{n} u_i A_i$ where $i$ are all the parts of the thermal envelope (i.e. walls, windows, roof, floor) and the thermal bridges.
2. To assess the real energy demand the prebound effect should be considered for low insulated buildings [35].
PHPP is a quasi-steady-state tool based on Standard ISO 13790:2008 [30] and it has been shown that it can accurately predict the HD of the building [31]. In addition, PHPP can calculate the HL of the building, but in contrast to the standard EN 12831-1 [32], it accounts also for heat gains and considers two different weather scenarios (i.e. cold and sunny day and moderately cold but overcast day).

Therefore, for the sizing process of the radiators, the room-wise heating load is calculated according to the standard EN 12831-1 [32] for each renovation scenario.

As regards the DHW profile, the tapping cycle M described in EN 16147:2017 [33] is used. A reduction factor of 0.625 (resulting in an energy demand of 3.7 kWh/(flat day)) is applied considering an average of 2.5 persons per flat resulting in the profile reported in Table 2. A supply temperature of 55°C is considered for the DHW preparation due to legionella requirements.

Table 2: Hourly useful energy demand for DHW preparation for the whole building.

| Hour of day | 1-6  | 7    | 8    | 9    | 10   | 11   | 12   | 13   | 14   | 15   | 16   | 17   | 18   | 19   | 20   | 21   | 22-24 |
|------------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|------|
| kWh        | 0.00 | 6.04 | 1.58 | 0.79 | 0.39 | 0.79 | 1.18 | 0.00 | 0.39 | 0.39 | 0.39 | 0.39 | 0.00 | 1.18 | 0.39 | 2.76 | 5.64 | 0.00 |

2.4. Dimension of Radiators and supply temperature evaluation

Three different scenarios are considered for the sizing of the radiators: radiators sized in the renovation scenario 1 with a supply temperature of 90°C, radiators sized in the renovation scenario 2 with a supply temperature of 90°C and radiators sized in the renovation scenario 8 with a supply temperature of 45°C. All of these three cases are calculated considering once the room-wise HL according to EN 12831-1 [32] without reheating power and once considering a reheating power of 12 W/m².

Since the radiator exponent could range from 1.2 to 1.4 depending on the radiator model and the temperature difference between supply and return over the radiator could range between 10 K and 40 K (except for the low-temperature radiators, where the ΔT could range between 5 K and 10 K) the sizing of the radiators for the different scenarios is performed considering 10 different exponents from 1.2 to 1.4 with a step of 0.02 in combinations with a ΔT ranging from 10 K to 40 K with a step of 10 K for the high-temperature radiators and ranging from 5 K to 10 K with a step of 5 K for the low-temperature radiators.

In the first step the radiators are sized for each room ($n_{el,room}$) using equations (1) knowing the room-wise reference HL ($HL_{Ref,room}$), the nominal power of each radiator element ($P_{nom}$), the radiator exponent $n$, the reference temperature difference (fixed to 50 K) between the average radiator temperature and the air temperature ($ΔT_{ref}$) and knowing the supply and return temperature to the radiator by means of equation (2) it is possible to calculate the logarithmic temperature difference $ΔT_{log}$.

$$n_{el,room} = \text{ceil}\left(\frac{HL_{Ref,room}}{P_{nom}}\right) \cdot \frac{1}{\Delta T_{ref}}$$

(1)

$$ΔT_{log} = \frac{(T_{sup}-T_{air})-(T_{ret}-T_{air})}{\ln\left(\frac{T_{sup}-T_{air}}{T_{ret}-T_{air}}\right)}$$

(2)

Sizing the radiator with different ΔT implies different dimensions (i.e. pipe diameter) of the distribution system as for a given reference power different ΔT are achieved by changing the mass flow. Therefore for every ΔT used during the sizing process, the diameter of the pipe serving one flat is determined using equation (3) considering a speed of 0.5 m/s. Considering that this system (distribution and emission) is kept constant during the following renovation steps it is considered that the water velocity can be increased up to 1.5 m/s avoiding noise problems but helping to reduce the ΔT and therefore the supply temperature after the renovation.

$$m_{flat} = \frac{HL_{Ref,flat}}{c_{water} \Delta T} = v_{water} \cdot \rho_{water} \cdot \pi \left(\frac{d}{2}\right)^2$$

(3)

For each subsequent renovation (with respect to the sizing case) knowing the HL of each room, and the number of elements of the radiator, the $ΔT_{log}$ can be calculated by reversing equation (1). Knowing the minimum and maximum water mass flow and the HL of the renovated flat, the $ΔT$ over the radiator can be determined inverting equation (3) and knowing $ΔT_{log}$ and $ΔT$ the supply and return temperatures can be calculated using equation (2).

---

1. This is fixed to 100 W as changing $P_{nom}$ will linearly influence $n_{el,room}$ without changing the final conclusions on the minimum required supply temperature. $P_{nom}$ influences the dimension of the radiator that is not fixed within this study.
At this point for each renovation case, a set (i.e. 44 cases for the high radiator temperature and 22 cases for the low-temperature radiator) of possible supply and return temperatures are obtained (considering the different sizing possibilities varying $\Delta T$ and $n$ and the mass flow rate). In the results section, for sake of simplicity, the minimum supply temperature (that will be obtained when the radiators are sized with the highest $\Delta T$, the minimum exponent $^4$ and using the maximum flow rate) and the maximum supply temperature (that will be obtained when the radiators are sized with the lowest $\Delta T$, the maximum exponent $^4$ and using the minimum mass flow rate) are shown and used for the evaluation of the heat pump performances.

2.5. Heat Pump performance evaluation

To estimate the impact of the renovation scenarios and radiator sizing on the performances of a central air to water Heat Pump (HP) a Carnot-based approach is used considering a conservative Carnot performance factor of 0.35 [23]. The building-wise heating demand for each time step (i.e. 10 min) is defined by means of the dynamic building simulation and the ambient temperature is known from the TRY. For each sizing scenario of the radiators (i.e. radiators sized in renovation scenario 1, 2 or 8 considering or not the reheating power due to intermittent operation) a maximum and minimum supply temperature is defined for each renovation scenario and this is used as a constant throughout the year in equations (4) and (5) to calculate the COP and electricity demand of the HP.

\[
COP(t) = \frac{\eta_{Carnot}}{T_{supply} - T_{ambient}(t)}
\]

(4)

\[
P_{el,HP}(t) = \frac{H_{building, sim}(t)}{COP(t)}
\]

(5)

Only the cases in which the required supply temperature of the heating system is below 60°C are considered compatible with a HP operation.

As regards the DHW preparation, equations (4) and (5) are used considering $T_{supply}$ equal to 55°C and instead of $H_{building, sim}(t)$ the DHW demand shown in Table 2 is used.

3. Results

3.1. Heating demand and Heating Load for the different renovation scenarios

Fig. 5 shows the HD calculated using the PHPP flat-wise (i.e. for each of the six flats), PHPP building-wise and by means of dynamic simulation for the whole building. From here it can be noticed that the annual HD predicted by the building-PHPP presents a good match with the annual results of the dynamic simulation with a relative deviation of maximum 8% for the renovation scenario 1.

![Fig. 5: HD calculated with the PHPP-flat-wise, PHPP-building-wise and by means of dynamic simulation for the whole building for all the renovation scenarios.](image)

In addition, it can be seen that the HD of the flats depends on the orientation (i.e. in this case south-north) due to the solar gains and on the position of the flat within the building. In fact, the middle flats present always

---

$^4$ Higher radiator exponent leads to a higher reduction of the radiator emitted power when the average radiator temperature is reduced. Sizing the radiator with higher $\Delta T$ for a fixed supply temperature leads to bigger radiators since they have to deliver the required power with a lower $\Delta T_{log}$. 

the lowest HD while the top and bottom flats have the highest HD. Insulating the roof in renovation 1 and 2 leads to lower HD of the top flats compared to the bottom flats. When also the floor is insulated (in step 7), top and bottom flats have similar HD. The best renovation scenario (i.e. 13) leads to a building HD of around 30 kWh/(m² net a).

Fig. 6 reports the HL calculated by means of flat-wise PHPP for all the renovation scenarios. Comparing Fig. 5 with Fig. 6 it can be noticed that the HD and HL follow the same trend. In addition, it is important to mention that in the case of installation of a decentral flat-wise HP solution the HL reported in Fig. 6 should be used for the HP sizing process.

Fig. 7 reports on the left-hand side (a) the HL of all the renovation scenarios calculated with the PHPP-building-wise, the building HL calculated room-wise according to the standard EN 12831-1 considering or not the additional reheating power and the maximum HL derived by means of dynamic simulation. While on the right-hand side (b) of Fig. 7 the load duration curves for each renovation scenario as a result of the whole building dynamic simulation are shown. The HL from the dynamic simulation reported in Fig. 7a corresponds to the maximum of the sorted HL in Fig. 7b (the maximum HL is only required for a few hours a year). From Fig. 7a it can be seen that the HL predicted by the building-PHPP match well with the maximum HL from dynamic simulation except for the renovation scenario 1. It is noteworthy to mention that the HL predicted by the building-PHPP is in average -40% compared to the HL calculated according to EN 12831-1 and -50% when also the reheating power is considered. This is justified by the fact that in the standard stricter conditions are applied for the calculation (i.e. no internal gains, non-heated neighbouring apartments, high ventilation rate, low ambient temperature). These boundary conditions represent the worst-case scenario in terms of HL, which is anyway unlikely to happen at least for long heating periods.

To avoid oversize the HP system, it is recommended to calculate the heating load also through dynamic simulation [34] or using the PHPP (that according to [31] is in good agreement with the results of the dynamic simulation tool). This is important to avoid, a reduction of the HP efficiency due to frequent “on-off” cycles. On the contrary, regarding the dimensioning of the heat emitters, it is recommended [34] to perform a room-wise calculation of the heat load based on the EN 12831. The power needed for the preparation of the DHW has also to be considered during the sizing process of the HP and this depends on the DHW demand, but also the storage capacity and HP operation.
3.2. Supply temperature

Fig. 8 shows the possible supply temperature span for each renovation scenario assuming that the radiators could be sized: in the renovation scenario 1 considering the additional reheating power due to intermittent operation of the heating system or not (i.e. Case_1+RH and Case_1), in the renovation scenario 2 (i.e. Case_2+RH and Case_2) and in the renovation scenario 8 with low-temperature radiator (Case_8+RH and Case_8), see also Section 2.4 for additional information. Each case is represented by a temperature span instead of a point as a possible range of radiators was considered (i.e. with different exponent n) sized with different ΔT and run with a range of mass flow that keeps the water speed between 0.5 m/s and 1.5 m/s. The renovation scenarios in which the radiators are installed are exemplarily chosen in this work. In reality, the radiators could be changed/installed in any renovation scenario and could be sized considering different supply temperatures leading to an even wider range of possible supply temperatures required in each renovation.

From Fig. 8 it can be seen that starting from renovation 8 to 13, a wide range of possible supply temperatures could be expected depending on the choice made in the previous renovations of the building. This range goes from low temperatures (i.e. around 35-40°C) up to 80°C (i.e. Case_2).

It is not recommended to apply a monovalent heat pump system if a flow temperature of more than 60°C is required, as its performance would be too low, however, new-generation heat pumps (e.g. propane R290) can reach flow temperatures of 70-75°C. For this reason, the performance of all cases that guarantee a flow temperature below 75°C has been calculated (see Fig. 8, Fig. 9 and Fig. 10). Another noteworthy aspect is that in some countries subsidies for heat pumps are only given if the design flow temperature is below a certain value (e.g. 40°C for Austria). It is important to mention that the temperatures reported in Fig. 8 are design temperatures required in the worst winter conditions and that during the heating season a weather compensation control could be applied reducing the supply temperature based on the ambient temperature allowing higher performances of the HP system and/or longer operation time.

Another aspect highlighted by the supply temperature analysis of Fig. 8 is that renovating only part of the building (e.g. the roof and west-wall from ren. 2 to ren. 3 see Table 1) leads to a reduction in terms of building wise HD and HL (see Fig. 5 and Fig. 6) but might not lower the HL of some rooms, which may then become the bottleneck for the definition of the maximum flow temperature (e.g. see ren. 2 ren. 3 in Fig. 8).

![Fig. 8: Design supply temperature ranges required in the different renovation scenarios considering different sizing conditions (i.e. Case 1,2,8 w or w/o reheating (RH)). The different radiator typologies (i.e. different exponent n) sized with different ΔT and considering different mass flows that keep the speed between 0.5 m/s and 1.5 m/s define the high of each bar.](image)

3.3. HP performances

Fig. 9 shows the annual electricity demand and Fig. 10 the SPF of the HP for space heating considering the different renovation scenarios (see Fig. 5 and Fig. 7b for annual and sorted heating demands of the different renovations) and the different cases for the design supply temperature (see Fig. 8). The calculation of the electricity demand and SPF of the HP is performed as explained in Section 2.5 considering a Carnot performance factor of 0.35. Only the cases that allow for a supply temperature below 75°C are considered to be compatible with an HP operation and therefore their results are reported in Fig. 9 and Fig. 10. From Fig. 9 it can be noticed that the reduction of the heating demand with increasing quality of the building envelope and

![Diagram with supply temperature ranges and SPF values for different renovation scenarios.](image)
ventilation system leads to a reduction of the electricity demand. Nevertheless, for some specific renovation scenarios (i.e. for the considered cases from 8 to 13) the electricity demand could be further reduced of 38% by reducing the supply temperature and therefore increasing the SPF (see Fig. 10). It is important to mention that the absolute difference in terms of electricity demand between the different cases of one specific renovation scenario is reduced when the heating demand is reduced making the building system more robust against non-optimal operation.

For all the renovation scenarios the domestic hot water (thermal energy demand of 23.5 kWh/(m² net a)) is prepared by the air to water HP with a constant supply temperature of 55°C leading to an SPF of 2.5 and an electricity demand of 9.3 kWh/(m² net a).

4. Conclusions

Within this work, an overview of the development of energy policies in Europe is provided to show the requirements in terms of heating demand. To show the impact of these regulations on the heating load and therefore on the required heat pump size and performance a multi-family house located in Potsdam (DE) is
used as a reference. Thirteen different renovation scenarios are analysed. These lead to progressively reduced heating demand and load, which is calculated on the building and flat level using the Passive House Planning Package (PHPP). The performance of the heat pump and the feasibility of installing this type of system in a renovated building highly depend on the required supply temperature, which is defined by the size and typology of the installed radiators and the design heating load. In this study, the room-wise heating load is calculated according to the EN 12831-1 for each renovation scenario and it is used as a basis for sizing the radiators (different radiator exponents, temperature difference for the sizing process and mass flow are taken into account) considering that high-temperature radiators might be installed in the non-renovated case, or in a slightly renovated case and low-temperature radiators might be installed on a moderately renovated case. Based on the different scenarios for the sizing of the radiators, a range of possible supply temperatures for each renovation scenario is defined. Finally, the performances of a central air-to-water heat pump with a Carnot performance factor of 0.35 are evaluated using the calculated supply temperature and the heating demand of the building obtained by means of building-wise dynamic simulations.

The results show that the heating load of the reference building, characterized by a net floor area of 340.8 m², can be reduced from 32 kW to 8 kW (the heating demand from 264 to 30 kWh/(m²a)) by means of thermal renovation of the building envelope and the introduction of mechanical ventilation. The heating load flat-wise, for the worst flat, decreases from 6.8 kW to 1.4 kW. This demonstrates the need of introducing more small-size (i.e., micro) heat pumps on the market as their demand in the future will increase.

The analysis of the supply temperature shows that to enable an efficient heat pump operation, it is necessary to have highly over-dimensioned radiators, very deep thermal renovation or to have at least a moderate thermal renovation in combination with a replacement of the existing radiators with low-temperature radiators. Depending on the installed emission system, for a given renovation, the SPF of the heat pump could vary between 1.7 and 3.2 leading to a reduction in electricity demand of up to 46%. As expected, the best efficiency is reached with the floor heating system. Also substituting the existing radiators with low temperature radiators (case 8) might highly contribute to improve the SPF. The worst scenario is represented by the case 2 (high temperature radiators installed during a partial renovation e.g., ren. 2). In this case, the radiators are only slightly oversized compared to case 1 (radiators sized for the non-insulated building — ren. 1), thus they do not allow for significant temperature reduction throughout the various renovation levels.

It is also important to remark that a high-quality thermal renovation not only allows an efficient operation of the heat pump but also makes the building-HVAC system more robust against non-optimal operating conditions.

In a future work, the effect of changing radiators only in the bottleneck rooms should be considered, the performances of the system should be analyzed also considering a reduction of the supply temperature throughout the year based on the ambient temperature and different heat pump typologies (e.g., air source or ground source heat pumps) with different performances should be included in the evaluation.

Abstract

A new innovative high temperature heat pump solution developed by GEA, ANEO and EPCON is presented in this paper: High efficiency and high temperature heat pump for generating steam in the processing industry. By using natural refrigerants ammonia and steam it is possible to ensure the highest possible efficiency without causing any potential harmful damage to the global environment. The heat pump harnesses the heat from the exhaust moist air from the drying process, air is cooled and dehumidified. It is important to dehumidify the air as a substantial amount of energy is latent energy in the moist exhaust air. Chilled water as low as 20 °C is needed for the energy extraction and a 2-stage ammonia heat pump is used as the first step to generate 85 - 90 °C steam. The dry steam is then compressed to the required steam pressure of 2 bar (around 120 °C) with 4 centrifugal fans in series. This multistage cascade solution gives a high efficiency and minimize the cost by combining two technologies (steam compression and ammonia compression) each operating in the application area where they are the best available technology and hereby achieving a temperature lift of 100K with a heating COP of 3.1.

1. Introduction

There is an increased focus on decarbonization of industrial processes. The first step in decarbonizations is reducing energy consumption. By closely looking at the whole process and establishing where the quick wins are that, without significant cost, can reduce the primary energy usage. Other improvements are to optimize the heat exchanged within the process and reduce temperature differential across heat exchangers. Many processes are designed for usage of 5 – 10 bar steam (150 °C to 180 °C) for all heating needs even if the temperature needed for the process, is well below 100°C. After energy reduction and optimization, the next step is to establish where waste energy from one process can be used in other parts of the process. This step often leads to installation of heat pumps as the waste energy often are at lower temperatures than required for the process. The many companies who are going through this process often see that most of their heating demand can be met with hot water circuit below 100 °C. This makes the heat recovery easy as it can be provided by standard ammonia heat pumps (preferred refrigerant within the food, beverage and dairy industry). With most of the process heating being decarbonized there is often still some heating demand above 100 °C, which so far have been provided by with either gas fired or electrical boilers. However, this can now be done more efficiently by using natural refrigerant heat pumps (although not ammonia).

Before starting to decarbonize production processes it is important to follow the right strategy. In the pyramid below is shown a sensible approach to decarbonization. The easy and most beneficial gains can be achieved from the bottom of the pyramid, by looking at energy efficiencies in the production. Next step is heat recycling. If the heat demand is large than what can recovered from waste heat the next step is to look for onsite heat generation like solar thermal of geothermal heat. If this is not an option then electrical boilers could

\textsuperscript{*} Corresponding author. E-mail address: kenneth.hoffmann@gea.com
be an option and finally the most expensive options of renewable fuels or offsetting emissions, which can achieve the decarbonization but at an added cost making the business less competitive.

Fig. 1. Decarbonization pyramid.

2. Refrigerants available above 100°C

Before developing a heat pump solution for delivering temperatures above 100 °C, we did an analysis of the available refrigerants for the market. From the table below is a comparison of some of the most common refrigerants considered for heat pump applications above 100 °C.

R245 have been around for 20 years and several projects with this refrigerant have been implemented for ultra-high temperature heat pumps (ultra-high = heat pumps delivering more than 100 °C). However, R245 have a global warming potential (GWP) over a 100-year period of 1030. In 2016 the UN countries agreed on phase down of all high GWP refrigerant in the Kigali agreement. Almost all countries have since ratified the agreement and made it local legislation. With a looming ban of high GWP refrigerants it does not make sense to invest in developing solution using these high GWP refrigerants.

R1233zd(E) is one of the new generation F-gasses with low GWP value (<5). This refrigerant has the benefit of being in safety category A1 (non-toxic and non-flammable), which broadens the application area. Unfortunately, the chemical includes Chloride molecules in it structure which is banned in some countries as it leads to ozone depletion (ODP) when released to nature. The ozone depletion is very low for the refrigerant and is registered as having 0 ODP according to UN protocol. The main consideration before applying R1233zd(E) refrigerant is that there now is increased focus on the degradation products of F-gas refrigerants. In Europe long chain Perfluoroalkoxy alkane (PFA) have been banned for several years due to their environmental damage and long life in the nature (also knowns as forever chemicals), but this has led to an increase in use of chemicals which breaks down to shorter chain PFAs. These chemicals have proven to be just as damaging to the freshwater environment as the banned PFA, so it is likely that there in the future will be a restriction in the use of chemicals which breaks down to any PFA. One of the breakdown components from refrigerants containing fluoride components are Trifluoroacetic acid (TFA) which is one of the chemicals which is defined as a PFA with short chain fluoride molecules. With these issues in mind there need to a clear efficiency benefit of using these refrigerants with focus on zero leakage system design and a plan for refrigerant recovery at the end of life, to minimize the environmental damage of the refrigerant in the environment.

R601 (Pentane), is one of the hydrocarbons recently identified as suitable for ultra high temperature heat pump applications. With a critical temperature of 196.6 °C, it is a suitable refrigerant for delivering hot water or steam above 160 °C. This refrigerant has the benefit of being a natural refrigerant with known environmental footprint. When comparing the thermodynamic specifications for the different refrigerants it has been proven
in previous papers that R601 offers a higher efficiency than alternative F-gas refrigerants. The main obstacle for a mass implementation of heat pump solutions with R601 is that it is in safety category A3, which is non-toxic but highly flammable. The high flammability will limit the applications where is can be applied.

R718 (water), have been proven to be a very efficient refrigerant and with a critical temperature of 373.9 °C, it is suitable for heat pumps delivering more than 200 °C water or steam. It is non-toxic and non-flammable and no environmental impact of the refrigerant. The main issue is the high boiling point at atmospheric pressure of 100 °C with the correlated high-volume flows in vacuum application as well as the high superheat generated during compression. An analysis of the food, dairy and beverage industry have shown that heat sources in general are below 100 °C, so steam compressors will have to operate in vacuum and with steam in vapor phase below 100 °C, there is a requirement for compressors with a large volume flow.

3. Heat pump application

Industrial food processes like sterilization, high temperature pasteurization or drying requires more than 100 °C heat supply. Outside the food industry there are more processes requiring higher than 100 °C steam like paper, pulp, chemicals etc. for many of these processes it is possible to provide the heat by heat-recycling as the heat added in the front end of the process in most cases can be recovered later in the process. In food processing where pasteurization or sterilization is needed, you will most likely have a refrigeration plant which is used to cool the products after it has been heated and the refrigeration plant reject waste heat to ambient in the process, this heat can via a heat pump be upcycled to the right temperatures for the process. For drying facilities there is not always a refrigeration plant as the drying process removes the moisture content from the product, which gives the product a long shelf life without the need for keeping it refrigerated. For drying processes, you often have large amount of waste heat in the exhaust air, as the air used for drying is collecting the moisture and being heated up across the product. By cooling the air below the dew point sufficient energy can be recovered to recycle the heat and use the exhaust air as the heat source for providing steam for the drying process.

In the diagram below is shown a schematic of a typical pet food pelleting process. The energy flow for pet food pelleting is very similar to a spray drying process. The pellets are formed by mixing the ingredients with process steam and pressing them into their final shape. Hereby the product/pellets are moisturized and heated. In the next process step the pellets are cooled and dried in countercflow with cooling air. The air becomes moist and warm in the process. This exhaust air is used as heat source for a the heat pump and the sensible as well as the latent heat is transferred into the ammonia heat pump. The 2-stage ammonia heat pump system generates low pressure steam at 85 °C. The steam is then compressed via 4-stage centrifugal fans to the required steam pressure for the mixing process of 2 bar.
4. Heat pump design

The pelleting process requires 2000 kg steam per hour at 2 bar (120 °C). As the steam is injected into the product, no steam is recovered, and all the steam needs to be generated from the make-up water, which is entering the heat pump at 4 °C. The factory also needs hot water at 85 °C for other consumers, which they would like the heat pump to provide in addition to the steam demand. The heat source is via a water circuit in the exhaust air stream. The heat exchanger in the exhaust air is designed for a water temperature supply temperature of 25 °C and return temperature to the heat pump of 31 °C. With an evaporation temperature of around 22 °C for the heat pump and steam delivered at 120 °C, it is close to 100K temperature lift, for this to be economically attractive the efficiency of the heat pump needs to be best in class.

To achieve highest possible efficiency of the heat pump system, different heat pump configuration has been considered.
1. Purely steam compression
2. Low stage: Single stage ammonia heat pump. High stage: steam compression
3. Low stage: Two stage ammonia heat pump. High stage: steam compression

4.1. Purely steam compression

There are different compression technologies available for steam compression, however there are large differences in the efficiency of these compression systems. For lower pressures (below 2 bar), the centrifugal turbo compressors have proven to offer the highest efficiency with an isentropic efficiency around 80-85% for the compressors. The centrifugal turbo compressors offer 9 – 10K temperature lift per compression stage for their standard range. There are centrifugal compressors on the market which almost double this temperature lift in a single stage. However, for smaller capacities the cost per kW is not economical for compressors with higher temperature lift and it is more affordable to have 2 compressors with smaller temperature lift. For a project of this size and temperature lift it is necessary with 11 – 12 MVR turbo compressors for the most efficient steam only system. Due to the cost and space requirement this solution was discarded.

4.2. Low stage: Single stage ammonia heat pump. High stage: steam compression

Low stage ammonia piston compressors have an isentropic efficiency of 88% at the chosen design point. Ammonia piston compressors is a price competitive solution with a small footprint and high efficiency. Figure 3 shows the application area for the GEA ammonia piston compressors. The graph shows that at an evaporation temperature of 22 °C it is not possible to condense above 80°C this will give a steam evaporation temperature of 76 °C and the compressor will be operating on the limits of its operation area. For delivering steam at 120°C, we would require 6 or 7 centrifugal compression stages, to lift the steam temperature from 76 °C to 120 °C. With the operational limitation in mind a 2-stage ammonia heat pump was considered.
4.3. **Low stage: Two stage ammonia heat pump. High stage: steam compression**

With a two-stage ammonia compression cycle it is possible raise the suction temperature of the high stage ammonia compressor, so it no longer operates at the limits of the application area. This also gives more flexibility of the suction temperature of the steam compressors. The steam evaporation temperature was set at 85 °C, with the ammonia heat pump able to increase this to 90 °C. This flexibility will give valuable information regarding heat pump design for future projects.

![Diagram](image)

**Fig. 3.** Application area for the VXHP compressor range, the limitations are: 1: minimum evaporation temperature, 2: maximum discharge temperature at full load when superheat is 0K, 3: discharge temperature with some cylinders disengaged, 4: maximum condensing temperature, 5: maximum evaporating temperature, 6: minimum pressure ratio

4.4. **Heat pump system description**

The heat pump is designed with a low stage screw compressor operating from +22 °C to +45 °C. The chilled water circuit is designed for 25 °C / 31 °C flow and return temperature. If the exhaust air has a higher moisture content or higher outlet temperature, it will be possible to extract sufficient heat with higher chilled water temperatures and approving the efficiency of the heat pump. The absorbed power of the low stage compressor reduces with approximately 2% per degree higher suction temperature. If it is possible to operate at 5K higher suction temperature it reduces the absorbed power with approximately 10% or 15 kW. The screw compressor will need a small amount of oil cooling to ensure sufficient lubrication ability. A high oil temperature will result in a lower viscosity and provide less lubrication, which can lead to increased wear of the compressor. Around 20 kW of oil cooling is provided by the chilled water circuit. Alternative ways of doing the compressor cooling were considered, like thermosyphon oil cooling or liquid injection into the discharge of the compressor. Each solution gives more heat recovery, but are also more difficult to operate, so as this is a trial installation, the system which is easiest to control have been chosen for the oil cooling circuit.

The chilled water circuit is also connected to the oil-cooler on the reciprocating high stage compressor. It is not necessary to have oil cooling of the high stage compressor during normal full load operation, but during part load it might be necessary. Both ammonia compressors are using the same oil.
The evaporator is a plate and frame in stainless steel AISI316L, in combination with the low charge separator it gives a good performance at variable working conditions. After the discharge from the low stage compressor the superheated discharge gas is injected into an open separator vessel below the liquid level in the separator to ensure the gas temperature in the vessel is not superheated. The saturated gas from the low stage screw compressor is compressed in the high stage piston compressor. The high stage compressor is a 6-cylinder high pressure compressor which is able to condense at up to 95 °C. It will be operating between the suction pressure of 45 °C and the saturated discharge pressure of 89 °C. The superheated refrigerant is condensed in a AISI316L stainless steel plate and frame cascade condenser/evaporator. Low pressure (0.58 bar) steam is evaporated in the cascade condenser/evaporator. Due to the large volumetric difference of liquid water and water vapor, 30% of the water entering the heat exchanger at the bottom is exiting the heat exchanger at the top together with the steam bubbles. To separate the water from the steam a separation tank is installed. The dry steam is compressed through 4 stages with centrifugal fans to the desired end pressure of 2 bar steam (120 °C). On the inlet side of the centrifugal fans is liquid injection to control the superheat of the discharge steam.

Fig. 4. Flow diagram for the complete heat pump system with both the ammonia compression heat pump and the mechanical vapor compression part.

4.5. Steam generation

With an ammonia design pressure of 60 bar and steam evaporating at 0.56 bar, it is important to select the right heat exchanger for exchanging energy between ammonia and water. Several different types of fully welded heat exchangers were considered. On figure 5 is shown 2 different solutions. The solution to the left has the heat exchanger plate pack within the water/steam separation vessel. This ensures practically 0 kPa pressure drop, which helps with the efficiency, however, there is concerns about potential deformation of the plates within the vessel, as there is no frame support at the end of the plate pack and with a pressure inside the plate pack of 60 bar, it seems like a high risk. To the right is a fully welded heat exchanger with a separation vessel on top of the heat exchanger, this gives a compact design suitable for the required water and ammonia pressures without any risk of leakages. The steam generated from the heat pump is injected into the product, so it is required to have fresh water through the heat exchanger, which for this installation raised concern regarding corrosion of the shell of the heat exchanger as the water would be in direct contact with the carbon steel shell. There was also concern regarding scaling of the heat exchanger, which can be solved by descaling the heat exchanger, but for heavy lime scale it might be necessary with a mechanical cleaning of the heat exchangers which is not possible with the fully welded plate and shell design. It was concluded that these type of heat exchangers are more suitable for closed water circuit systems, which is only fed by recirculated water and a small amount of ionized make-up water.
For this project a plate and frame heat exchanger were selected. The plates are welded together on the ammonia side and has gasket between the plates on the water side. This design also add further safety to the system as a potential failed welding of the plates will not leak ammonia into the water system and potential contaminate the products. The pressure drop on the water side is 4 kPa at full load operation, at the low-pressure operation (0.56 bar) this is equal to 1.5K temperature drop.

4.6. Cascade Steam Compression

The steam supplied from the Ammonia heat pump is further compressed to the required steam pressure of the process by a multi-stage Mechanical Vapour Recompression system (MVR-HP). For the MVR system vertical arranged high pressure centrifugal fans (so called MVR compact fans) are used. The MVR fans are characterized by a relative moderate pressure increase which results in a temperature increase of approximately 10K per stage. Since the process requires a steam pressure of 2 bar it is required to install 4 pcs MVR fans in series in order to increase the pressure from 0.56 bar (85 °C) to 2 bar (120 °C).

The compact fans are vertically arranged machines which are equipped with a frequency controlled direct drive and a high-speed motor. Depending on the operational requirements the MVR fans are rotating at up to 13,000 rpm.

Using water-steam in heat pump applications has in general two disadvantages compared to traditional refrigerants. The first is the high volumetric flow at low pressure applications, however this is compensated by the integration of MVR fans in this case. The second is the relatively high superheated steam temperature during compression, which is a consequence of the thermal properties of steam. Due to the 4-stage compression stages, hence moderate pressure ratio each stage, the steam flow is de-superheated by direct water injection. The injected water is hereby evaporated and is cooling the steam back toward the saturation line of the steam. The amount of injected water is controlling by the degree of de-superheating. The production process requires a certain amount of superheat, which is controlled by the water injection in the last stage. The total amount of injected water for the design condition is 150 kg/h and is increasing the amount of supplied steam.
For the presented case the efficiency and energy saving potential must be based on the combined energy consumption of the two heat pumps systems and the total amount of delivered energy: The combined COP considered in this case is the pre-heating of the feed water and the evaporation at low pressure and the required energy to increase the steam pressure to 2 bar. The total thermal capacity of the system is 1880 kW and consist of approximately 1464 kW for steam generation (equals 2 ton/h of process steam) and 416 kW preheating of feed from 4 °C to 85 °C. The electric power is defined as the shaft power of to the compressors. Auxiliary equipment is not included in the calculation.

To produce 2 ton/h of process steam the COP of the Ammonia heat pump is 4.5 and for the water compression is 7.5. This gives a combined COP of 3.1 for the total system for the steam production by the heat pump system from moist air.
The operational time of the system is estimated to be 5000 hours per year for the production site. Hence the system will deliver around 9.40 GWh of thermal energy per year. The alternative energy source is an electric steam boiler with an estimated 90% efficiency. The primary energy consumption for the heat pump solution is hence 3.03 GWh per year while the boiler would need 10.4 GWh or fossil; this gives more than 70% energy saving for the production process.

5. Summary and Conclusion

This project has led to a thorough evaluation of different refrigerant and heat pump technologies for providing steam at 120 °C for a commercial petfood manufacturer. Although several refrigerants are available for the temperature range, none of them offer the same longevity, flexibility, and efficiency as the chosen ammonia / steam combination. The chosen technologies are readily available on the market but have for the first time been combined to create a heat pump with a temperature lift from heat source to heat sink of close to 100K. Being able to reduce the energy usage from 10.4 GWh per year for electrical boiler to 3.03 GWh for the heat pump is key to the project being a success. Through the operation of the heat pump further optimization is expected for generating the best-in-class ultra-high temperature heat pump for the future.

Abstract

The additional subcooling of the refrigerant is an interesting way to improve the efficiency of the refrigerant system. On behalf of the Swiss Federal Office of Energy, the seasonal saving potential of using an external subcooler in a refrigeration machine considering application limits and plant specific conditions was investigated based on computer simulations.

The result of the investigation is presented as a guideline. With this method, a user can determine the optimum subcooling for his application with the given environmental conditions. By considering the operating limits of the refrigeration machine and the environmental conditions, the method can be used directly for the planning and adjustment of a refrigeration machine.

The results show that a refrigeration machine for air conditioning with a direct evaporator and the refrigerant R290 (propane) can significantly improve efficiency by using an external subcooler. There is an annual energy saving potential of 7\% if the external subcooler is used with cold wastewater.

1. Introduction

1.1. Related research on the subject

In compression refrigeration systems, subcooling of the liquefied refrigerant is an important issue that can affect the efficiency of the entire cycle. There are many studies in the literature that deal with the subcooling of the refrigerant. This concerns, for example, the type of subcooling that can be realized externally or by means of an internal heat exchanger. Experimental investigations on subcooling with refrigerants R134a and R1234yf have been carried out by Pottker and Hrnjak\cite{1}, who investigated the operation with internal heat exchanger regarding the efficiency. It was shown that the efficiency of a refrigeration cycle system with R1234yf can be increased up to 18\% by using an internal heat exchanger. With R134a, the efficiency could be increased by 9\%.

The choice of refrigerant has a significant impact, as various other studies have shown. Ansari et al.\cite{2} investigated the effects of subcooling on the operation of the refrigeration machine. They investigated the refrigerants R1243zf and R1233zd(E), which were not considered in our research. The results were compared with the performances of the refrigerant R134a and have shown that R1233zd(E) performs better with subcooling than R134a, while 1243zf is slightly less efficient both energetically and exergetically.

Furthermore, some studies have already been conducted on supercooling by ejector. Yilmaz and Erdinc\cite{3} investigated a new ejector subcooling system, where part of the refrigerant is expanded after the condenser.

The tests were carried out on seven different refrigerants. With a COP improvement of 20% and an exergy efficiency improvement of 18% the best performance was obtained by R1234yf.

1.2. Purpose of subcooling

Subcooling is necessary to avoid vapor bubbles (flashgas) in front of the expansion valve which is essential for stable and safe operation of the refrigerating machine.

Vapor bubbles before the expansion valve reduce the refrigeration capacity [4] and can lead to cavitation in the expansion valve, which can damage it. If the valve is operated in this condition for a longer period of time, there is a risk of wet operation, as the valve no longer closes completely due to the damage.

With electronic injection control, the amount of refrigerant injected into the evaporator is metered by means of an expansion valve so that the superheat at the evaporator outlet remains constant. The mass flow depends on the pressure difference across the expansion valve, the cross-sectional area, and the inlet density of the refrigerant. The expansion valve changes the cross-sectional area by its degree of opening and thus regulates the flow or the refrigerant charge level in the evaporator. If the refrigerant is not sufficiently subcooled, flashgas may form in the liquid line due to pressure or heat losses, which significantly interferes with the control of the injection rate. The influence of flashgas on the injected mass flow and superheat is shown schematically in Figure 1.

![Fig. 1. Influence of flashgas on mass flow and superheat](image)

The gas bubbles have a significantly lower density than the liquid refrigerant. If gas bubbles appear in the liquid refrigerant upstream of the expansion valve, the quantity of refrigerant injected is reduced without the opening position of the expansion valve having changed. This reduction in mass flow leads to an increase in superheat and the controller opens the expansion valve as a countermeasure.

If the proportion of flashgas at the inlet of the expansion valve is reduced, e.g., for a short time completely liquid, the mass flow increases due to the greater density, the superheat decreases, and the controller reduces the opening cross-section of the expansion valve as a counter-reaction. The system may start to oscillate and may no longer be stable [5].

1.3. Aim of the study

The investigations on additional subcooling were carried out for five different subcooling types, five different applications (each with different evaporating temperatures) and eight different refrigerants. All information and results on the investigations are given in the final report on refrigerant subcooling [6] (in German). This paper is limited to the investigation of subcooling with external subcooler for the air conditioning application with a direct evaporator (evaporating temperature of 10 °C) and the refrigerant R290.

The aim of the study is to present the result as a guideline. This allows a user to estimate the potential of additional subcooling in each case for his individual application and the given environmental conditions.
2. Methodology

2.1. Cycle with external subcooler

The investigations for this report were all carried out using computer simulations with MATLAB [7]. To show the influence of subcooling on the refrigeration circuit, a reference process with the same application and the same refrigerant, but without additional subcooling, is calculated in each case. Subsequently, the refrigeration circuit is supplemented by an external subcooler and calculated again. For a seasonal consideration, this procedure is repeated at different operating points. The comparison is shown schematically in Figure 2.

In the case of an external subcooler, the refrigerant is subcooled after the condenser (3) with an additional heat exchanger (4). The total subcooling ($SC_{\text{tot}}$) therefore results from the subcooling by the condenser ($SC_c$) and the additional subcooling by the external subcooler ($SC_e$). How much the refrigerant can be subcooled depends on the temperature and capacity of the heat sink of the external subcooler. The external subcooling increases the enthalpy difference at the evaporator ($h_1 - h_5$) and thus the refrigeration capacity. The operating point of the compressor and its power consumption remain unchanged. The efficiency of the chiller therefore increases with increasing subcooling. For a correct assessment of the efficiency, however, the required auxiliary energies must also be taken into account. The estimation of the auxiliary energies requires a consideration of the entire system. If the efficiency of another system is reduced due to the subcooling or if additional energy is used to ensure the heat sink (e.g. pump capacities), this must be taken into account. Only if the energy saving at the refrigeration machine is more than the required auxiliary energies, the efficiency of the overall system increases.

2.2. Operating points

The operating point of a refrigeration machine is defined by evaporating and condensing temperature. These are defined as follows:

The evaporating temperature $T_0$ depends on the application and is constant for all operating points. For air conditioning with direct evaporator, the evaporating temperature is $10 \, ^\circ\text{C}$. The influence of the vapor quality on heat transfer and distribution in the evaporator are not considered.

The condensing temperature $T_c$ depends on the ambient temperature and is therefore variable. To consider the operation of the refrigeration machine at different ambient temperatures, the simulations are carried out with five different condensing temperatures at intervals of $5 \, ^\circ\text{C}$ each. These can be seen in Table 1.

2.3. Parameters of the cycle simulations

Apart from total subcooling, the input parameters for the cycle simulations are identical in both cycles. Table 2 shows the parameters used for the simulations of the reference process and the process with external subcooler. While in the reference process the total subcooling is the same as the subcooling in the condenser, in the external subcooler the total subcooling is varied from 5 K to 25 K (in 5 K steps) at each operating point. How much the refrigerant can be subcooled depends strongly on the available heat sink. This can very differently, depending on the object. Therefore, different degrees of subcooling are investigated in this study.

2.4. Computer simulations

The investigations for this report were all carried out using computer simulations with MATLAB [7]. The fluid properties of the refrigerants were calculated using the software REFPROP [8]. The specific enthalpies are calculated for all four or five points of the cycle (see Fig. 2a and 2b). The specific enthalpy depends on the pressure and temperature of the fluid and can be calculated for each point. In the 2-phase area, this also allows the vapor quality to be calculated. Accordingly, the most important input parameters are the evaporation temperature $T_0$ and the condensing temperature $T_C$, which are listed in Table 1. With the extended cycle parameters of Table 2, the specific enthalpy is calculated for each point in the cycle. The process at the expansion valve (Fig. 2a): 4 $\rightarrow$ 5) is assumed to be isenthalp, so that $h_5 = h_4$ in each case (compare with Fig. 2b)).

The cooling capacity is calculated according to equation 1:

$$Q_0 = \dot{m} \cdot (h_1 - h_5)$$  \hspace{1cm} (1)
Since the mass flow $\dot{m}$ is the same everywhere in the refrigeration cycle with external subcooler as well as in the reference refrigeration cycle, the EER is calculated independently of the mass flow $\dot{m}$ according to equation 2:

\[
EER = \frac{h_1 - h_5}{h_2 - h_1}
\]  

(2)

The calculation of the EER is performed for both the refrigeration circuit with external subcooling and the reference refrigeration circuit without additional subcooling. The savings potential corresponds to the change in efficiency and is calculated according to equation 3. For all 5 operating points this procedure is repeated.

\[
\Delta EER = \frac{EER_{\text{External SC}}}{EER_{\text{Ref Process}}}
\]  

(3)

3. Limits of subcooling

3.1. Minimum subcooling

The minimum subcooling is essential for stable and safe operation of the plant. Whether this leads to an increase in efficiency is secondary. Subcooling can be reduced by pressure losses and heat inputs between the receiver and the inlet to the expansion valve. The pressure losses are composed of the static height difference between the header and the expansion valve and the pressure losses of the pipelines and fittings. The influence of pressure loss and heat exchange on subcooling (SC) is shown schematically in Figure 3.

Fig. 3. Reduction of subcooling for a) due to pressure losses, for b) due to heat input, and for c) due to pressure losses and heat input.

In Figure 3 the upper left section of the log p-h diagram is shown enlarged. In Figure 3a) the influence of the pressure loss, which is caused by pipelines, fittings, or lines with large height difference, is shown ($3 \rightarrow 3_{\Delta p}$). In case of pressure losses, the refrigerant temperature remains constant ($T_3 = T_3_{\Delta p}$). However, the subcooling reduces because the boiling temperature reduces due to the pressure loss ($T_3 > T_3_{\Delta p}$). In the plot of Figure 3b), the influence of heat exchange between the pipe and the environment is shown ($3 \rightarrow 3_{\Delta T}$). Heat exchange takes place through the piping and fittings. Depending on fluid and ambient temperature, heat input or heat output results for the refrigerant. During heat exchange, the pressure and thus the boiling temperature remain constant ($T_3 = T_3_{\Delta T}$). The subcooling changes as the refrigerant heats up or cools down further due to the heat exchange. In Figure 3c), the combination of pressure losses and heat exchange is shown. These two effects can compensate each other. Due to the pressure loss, the boiling temperature of the refrigerant is reduced. However, if the ambient temperature is lower than the fluid temperature, the refrigerant is additionally cooled via the tube wall.

The minimum subcooling is therefore dependent on pressure losses and heat inputs and is therefore very plant specific.
3.2. Maximum subcooling

The maximum subcooling is primarily about optimizing efficiency and therefore varies depending on the refrigeration machine. In particular, the influence of large subcooling on the piping components and the vapor quality must be considered.

The subcooling beyond the minimum subcooling is only useful if it can increase the efficiency of the system. This may vary depending on the subcooling method, operating control, and refrigerant. How much the refrigerant can be subcooled is limited by the vapor quality at the outlet of the expansion valve. The influence of subcooling on the vapor quality can be seen in Figure 4.

Increasing the subcooling reduces the vapor quality at the outlet of the expansion valve. Thus, the minimum vapor quality there defines a limit to how much the refrigerant can be subcooled. Figure 4a) shows the influence of the condensing temperature (operating point) on the maximum possible subcooling. A reduction of the condensing temperature also reduces the maximum possible subcooling. Figure 4b) shows that a reduction in the evaporating temperature (application) increases the maximum possible subcooling.

4. Results

4.1. Overview

The results of this investigation show the influence of different amounts of subcooling on the efficiency of the system. At the same time, different auxiliary variables are displayed, which are important for the estimation of the minimum necessary and maximum possible subcooling.

The combination of these factors allows a plant specific and seasonal assessment of efficiency improvement. Identical plots have been created for different subcooling types, refrigerants and applications. Therefore, auxiliary variables are also shown, which are not of interest for the assessment in the case of external subcooling. The plots can be seen in the appendix of the final report of the project [6].

Figure 5 shows the influence of additional subcooling on the efficiency as well as important auxiliary variables for a system with an external subcooler and refrigerant R290, for an application with $T_0 = 10 \, ^\circ C$ (air conditioning with a direct evaporator).
Figure 5 shows the result as an overview. The top left box shows the potential for EER improvement as a function of condensing temperature for subcooling values of 5 - 25 K. However, in order to determine the efficiency improvement, the limits of subcooling (top right box in Fig. 5) and the auxiliary variables (bottom box in Fig. 5) must also be considered.

The diagrams in Figure 5 allow a comprehensive assessment of the additional subcooling as well as the expected efficiency gain at different operating points. The use of the result, as shown in Figure 5, is described in the following subsection.
4.2. Interpretation and use of the result

To be able to use the result, the heat sink of the external subcooler must be known. As an example, a use of a cold wastewater, which allows cooling of the refrigerant to constant 15 °C, is investigated. The maximum possible subcooling, given by the heat sink, is thus dependent on the operating point and is between 10 - 30 °C. To estimate which subcooling or which efficiency increase can be achieved with this heat sink, the following three limits must be considered and drawn in the upper right diagram in Figure 5 (Limits) and are shown larger for explanation in Figure 6:

① Minimum subcooling

As described in chapter 4.1, minimal subcooling is necessary for safe and stable operation of the system. Based on the upper diagram, the minimum subcooling can be estimated due to the plant-specific pressure losses. In this example, a plant with large differences in height and therefore 2 bar pressure losses is examined. Due to the pressure losses a minimum subcooling of 6 - 9 K is necessary. This value can also be plotted in the lower diagram and shows the lower limit of subcooling.

② Maximum possible subcooling (Heat sink)

The maximum possible subcooling depends on the heat sink of the external subcooler and its seasonal behavior. In this case, the heat sink is cold wastewater, which allows subcooling to a constant temperature of 15 °C. As can be seen in Figure 4, a steady outlet temperature from the subcooler means different degrees of subcooling, depending on the condensing temperature. This is shown in the Figure 6 by line (2).
③ Maximum subcooling (vapor quality)

The maximum possible subcooling is limited by the heat sink. An additional limitation is the minimum vapor quality at the outlet of the expansion valve. In this case, a minimum vapor quality of 0.1 is examined. This value can be defined by the designer’s experience or by the expansion valve’s operating limits. This is shown in the Figure 6 by line ③.

Based on the three plant specific limits, a range of possible subcooling results. Between the minimum necessary ① and the maximum possible subcooling ②, which are determined from the pressure losses and the heat sink, there is a range of subcooling which is theoretically possible (yellow area). Considering the minimum vapor quality ③, this area can be further restricted.

At high condensing temperatures ($T_C > 31^\circ C$), both the minimum subcooling and the minimum vapor quality can be maintained. All operating points between the two lines are theoretically possible. For efficiency reasons, the optimum subcooling is as close as possible to the minimum vapor quality, provided those other auxiliary variables, such as the end of compression temperature, are not in a critical range.

At low condensing temperatures ($T_C < 31^\circ C$), it is not possible to ensure the minimum subcooling without falling below the minimum vapor quality. The designer of the machine should consider operating points in this area in more detail.

Before determining the increase in efficiency of the individual operating points, the influence on other important parameters in the refrigeration cycle can be checked using the additional diagrams. Especially in applications with large pressure differentials, it is possible that the end of compression temperature $T_2$ comes into a critical range. To verify that the selected subcooling is feasible, the end of compression temperature $T_2$ must be within the compressor’s operating limits. The compressor operating limits are defined by the manufacturer. Figure 7 shows the diagram for estimating the end of compression temperature, which is at the auxiliary variables in Figure 5.

![Fig. 7. Plot for estimation of the end of compression temperature ($T_2$)](image)

The potential efficiency increases from the additional subcooling can be determined in Figure 8. It shows the savings potential $\Delta EER$ of the external subcooler at different operating points. In the case with a wastewater heat sink of $15^\circ C$ $\Delta EER$ is between 6 – 18 % depending on the condensing temperature $T_C$. For condensing temperatures of 25 - 35 $^\circ C$, a total subcooling of 10 K is possible. This was determined using the limits of subcooling (see Fig. 6). The total subcooling for a condensation temperature of 40 $^\circ C$ is 15 K (yellow line), at $T_C = 45^\circ C$ is $SC_{tot} = 20$ K (red line).
The efficiency improvement values can be used as the basis for an economic efficiency calculation. It should be noted that the operating points vary in frequency depending on the location. The individual operating points must therefore be weighted differently to estimate an annual energy saving, which is described in chapter 5.

5. Application for profitability calculation

The evaluation of the economic efficiency depends on the investment costs, the savings potential of the subcooling type, and the required auxiliary energies. The diagrams created in this report primarily help to estimate the annual savings potential of the subcooling type ($\Delta EER_a$), which is determined according to equation 4.

$$\Delta EER_a = \sum_{i=1}^{5} w_i \cdot \Delta EER_i$$

In the previous chapter, the savings potential ($\Delta EER$) of external subcooling by means of cold wastewater at different condensing temperatures was estimated. Figure 8 shows that the EER increases between 6 - 18 % depending on the condensing temperature.

For a seasonal consideration, the individual operating points must be weighted according to their energetic share of the annual consumption ($w_i$). The weighting of the individual operating points depends on the location and planned use (load profile). The final report on the investigation of refrigerant subcooling [6] shows in the appendix weighting factors for various locations in Switzerland and load profiles. The methodology for the energetic weighting of several operating points is described in detail in the final report on refrigeration compressors [9] (in German). Table 3 shows the seasonal consideration for the Basel site as an example. The load profile of the application must also be considered.

The results in Table 3 show the energy weighting of the individual operating points for the Basel site. The annual savings potential is 7%. This is due to the hourly frequency of ambient temperatures at the investigated site. It can be seen that the operating points with the highest savings potential are significantly less relevant in terms of energy. It should be noted that this only applies to the refrigeration machine and that any possible changes in the consumption of auxiliary energies have not been considered.

6. Conclusion

The studies on seasonal energy savings potential with additional subcooling have provided a useful basis for proper subcooling. The plots in Figure 5 can be used to determine the limits and energy savings potential of a refrigeration cycle with external subcooling.

It has been shown that there is a significant savings potential for refrigeration machines with direct evaporator and R290 as refrigerant if they can be operated with an external subcooler with constant heat sink.

Based on the seasonal evaluation, an economic efficiency calculation can be performed in addition to the annual savings potential. The study shows that the savings potential is strongly dependent on the operating point due to the limitations. For a seasonal evaluation, it is therefore always necessary to consider several operating points. However, the results are not only important for estimating the energy savings potential, but also for setting the operating limits. Compliance with the limits is important for safe and reliable operation of the refrigeration machine.

The study was carried out only based on computer simulations, which were verified by experts. There is no experimental comparison of the results. Accordingly, it would be interesting if the investigations could be compared with measurements on real refrigeration machines.

Free cooling in air conditioning: Investigation of its potential in Switzerland

**Zurich University of Applied Sciences, Institute of Energy Systems and Fluid Engineering, Technikumstrasse 9, 8400 Winterthur, Switzerland

Abstract

In air conditioning, free cooling is often used for saving energy. Free cooling is understood here as a bypass water circuit with direct recooling by the environment, not heat removal by nightly ventilation. Contrary to common practice in Switzerland, free cooling is not always economically beneficial. To estimate its potential in air conditioning systems, there are no generally applicable evaluation criteria or guidelines available. The aim of this work is to assess the free cooling potential in Switzerland by applying quasistatic simulations depending on supply temperature, application, location, circuit and type of heat discharge. The results show that supply temperature is the most influential parameter. Below 14 °C all investigated applications (except data centers) show generally less than 10% of free cooling amount in total annual cooling load, therefore not economically benefitting from it. Furthermore, the potential is strongly dependent on climate at the location. Cold regions like the Swiss alps allow longer yearly free cooling operation than warmer regions. If recoolers are used to pre-cool the returning cold water flow, the free cooling potential can almost be doubled.

1. Introduction

Free cooling (FC) is generally used in refrigeration systems for saving energy and reducing refrigeration costs. Recent literature also reflects this trend: Lot of successful effort is put into assessing the worldwide/european/swiss FC potential of data centers [1-3] and reviewing/optimizing existing FC systems in data centers [4-7]. This topic is of utmost importance considering the environmental impact of ever-increasing data traffic around the globe. Furthermore, it strongly improved expertise on how and where FC brings significant energy savings in data centers. Regarding FC potential for general air-conditioning applications, sophisticated work can be found addressing either the FC potential in specific cooling applications [8], [9], assessing it more generally at specific locations [10] or over a wider geographical scope [11]. As FC is a known technology by now, efforts are also put into expanding FC use, for example by applying phase change materials in combination with innovative cooling concepts [12-16]. As to FC potential in Switzerland, specific systems have been reviewed [17], [18]. Matthey and Affolter were able to determine the FC potential of the city of Neuchâtel [19], whereas Artmann, Manz and Heiselberg determined the FC potential by nightly ventilation over Europe [20]. This work aims to gain insight on FC potential in Switzerland with particular attention to influencing factors such as cold water supply temperature ($T_{CWS}$), application, location, hydraulic integration (circuit) and type of heat discharge.
2. Modelling

The analysis is intended to provide findings on appropriate use-cases for FC in air conditioning. For this purpose, applications in specific sample buildings were considered. With regard to modelling, they were all divided into three subsystems: recooler (refrigeration machine heat discharge), cold generation and cooling distribution/building (see Fig. 1). FC is assigned to the cold generation subsystem.

2.1. Parameter set

To assess influential variables on the FC potential, a suitable parameter set was established. It consists of varying values for the editable subsystems and boundary conditions: hydraulic integration (circuit), type of heat discharge, $T_{\text{CWS}}$, location with associated boundary conditions as well as type of cooling application.

Firstly, to clarify the influence of different hydraulic integrations, a total of five circuits (Fig. 1) were examined in consultation with experts. Each circuit contains the aforementioned subsystems and can be assigned to an operating group. Circuits 1, 2 and 4 are bivalent-alternative systems, where the cooling load is covered either by the refrigeration machine or FC. Circuits 3 and 5 are bivalent-parallel systems, whereby cold water can be precooled by FC and is simultaneously run with the refrigeration machine.

Secondly, various types of heat discharge systems were investigated. Depending on the type, FC return temperatures and therefore the possible FC operating time is affected. All types were simulated with a maximum capacity, which is never exceeded. This maximum capacity is defined as the design cooling load of the building, which was calculated site and application specific according to the standard of the Swiss Society.
of Engineers and Architects (SIA) 2024 [21]. In other words, separate discharge systems for FC (circuit 2 to 5) are able to dissipate the complete design load. The design also takes into account site-specific boundary conditions of the outside air (according to summer design data from SIA 2028 [22]) as well as application-specific sizes (according to SIA 2024 [21]). Every type leads to specific input parameters, which are summarized in Table 1. One value is the temperature difference between wet bulb and heat discharge return line \((dT_{WB-RL})\), which was assumed to be constant. The second value is the reference temperature \((T_{ref})\) at which heat can be discharged to.

<td>Location dependent wet bulb temperature according to standard SIA 2028 [22]</td>
</tr>
</tbody>
</table>

Some simplifications and delimitations must be considered: Hybrid recoilers were modeled to be sprayed on with water constantly, leading to the maximum possible FC potential. In every simulation run, the used heat discharge system (dry/hybrid) of the refrigeration machine was the same as for FC. Regarding geothermal probes and groundwater collection, soil temperature changes as well as legal regulations were neglected, also resulting in maximum FC potential. Ground temperature could only be estimated and varies strongly with subsurface conditions and drilling depth, only allowing a rough estimation of FC potential. For circuits 2 to 5, separate FC with geothermal probes or groundwater is excluded. Usually, those heat discharge systems are built for recooling the refrigeration machine and are additionally used for FC, which reduces circuits 2 to 5 to circuit 1 in this regard. The effect of water fed heat discharge systems was therefore only calculated with circuit 1.

Thirdly, \(T_{CWS}\) was varied to investigate its influence. By choosing the temperature level of the cold water, that for FC is also determined which in turn affects its possible operating time. According to SIA 382/1 [26], temperatures of 6, 10 and 14 °C were used representing typical values for air conditioning applications. 18 °C serves as an interpolation value and with 22 °C a typical temperature for data center cooling was included. \(T_{CWS}\) is always assumed to be constant, hence no adjustment to the outside temperature is considered.

Fourth, different locations were evaluated. Due to various environmental conditions, the heating and cooling demand of an application as well as the minimum temperature of heat discharge are affected. To evaluate the site dependency, data of the weather measuring stations Zurich, Basel, Geneva, Lugano and Davos were included (Fig. 2). These can be assigned to one of the three climatic/geographical regions of Switzerland: Central plateau, Swiss alps and Ticino (Table 2). This assignment serves to extrapolate to a more general view over Switzerland. Weather data was obtained from the Federal Office of Meteorology and Climatology (MeteoSwiss) [27]. In the years 2010 to 2016, the year 2013 shows the smallest deviation of annual mean values from the norm across all stations considered (according to MeteoSwiss). Therefore, 2013 was finally used for weather data.

Table 3 shows weather parameters (measured in hourly mean values) used for the calculation.

Fifth, different proportions of internal heat were evaluated by including different types of applications according to standard SIA 2024 [21]. As Table 4 shows, the selection was based on the widest possible spread of internal heat load share.

2.2. Calculation Model

The applied calculation model is based on thermal energy balances of hourly intervals over a calendar year. This leads to a quasi-static view of the system, which means that storage effects of the building mass and in possible cold or heat storages are not considered. As depicted in Eq. (1), the hourly target thermal load of a building was calculated according to the standard SIA 2024 [21].

\[
Q_{dem} = (\Phi_T + \Phi_v + \Phi_i + \Phi_s) \cdot A_{NFA}
\]  

(1)

\[
Q_{dem} \leq 0 \Rightarrow Q_{dem,c} = Q_{dem}
\]  

(2)

\[
Q_{dem} \geq 0 \Rightarrow Q_{dem,H} = Q_{dem}
\]  

(3)

Here, \(Q_{dem}\) is the hourly heating/cooling demand, \(\Phi\) is the specific heating/cooling load with indexes \(T\) for transmission, \(v\) for ventilation, \(i\) for internal and \(s\) for solar load. \(A_{NFA}\) is the net floor area of the representative building. If the target thermal load is negative, cooling load is present (Eq. (2)) and if it results positive, heat load exists (Eq. (3)). Specific heating/cooling loads were calculated according to the standards SIA 2024 [21] and SIA 2028 [22]. Further information on the calculation can be found in [28].

2.3. Evaluated quantities

The value of greatest interest is the FC potential, as shown in Eq. (4). It is intended to provide information on the usefulness of FC in relation to the total cooling load. For this purpose, the yearly amount of discharged heat by FC (\(\sum Q_{C,FC,a}\)) was compared with the yearly total cooling load (\(\sum Q_{C,\text{tot},a}\)) for each parameter combination.
In order to provide assistance to the reader, a calculation of the economic efficiency for a 200 kW refrigeration plant was carried out [28]. To keep annual costs of a system with FC at the same level as a conventional one, a FC potential of at least 11% (best case) or 39% (worst case) must be achieved. Otherwise, FC is not considered economically viable. This classification is listed consistently in the results (cf. section 3).

3. Results

A total of 1200 parameter combinations were simulated and evaluated using the procedure described in section 2. The most important findings are outlined below.

3.1. Influence of cold water supply temperature

Out of all parameters $T_{CWS}$ has the most significant influence on FC potential. As an example, the evaluation for Zurich (representing the central plateau region) with dry recoller heat discharge is displayed in Fig. 3. It shows that the FC potential decreases with decreasing $T_{CWS}$. At $T_{CWS} < 10 \, ^\circ C$, the FC potential drops below 2% for all circuits and applications, except the data center. This tendency applies to all locations, heat discharge types, applications and circuits [28]. Applications with a low proportion of internal heat loads (hospital/doctors office, office buildings) show the strongest response to this tendency.

The data center application represents a special case: Due to year-round cooling load, a considerable proportion can be served by FC, even with relatively low $T_{CWS}$. This confirms the common use of FC in data
center chiller systems. However, it stresses the crucial point that cooling with high $T_{CWS}$ leads to great FC potential (up to 81 % in this evaluation) and therefore high energy savings.

3.2. Influence of hydraulic integration (circuit)

The FC potential is further influenced by the choice of hydraulic integration. The evaluation for Zurich with dry recooler heat discharge (cf. Fig. 3) serves as an example again. Across all locations, heat discharge types, applications and $T_{CWS}$, three main influences of the circuit can be identified:

**Temperature difference across heat exchangers**

Large temperature differences across heat exchangers have a negative influence on the FC potential since they reduce the necessary spread between $T_{CWS}$ and the return temperature of the FC. Parameter combinations with circuit 1 (largest temperature differences over the heat exchangers) therefore generally have the lowest FC potential.

**Operating mode of FC**

The operating mode of FC has an influence on the performance, independent of all other parameters. With bivalent-parallel mode the cold water return flow can be precooled as soon as the return temperature of the heat discharge is lower. This allows longer FC operating periods and consequently higher FC potentials. It can be seen that bivalent-parallel systems generally have higher FC potential than bivalent-alternative ones (compare results of circuits 2 & 3 as well as those of circuits 4 & 5).

**Type of refrigeration machine condenser**

Comparing circuits 2 & 4 as well as circuits 3 & 5, they differ only in the type of refrigeration machine condensation (cf. Fig. 1). No influence on the FC potential can be determined. Circuits which only differ by direct or indirect condensation show the same FC potential for identical parameter combinations.
3.3. Influence of location

The location defines $T_{0,a}$, which influences both $T_{Ref}$ and the application’s heat load profile, which in turn significantly influences the FC potential across all parameter combinations. The decisive factor for this influence is the dependence of the heat discharge system return temperature on the outside air temperature.

As an example, the FC potential evaluation with dry recooler heat discharge and $T_{CWS} = 14^\circ C$ for different regions is shown in Fig. 4. Regardless of the remaining parameters, it can be determined that low ambient temperatures increase the FC potential. Thus, with the same application and circuit, greater potential can be achieved in the Swiss alpine region rather than the Central plateau or Ticino. All investigated locations in the Central plateau show only minor FC potential changes to Zurich.

3.4. Influence of heat discharge system

Dry recooler vs. hybrid recooler
As an example, the evaluation of FC potential at $T_{CWS} = 14^\circ C$ and $T_{CWS} = 22^\circ C$ for Zurich is shown in Fig. 5. It must be considered that the hybrid recooler was modeled as if it were constantly sprayed on with water. Therefore, the results for hybrid recooling show the maximum possible FC potential. With hybrid recooling, the FC potential can be greatly increased compared to dry recooling. In some cases, it can be even more than doubled.

Geothermal probes and groundwater collection

Due to the simplifications made (cf. section 2.1), only an estimation of the maximum FC potential of geothermal probes and groundwater is possible. Reminder: In order to determine the effects of water-fed heat discharge systems, only circuit 1 was simulated.

The evaluations (Fig. 6) show a large FC potential at high $T_{CWS}$ over all investigated locations. In generally cold regions such as the Swiss alps (Davos), FC by groundwater collection can also be useful with low $T_{CWS}$ due to lower soil temperatures. It should be noted that heat discharge may be limited by legal restrictions. A more exact statement would require a further investigation, in which the dynamic behavior of the geothermal probe as well as groundwater collection is analyzed under consideration of the heat inputs.

Fig. 5: FC potential for dry and hybrid recooler heat discharge in Zurich.
4. Conclusion and Outlook

The main objective of the present study was to investigate the FC potential in Switzerland. This was done by applying quasistatic simulations on typical FC use-cases for different $T_{CWS}$, applications, locations, circuits, and types of heat discharge. A total of 1200 parameter combinations were calculated where 700 cases (58.3 %) belong into the category “FC not recommended”, with FC potential under 11 %. Another 280 cases (23.3 %) belong to the category “FC to be evaluated”, with FC potential between 11 % and 39 %. These cases can economically benefit from FC, depending on the exact operating conditions. Last but not least, 220 cases (18.3 %) belong to the category “FC recommended” with FC potential over 39 %. This means that, according to this assessment, only less than half of all parameter combinations considered have a potential for which FC should be evaluated or for which it is recommended. However, it should be noted here: Not all investigated parameter combinations make practical sense (e.g., data centers usually aren’t cooled with $T_{CWS} = 6 \, ^\circ C$). Nevertheless, this study reveals important principles for the use of FC, which are summarized below.
1) Cooling and FC should be carried out at the highest possible $T_{CWS}$. This increases the FC potential on one hand and the general energy savings on the other.

2) Regarding hydraulic integration (circuit), the difference between direct and indirect condensation of the refrigeration machine is negligible. Bivalent-parallel systems with precooling the cold water return flow generally show higher FC potential than bivalent-alternative systems.

3) In terms of used heat discharge systems, hybrid recoolers or geothermal probes/groundwater collections show large improvements in FC potential in some cases. Especially at high $T_{CWS}$, water fed heat discharge systems show great advantages.

The analysis of the data center even allows to transfer some conclusions of the results onto industrial refrigeration applications. If it is assumed that an industrial application has a year-round cooling demand, increased FC potential can be expected. If, in addition, high $T_{CWS}$ are present the FC potential can be maximized. From this point of view, FC is a very interesting technology for certain industrial cooling applications. However, the exact relationships would have to be investigated in more detail. In addition, it must not be forgotten for industrial refrigeration applications, that a possible heat utilization is clearly preferable to a heat release to the environment. With the results in this study, it is possible to estimate the FC potential for a specific cooling system. For this purpose, various diagrams and a description of the procedure are provided in the original research report [28]. Furthermore, detailed analyses can also be found there.

With the Swiss Federal Office of Energy as contracting authority, this study was limited to investigations in Switzerland. Further studies for regions with warmer or colder climates than Switzerland can provide information on the validity of this approach as well as further insights on the FC potential in those regions.

Acknowledgements

The Authors would like to thank the Swiss Federal Office of Energy for their financial support in this project. Mr. Martin Stettler is expressly thanked. Thanks for the valuable support and constructive cooperation also go to the contributing experts Arnold Brunner (Brunner Consulting), Robert Dumontier, Michael Kriegers (Meierhans und Partner) and Thomas Lang (Zweiweg GmbH). For further technical support we would also like to thank Luk End and Matthias Brügger (Leplan AG).

Abstract

Rotation Heat Pumps (RHP) offer the advantage of a flexible process in terms of temperature with an environmentally friendly, non-flammable working fluid. The application has already proven successful in the operation of a reference plant and prototypes. A RHP uses a Joule cycle in contrast to compression heat pumps using a vapor compression cycle. Due to the rotation of a rotor filled with the working fluid, the temperature of the fluid rises outwards as the working fluid is compressed. Basic elements are the heat exchangers, the compression and expansion pipes, and a fan to circulate the working fluid. Due to the rotation, these components differ in their operating behavior according to available literature data. Regarding control, numerous publications and theoretical principles and commercial controllers are available for compression heat pumps. The current state of the art for an RHP is a fixed/rigid presetting of the parameters to achieve a certain operating state. This results in a simple but non-optimal control, e.g. regarding energy efficiency. In this work, different control concepts based on the fundamentals of a DigitalTwin have been developed and compared to each other (e.g. extremum-seeking control and model predictive control). The proof-of-concept is first performed on the machine controller (PLC) by means of controller-in-the-loop tests. Subsequently, the control concepts are implemented and verified on a real industrial scale RHP.

Keywords: Thermodynamics; Energy; Exergy; Sustainability; Control; Rotation Heat Pump.

1. Introduction

1.1. Rotation Heat Pump

A Rotation Heat Pump (RHP) uses a Joule cycle in contrast to conventional compression heat pumps which use a vapor compression cycle. Basic elements of an RHP are heat exchangers, compression and expansion pipes, and a fan to circulate the working fluid. The Joule process describes the counterclockwise cycle in a closed system, where the working gas never condenses or evaporates, but always remains in the gaseous state. Figure 1 shows a schematic comparison of the Joule and the vapor compression cycle.

* Corresponding author. E-mail address: michael.lauermann@ait.ac.at
For implementing the Joule process in an economically viable manner, highly efficient compression of the working gas is necessary. In an RHP this is achieved by centrifugal forces. Due to the rotating rotor filled with a working fluid, the temperature of the fluid rises outwards while the working gas is compressed. This concept is schematically shown in Figure 2 (left): Two heat exchangers on low- and high-pressure side as well as compression and expansion pipes and a fan are depicted. These components represent the area flowed through with working gas. Also shown are the connections of source and sink as well as the flow through the heat exchanger. The results of computational fluid dynamics (CFD) calculations for the Joule process are shown in Figure 2 (right). Exemplary temperatures are assumed, but the process can be flexibly implemented at different temperature levels.

The first reference plant of an RHP, shown in Figure 3 (right), is already in operation, measured values from previous test runs have already been published [1]. The design model (left) with opened housing shows the rotor with heat exchangers and pipes.

1.2. Motivation

For controlling conventional compression heat pumps, numerous publications, theoretical principles and commercial controllers are already available. Here, a well-tuned system can be provided in advance using
"default settings" for e.g. the expansion valve. To determine the main differences between an RHP and a conventional compression heat pump in terms of basic principle, design and operation, basic knowledge must be acquired, and the individual components be analyzed in detail. Control systems and strategies for commercial heat pumps cannot be transferred easily, as additional control parameters are available and further non-comparable complex correlations must be taken into account. Due to the lack of literature, the associated behavior of an RHP regarding the unusual physical relationships of its components needs to be explored, cmp. [2]. The current approach is based on flow simulations of the main components (heat exchangers, fan, pipes) for the entire operating range with variable boundary conditions. Out of these considerations, three major challenges in regard of controlling an RHP were identified:

- **Challenge 1:**
  Due to the rotation the component’s operating behavior differs from available literature data. Furthermore, measurements in the system are difficult to establish or even impossible for both, pressure and mass flow sensors, due to high loads on the outer diameter of the rotor, which are problematic for the transducers, and would require complex wiring. Therefore, the modeling approach was chosen and the model is tried to be validated on a global basis (energy balance, efficiency, etc.) for further control development.

- **Challenge 2:**
  The fan like every turbomachine has a characteristic curve with certain operating limits caused by flow phenomena. Both, the fan characteristics and the system curve of the refrigeration cycle furthermore change with the rotor speed of the RHP. Experiments have shown that there are combinations of fan speed and rotor speed, where the fan given the system curve cannot build up enough pressure difference to push the refrigerant mass flow, causing the refrigeration cycle to stop. With the help of CFD for flow phenomena and further modelling, those combinations can be identified and can be considered for controlling and successfully operating the RHP.

- **Challenge 3:**
  The current state of the art in terms of control is a fixed/rigid pre-setting of the fan speed and the rotor speed to achieve a certain operating state. This results in a simple but non-optimal control, especially regarding energy efficiency. A Digital-Twin of the heat pump offers the possibility to carry out the controller development in a time- and resource-efficient way. It requires correlations of the thermodynamic behavior of the components.

2. Digital-Twin

2.1. Method

In a recent work from us [3] the main objective was to gain basic knowledge and to identify physical relationships in an RHP. For this purpose, individual components of the RHP were modeled using CFD. Their behavior across a wide operating range was analyzed using parameter studies. The main components – heat exchangers for source and sink, the fan as well as compression and expansion pipes – were modeled and simulated. At certain boundary conditions (rotation, pressure, flow velocity, etc.), the components showed partly very high deviations from the generally known and validated operating behavior for non-rotational operation. However, by the help of the system simulations, a significant contribution could be obtained for a better understanding of these phenomenological interrelationships of the individual components. Additionally, mathematical relationships from CFD results were also generated and are now available in so-called meta models as functional mockup units (FMU). These FMUs and their position in the schematic refrigeration cycle are shown in Figure 4.
Within the dynamic simulation environment Dymola/Modelica [4], several FMU models were tested regarding functionality and plausibility in a first step, prepared for the integration (see Figure 5), and finally combined to build the whole RHP system within the framework of the TIL-Library [5], as shown in Figure 6.

Looking at the fan in Figure 5, we adapted the model – compared to [3] - in a way that the flow is given by a mass flow rate directly instead of a total pressure increase. Now, the model is much more robust in terms of initialization and forms a solid basis for further analysis. The two speeds of the rotor and fan as well as pressure, temperature and the total mass flow remain unchanged as input variables into the FMU.

The other two FMUs of the high (sink) and low (source) pressure heat exchangers (Figure 6) work on the same principle, but with different input variables. Those FMUs have been upgraded as well compared to [3] as there had been constructive changes on the heat exchangers in the real system.

Figure 6 depicts the complete model with all integrated FMUs. The grey line represents the rotating main axis of the machine. Green is the gaseous refrigerant circuit and blue the water-side heat dissipation and heat absorption of the sink and source. Figure 6 shows the complete model with all integrated FMUs. The grey line represents the rotating main axis of the machine. Green is the gaseous refrigerant circuit and blue the waterside heat dissipation and heat absorption of the sink and source. Furthermore, temperature, mass flow, volume flow and pressure sensors are integrated to determine the respective system status points.
2.2. Results - Validation based on RHP measurement data without controls

In [3] the simulation model was originally validated based on available operating points which were selected from different sets of measurement data of the existing plant. In this work, the operating points were generated with an adapted RHP, see Figure 7. The heating capacity based on the supply temperature $T_{sink,out}$ and the temperature lift $T_{lift, meas}$ (temperature difference between source inlet and sink outlet) is shown. Speeds of fan and rotor were fixed. The exact values are shown in Table 1. Compared to [3], 12 operating points are available at a slightly wider range of $T_{lift, meas}$ and higher values of heating capacity $Q_{heat, meas}$.

![Figure 6: RHP in Dymola/Modelica with integrated meta models as FMUs.](image)

![Figure 7: Performance map of the RHP from twelve steady state operating points, cmp. Table 1.](image)

Similar to [3] the following six input variables were implemented into the model:
- Inlet temperatures of source and sink ($T_{source, in}$, $T_{sink, in}$),
- mass flow rates of source and sink ($m_{source}$, $m_{sink}$), and
heating capacity \( \dot{Q}_{\text{heat}} \) of this extent should be fine as long as the qualitative \( T \) tendencies are reproduced. Nevertheless, one aim of the RHP, which is given by the coefficient of performance (COP), specifying the relation between the thermal output and electrical input

Table 1 shows the summary of all measured and available simulation results of the above-mentioned twelve operating points. With the simulation model in the current status, the heating capacity \( \dot{Q}_{\text{heat}} \) is purely overestimated from 3.52\% to 9.59\%. This makes sense in qualitative perspective as the model is not considering heat losses to the ambient. The supply temperature \( T_{\text{sink,in}} \) is also overestimated by the model analogous to \( \dot{Q}_{\text{heat}} \), which corresponds to the relation \( \dot{Q}_{\text{heat}} = \dot{m}_{\text{sink}} \cdot c_p \cdot (T_{\text{sink,out}} - T_{\text{sink,in}}) \). The efficiency of the RHP, which is given by the coefficient of performance COP is currently overestimated by the model.

</tbody>
</table>

Overall, the highest error between simulation and measurement is in the COP of approx. 21\%. With the same inlet temperatures and mass flows, the error in the sink outlet temperature \( T_{\text{sink,out}} \) is max. 1.61 K.

Compared to [3], where the model was under- and overestimating the experiments, now, with the improved components, we see an exclusive overestimation, which is inline with the current modelling approach of no heat losses in place.

The range of the model errors is not a problem per se, it depends on the intended purpose of the model. Using the models for the purpose of controls, errors of this extent should be fine as long as the qualitative tendencies are reproduced. Nevertheless, one aim in [3] of the project team was to reduce the model errors by deeper analyses of the deviations and its reasons, which was successful when comparing Table 1 with [3].
3. Control strategies for the RHP

3.1. Comparison of different principles

With the help of the validated model we develop control strategies in the direction of optimal control. As discussed in [3], Table 2 shows a list of the different control variants including their advantages and disadvantages. In this table we present our initial thoughts and expectations as it is given in the literature. In this work we will tap this and investigate it for the application of RHP.

3.2. Definition of the control scenarios

Based on the consideration of the advantages and disadvantages from Table 2, we decided to use the variant of the model-based look-up table. To us, it represents a good trade-off between control quality and feasibility on the RHP control system.

From the possible industrial applications, three main scenarios crystallize. There are, of course, more scenarios but in this work, the following three will be addressed:

- Scenario 1: Heat-driven by controlled $T_{sink,out}$, control variables are rotational speeds of the RHP.
- Scenario 2: Cooling-driven controlled by $T_{source,out}$, control variables are rotational speeds of the RHP.
- Scenario 3: Combination of scenario 1 and 2, controlled by $T_{sink,out}$ and $T_{source,out}$, control variables are rotational speeds of the RHP and secondary mass flows on source and sink side ($\dot{m}_{source}$, $\dot{m}_{sink}$).

The controlled variable, depending on the scenario, is either supply temperature on the cold side or on the hot side or on both sides simultaneously in combination of an optimality condition (either COP or thermal capacity). For each scenario, the control variables and disturbance variables are described in the following Figure 8.
Figure 8: Control scenarios with control variables (green) and optimization targets (orange), boundary conditions / disturbances (red), actuating variables (blue), and resulting variable (black).

3.3. Utilizing the Digital Twin

With the Digital Twin as described in section 2, the characteristic diagram of the entire RHP is created. Taking into account the defined operating limits, see below, a parameter variation is carried out, a so-called parameter sweep. The aim is to capture the optimality variables (green, orange values in Figure 8) and their dependence on the boundary conditions (red) and at the same time the influence of the manipulated variables (blue). Finally, this is the data basis for the subsequent analyses. In total, there were about 90,000 variations. However, only about 10,000 of these results were usable by filtering a valid range of heating capacity and pressure increase at the fan, i.e., only points were analyzed that made sense in that manner.

3.4. Results – Operating envelope of the RHP

In general, all boundary conditions result in a lot of superimposed points if showing the results – such as heating capacity or COP - in a 2D-surface plot. Nevertheless, we aim to illustrate the RHP operating limits in order to see unacceptable operating ranges due to stall conditions on the fan, which can be seen Figure 9. From our current experience, we assume that based on an actual operating condition, any change in operation, that is pointing to the bottom right can possibly lead to a stall condition on the fan. A change to the top left is limited by the pressure increase of the fan in combination with the fan motor. We also the opposite COP maximum and heating capacity maximum. Here, the temperatures of $T_{sink,out}$ are ranging from 71 to 83°C, Figure 9c.
In the following we show an exemplary situation for scenario 1 (heat-driven). We set a control target with the temperature range of 80°C ±3K around the desired value. At the same time we also have 4 different combinations of boundary conditions. That means, we do not only “cut out” of the above picture Figure 9, but we consider new combinations and thus new ranges than the ones shown above. Additionally, we have a relatively coarse grid, so we consider a control range that seems unusually large at first glance. However, the RHP can regulate to an exact value.
First example:

We consider unchanged rotational speeds of the RHP in combination with a disturbance change, which is a doubled mass flow on the source side. The RHP settled in the optimum point of COP (that is the lowest point in Figure 10a, yellow area), which is actually at the "stall limit" considering the total operating range (grey area in the background). When the source mass flow increases, the current speed settings for the maximum COP are suddenly outside the allowable operating range for the desired control target. In the best case, only the outlet temperature on the sink side (which is the controlled variable) cannot be maintained anymore in the event of a change in the disturbance variable, but in this case a stall at the fan happens, which leads to the immediate shutdown of the machine. This can be seen that the original operating point in Figure 9a (the point with the best COP in the yellow area) is now outside of the operating envelope as seen in Figure 9c.

Figure 10: Example 1: Shifting the operating range for deviating boundary conditions.
Second example:

As a second example, for a given set point of the sink outlet temperature \( T_{\text{sink, out}} \) of 95 °C±3 K, a reduction of the source inlet temperature \( T_{\text{source, in}} \) of 10 K results, see Figure 11. The starting point is again the optimum point (COP or heating capacity). In this example, there is a danger of passing through the white area when changing the manipulated variables (rotational speeds) from one operating point to another. To avoid the danger of a stall (area below right), the key message here is to always increase fan speed first and then increase rotor speed when increasing speeds in general. When reducing the rotational speeds, inverse procedure is relevant.

![Figure 11: Example 2: Shifting the operating range for deviating boundary conditions.](image)

Our analyses beyond the two examples shown here, show that the optimal operation of the RHP in terms of COP of heating capacity seem to be at the limits of the operating envelope. Here, however, there is, among other things, a danger of stall at the fan, which leads to shutdowns of the RHP. Shutdowns in general are not only bad because of the heat demand, but also for the machine itself. The remedy can be the definition of a so-called "safety distance consideration", which is therefore already mentioned in the outlook:

- **Case A:** Fixed speeds (e.g. for maximum COP), and suddenly a disturbance variable (or also several) changes rapidly and unforeseen. How far can they change (stationary!) without the RHP leaving permissible operating ranges?

- **Case B:** Optimum point is at the edge (because speeds can only be smaller or only larger when the setpoint of the controlled variable is maintained) Safety distance to this limit can be set arbitrarily,
e.g. 5% away from the edge in the sense of the speeds, or half distance in the direction of the nearest neighbor away from the optimum.

The limits of our considerations are that the results are valid in principle for stationary states, therefore results are generally not valid for start-up or transient changes (e.g. disturbance change or rate).

4. Summary and Outlook

In this paper, essential steps were described to model a digital twin of an RHP and prepare it for controller testing of such a heat pump. In a dynamic simulation environment, existing models, e.g. for pipes, and externally generated models using CFD were connected and simulated.

The RHP model was validated based on real measured operating points moving in realistic ranges. Here, attention was not paid to selecting operating points that could be validated easily, but rather those that could actually occur in real operation and have to be dealt by controls. Overall, the highest error between simulation and measurement is in the COP of approx. 21%. With the same inlet temperatures and mass flows, the error in the sink outlet temperature $T_{\text{sink,out}}$ is max. 1.61 K.

A total of approx. 62,500 simulation runs for a heating capacity range up to 750 kW and with different boundary conditions were carried out for the validated model. For example, the fan speed, rotor speed and temperatures were varied to cover a wide range of potentially possible operating points. These runs were performed based on the "parameter sweep" method.

Model errors excluded, valid operating ranges have been identified for specific boundary conditions. Only through the existing work (development and simulation of the Digital Twin) "operating envelopes" of the entire system in the defined operating limits (not only of the individual components) are available. Permissible control variable combinations for the desired influencing of the controlled variables for given boundary conditions are known. In particular, manipulated variable combinations depending on the scenario for maximum COP, $\dot{Q}_{\text{heat}}$, or $\dot{Q}_{\text{cool}}$, are known. The "look-up table" for optimal control of different scenarios can now be used for lab tests.

For the implementation in the laboratory, an integration table in the PLC including interpolation between the operating points is necessary and possible. Adaptive modelling is conceivable in order to determine further model errors, in particular at the optimum operating points. A comparison with PID controllers with the controlled variable according to scenario 1 is planned or will be presented at the Heat Pump Conference.

Abstract

In residential heating applications, electrically-driven heat pump systems enable the integration of renewable energy sources (RES) and, thus, systematic sector defossilization. Since the heating demand of buildings and RES availability are time-variant and time-shifted, it is challenging to ensure optimal heat pump system operation. Optimal heat pump system operation requires access to reliable system interfaces and consistent use of higher control strategies such as model predictive control (MPC). However, missing interfaces prevent the spread of MPC in the field and call for conventional controls such as heating curves reducing the overall potential. This work shows the potential of MPC for heat pump systems by exploiting system interfaces in an experimental case study. We use a heat pump test bench coupled to a dynamic building performance simulation model in the hardware-in-the-loop approach and investigate two control levels: The refrigerant cycle controller ensures stable superheat and resilient operation; the system controller minimizes the heat pump power consumption within the comfort constraints. We analyze two MPC interfaces to control the system: First, the MPC sets the flow temperature, while a PID controls the compressor speed. Second, the MPC directly adjusts the compressor speed. We compare both MPC strategies with a conventional heating curve controller. The results highlight the need for heat pump interfaces to widespread MPC. Both MPC strategies reduce the heat pump power consumption by up to 20.25\%. Adjusting the flow temperature by MPC results in the lowest energy consumption but many compressor starts and comfort losses. Direct compressor-controlled systems claim the best results concerning comfort constraints and lead to a resilient operation by reducing on-off behavior.

1. Introduction

For all sectors, the IPC report shows the need for consistent defossilization to meet climate goals and mitigate climate impact consequences [1]. In particular, the building sector is responsible for up to 30\% of total energy consumption [2]. While, in other sectors, standardized solutions already exist to reduce emissions on a larger scale, there are still major challenges in the building sector due to the high degree of individuality of buildings and occupants [3]. Solving one challenge to reduce the emissions related to heating purposes, heat pump systems can exchange conventional combustion-based heating systems. Electrically-driven heat pump systems are the most efficient solution for defossilization the building sector, as they can provide CO\textsubscript{2}-neutral heat when using electricity from renewable energy sources (RES). However, optimal heat pump integration and operation lead to complex system setups and controls since the heating demand and renewable energy sources (RES) availability are time-variant and time-shifted. To capture time-variance and time-shifting, model predictive

control (MPC) applications are a potential solution in the recent literature. MPC strategies reduce energy consumption by 13 \% to 28 \%, depending on the heat pump system setup [4]. However, most heat pump systems in the field operate in weather compensation mode using an outdoor temperature-dependent supply temperature (heating curve). As a result, heat pump systems are often not operated optimally, considerably reducing their potential in many cases.

To optimally operate heat pump systems and fully exploit the potential of MPC, there is the need to identify barriers preventing the transfer into practice. In the literature, there are multiple reasons for the slow implementation of MPC approaches in the building sector. First, the development of MPC in building energy systems (BES) needs deep expert knowledge and high hardware and software requirements [5]. Second, individual buildings require individual process models for the controller configuration and, thus, increase the development time [6]. In a recent theoretical study, Stoffel et al. show a data-driven MPC using black-box models (BBMPC) that perform similarly to detailed white-box MPC approaches [7]. In addition, online learning offers continuous improvement of the BBMPC process models reducing the gap compared to more development-intensive MPC approaches. While Stoffel et al. follow a theoretical approach where almost all interfaces can be made available, in practice, interfaces may not be available for safety reasons or the manufacturer's market strategy.

Today, the available interfaces to control heat pumps are very limited, preventing the optimal operation of heat pump systems. In the case of market-available heat pumps, a potential MPC can only control a manipulated variable via the SmartGrid Ready interface that indirectly controls a system variable (e.g., flow temperature). Typically, an internal heat pump controller (usually conventional PID-Controller) still adjusts the control variables of the heat pump (e.g., compressor speed) regardless of whether this is purposeful for the overall system. Hence, the literature shows only studies in which the MPC cannot directly control the compressor speed, which makes the internal controller the limiting factor for optimal system operation [8]. However, to the best of the author's knowledge, such limiting factors are not discussed in the literature.

In the literature, studies show high potential for MPC in BES based on numerical approaches and neglect limiting factors of real-world operation. In addition, many approaches use simplified black-box models or linearized models to predict the heat pump's behavior. However, the heat pump is a closed thermodynamic cycle inherently covering nonlinear dependencies between state and control variables. Considering the complex thermodynamic relationships leads to a complex and computationally intensive model that is often avoided in MPC approaches to solve the underlying optimization problem in a reasonable time. This paper closes the identified research gaps and proves the proposed method in a simulative and experimental case study:

- To reduce expert knowledge for setting up process models, we use data-driven models to minimize the modeling effort.
- To prove consistent thermodynamics and prediction accuracy, we conduct measurement campaigns that substantiate our approaches.
- To avoid manufacturer-related interface limitations, we use a fully controllable heat pump test bench with all relevant interfaces [9].
- To prove the proposed method under realistic, dynamic, and repeatable boundary conditions, we use the hardware-in-the-loop approach by coupling a heat pump test bench to a virtual building.

The paper is structured as follows:

- Section 2 describes the experimental setup and the controller's structure.
- Section 3 shows the results of the simulative and experimental case studies.
- Section 4 discusses the results and underlines the potential of the proposed method.
- Section 5 concludes all findings and gives recommendations for future work.

2. Method: MPC for heat pump systems

The proposed method of this work integrates an MPC system controller into a heat pump test bench. This work uses the experimental hardware-in-the-loop (HiL) approach to assess the potential of MPC compared to conventional controllers under dynamic, realistic, and repeatable boundary conditions. This approach couples real hardware with simulation models that lead to dynamic and realistic environments. This section describes the HiL setup and explains the developed system controller. Furthermore, we introduce the performed case studies and define the used key performance indicators (KPI).
2.1. Experimental Setup

This section presents the HiL approach for the experimental case study. HiL connects virtual buildings with real heat generators. In this work, we focus on the behavior of the heat pump and the potential of the MPC system controller. Figure 1 shows a schematical overview of the implemented HiL framework.

The system consists of an air-to-water heat pump in split design, test benches (climatic chamber and hydraulic test bench), a building performance simulation model, the cloud-based data infrastructure (MQTT-Broker and InfluxDB tick-stack), and the MPC system controller. The several components are described in the following:

**Air-to-water heat pump:**

In this work, we use a self-developed air-to-water heat pump with a nominal heating capacity of 7 kW in operating point A7W35 (ambient temperature: 7 °C, supply temperature: 35 °C). We built the heat pump in split design: the outdoor unit (OU) consists of the compressor, evaporator, and expansion valve; the indoor unit (IU) consists of a condenser and a water pump for the hydraulic cycle.

The heat pump uses an inverter-driven scroll compressor operating between 30 Hz and 90 Hz, indicating a possible part load operation of 1/3 of the full load. Using a PLC and measuring terminals, all sensor data are collected, and all set values are written. In previous work, we developed control strategies for a safe and efficient operation regarding superheat control [9]. Thus, the internal heat pump controller controls two subsystems (see Figure 2 and Figure 3).

First, the superheat control (Figure 2) regulates the expansion valve and ensures that gaseous refrigerant enters the compressor's inlet. The detailed controller development is described in Göbel et al. [9].
According to Figure 3, the flow temperature $T_{fl}$ can be controlled by manipulating the compressor speed $n_{com}$. In the market-available heat pumps, an internal PID controller is used to adjust the control variable. However, this controller has no direct interface for MPC applications. In this work, we open this controller interface to manipulate the compressor speed $n_{com, set}$ directly by the system controller. Within the HiL approach, the air-to-water heat pump is coupled to a virtual building, which is explained in the following.

**Building performance simulation model**

We calculate the building performance simulation for the HiL framework using the BESMod Modelica library [10]. In this context, we integrate MQTT communication blocks into the hydraulic subsystem. A single-zone Modelica building performance simulation model calculates the thermal behavior of a building. The air temperature of the single zone represents the room temperature, which is the controlled variable. The model's parameters are obtained from TEASER [11]. The building envelope covers a net floor area of 130 m². Following DIN EN 12831, the resulting heat load at -12 °C is 6,596 W. We implement an underfloor heating system model to transfer heat from the hydraulic cycle to the building envelope. The total activated floor's capacity is 52,629 kJ K⁻¹ which is equal to a water volume of 12.59 m³. Due to this high capacity, we avoid an additional buffer tank within the hydraulic system. To connect the described simulation model to the heat pump, we use test benches, which are explained in the following section.

**Test benches**

The air-to-water heat pump is located in a climatic chamber that emulates dynamic ambient conditions. The climatic chamber captures ambient conditions between -20 °C and 40 °C and humidity up to 100 %. For this purpose, the climatic chamber has an air handling unit with heat exchangers for cooling and dehumidification, an electric heating coil, and an isothermic steam humidifier. The hydraulic test bench controls the return flow temperature and the volume flow of the heating cycle, which the dynamic building performance simulation model calculates. The return temperature is adjusted using a three-way mixing valve, ensuring fast responses and low delay times due to mixing. While the test benches are the physical connection between the simulation model and the heat pump, the cloud-based data infrastructure is the digital connection between all components.

**Cloud-based data infrastructure**

All components (simulation models, test benches, system controller) communicate with the overall MQTT broker to which they can send data and subscribe to topics. The task of the MQTT broker is to distribute the data. Each component subscribes to the necessary topics. When the broker receives messages for corresponding topics, it is passed on to the corresponding component. The components send their data with a time increment of one second. The communication latency is in the range of milliseconds, allowing the components to receive the subscribed messages in the proposed time increment. While the time constants of thermal systems with high capacity (as shown above) are significantly higher than the time increment and the latency, the frequency, and the latency do not affect the system's interaction.

Completing the communication infrastructure, we use the InfluxDB time-stack to store and visualize all time-varying data, which is communicated via the MQTT broker [12], [13]. Since no historical data is available via the MQTT broker, the system controller requests this data directly from the InfluxDB time series database using HTTP. In this work, we integrate the system controller into the described framework, which we explain in more detail below.
System Controller

The controller needs access to the MQTT brokers and the InfluxDB tick-stack. In this framework, the MPC can run on any server in a cloud system. In this work, the system controller is the device under test, exploiting MPC’s potential using different interfaces compared to conventional heating curves. Section 2.2 describes the controller in detail.

2.2. Data-driven model predictive control

The developed MPC maintains thermal comfort by keeping the zone’s air temperature within the comfort constraints and simultaneously minimizes the heat pump’s power consumption. The cost function of the resulting optimal control problem (OCP) (1) – (7) is given in (1). We penalize the violation \( \epsilon \) of comfort constraints (4) with \( C_1 = 10 \). Furthermore, we consider energy consumption by minimizing the control input \( u \). Depending on the experiment, the control input \( u \) can either be the actual heat pump modulation (compressor speed) \( (C_{u,\text{com}} = 0.1) \) or the flow temperature of the heat pump \( (C_{z,\text{flow}} = 0.1 \cdot 1/300) \). The weight \( C_{z,\text{flow}} \) is scaled with 1/300 because the absolute values of the flow temperature are higher than the ones of the heat pump modulation. The third term \( C_3 \Delta u_k^2 (C_{z,\text{flow}} = 0.005 \cdot 1/300) ; C_{z,\text{com}} = 0.1 \) describes the cost of changing the manipulated variable, which prevents the system from oscillating. The term is squared so that both negative and positive changes are considered. We determine the values of all weights \( C \) heuristically. In future work, we also plan to model and minimize the heat pump’s electric power.

\[
\begin{align*}
\min_{u, \epsilon} & \sum_{k=0}^{N} C_1 \epsilon_k^2 + C_2 u_k + C_3 \Delta u_k^2 \\
\text{s.t.} & \Delta T_{\text{air}, k} = f_{\text{ann}}(T_{\text{air}, k}, \ldots; T_{\text{air}, k-m_f}; u_k, \ldots; u_{k-m_f}; d_k, \ldots; d_{k-m_d}) \\
T_{\text{air}, k+1} &= \Delta T_{\text{air}, k} + T_{\text{air}, k} \\
T_{\text{air}, \text{min}, k} - \epsilon_k &\leq T_{\text{air}, k} \leq T_{\text{air}, \text{max}, k} + \epsilon \\
0 &\leq \epsilon \\
u_{\text{min}} &\leq u_k \leq u_{\text{max}} \\
\forall k &\in [0, \ldots, N - 1]
\end{align*}
\]  

Crucial for the successful implementation of MPC is the underlying process model to predict the building’s and heat pump’s behavior (2) – (3). In this case, we use an artificial neural network (ANN) to predict the zone’s temperature with all inherent system dynamics. To predict the temperature change \( \Delta T_{\text{air}} \) during time step \( k \), we consider the last \( m_f \) temperatures, the last \( m_u \) controls, and the last \( m_d \) measured disturbances \( d \) (solar radiation and ambient temperature). Thus, we use a nonlinear, autoregressive process model with exogenous inputs (NARX). Using this process model leads to a nonlinear optimization problem, which we solve efficiently using Casadi and Ipopt [14, 15]. Details on the integration of ANNs as process models in an MPC can be found in previous works of the authors [7], [15]–[17]. The OCP’s prediction horizon \( N \) is 36 with a time step size of 10 min, which results in a prediction of 6 hours.

Safe operation of the MPC requires validity of the underlying process model in the whole operation range. For that reason, we pre-train the ANN with simulation data. The system identification of the simulation model is performed by choosing temperature setpoints according to a square curve for a baseline PID controller for two weeks each in winter, spring, and fall from a test reference year [18]. Here, the data set is split into 80% training, 10% validation, and 10% testing.

Besides the training data for setting up a reasonable process model using ANNs, the hyperparameter tuning of ANNs is crucial. Tuneable hyperparameters are the number of layers, the number of neurons in each layer, and the activation function. In this work, a brute-force hyperparameter optimization is performed. For this reason, several ANNs with different architectures are trained and evaluated on the test set. The ANNs with the
highest accuracy are finally used as a process model in the MPC. A batch normalizing layer serves as the input layer since it efficiently scales the features, stabilizes, and speeds up the training process [19]. The output layer uses a linear activation function. We constrain the hyperparameter optimization to use relatively small ANNs with one or two hidden layers and 4 to 32 neurons to compute the optimization problem more efficiently and reduce the risk of overfitting. After hyperparameter tuning, the final ANN has one hidden layer with 16 neurons. The activation function for the hidden layer's neurons is the softsign function. We analyze and benchmark the developed system controller in a case study described below.

2.3. Case Study

In this work, we integrate MPC into a heat pump system controller and investigate the impact of the interface between the system controller and the heat pump system on the overall performance of a building energy system.

For this purpose, we consider two interfaces and a benchmark control:

1. **Benchmark control: Heating curve:**
   The used benchmark control is a weather compensation heating curve which takes the nominal flow temperature \( T_{f,\text{nom}} \), the current room set temperature \( T_{\text{room,set}} \), the ambient temperature \( T_{\text{amb}} \) and the nominal ambient temperature \( T_{\text{amb,nom}} \) into account to calculate the set flow temperature \( T_{f,\text{set}} \) for the heat pump. Equation 8 shows the correlation between the variables.

   \[
   T_{f,\text{set}} = \left( T_{f,\text{nom}} - T_{\text{room,set}} \right) \cdot \left( \frac{T_{\text{room,set}} - T_{\text{amb}}}{T_{\text{room,set}} - T_{\text{amb,nom}}} \right)^n + T_{\text{room,set}}
   \]  

   The parameter \( n \) describes the heat curve's gradient and is constant at 1.2. The equation results in the nominal flow temperature at the nominal ambient temperature. Because the equation considers the current room set temperature, the set flow temperature is decreased during periods of low room set temperatures. Besides the flow temperature control, a valve manipulates the volume flow into the underfloor heating to further control the room temperature resulting in a dynamic volume flow.

2. **Manipulated variable: Flow temperature:**
   The MPC controls the room temperature by manipulating the flow temperature of the heat pump. The internal controller of the heat pump regulates the supply temperature with the help of the compressor speed. Furthermore, the internal controller considers the heat pump's physical constraints (e.g., min compressor speed = 30 Hz). The volume flow is constant at the nominal flow.

3. **Manipulated variable: Compressor speed**
   The MPC controls the room temperature by manipulating the compressor speed. The heat pump's internal control only interacts with security issues. The MPC knows the heat pump's constraints. Since the manipulated variable has a discontinuous step between 0 and 30 Hz, the heat pump gets turned on above 30 Hz. Below a compressor speed of 30 Hz, the compressor does not operate. The volume flow is constant at the nominal flow.

Figure 4 shows the reference variable for the heating curve and the comfort band for evaluating the room temperature. The approaches with MPC use the band directly as a reference variable. For the heating curve, we shift the reference variable so that the room temperature corresponds approximately to the room setpoint temperature at the beginning of the comfort phase (interval of the higher room setpoint temperature).

We use weather data for the location of Potsdam as a boundary condition of the energy system [18]. We determine reference days with the help of sensitivity analysis and clustering [20]. This work only considers this system’s winter reference day, Jan. 11. The day has a mean temperature of 1.32 °C, representing 114 days in the year in Potsdam.

We perform a simulative and experimental case study for this work. The simulative study consists of three cases. The study considers the system with the heating curve controller, the MPC manipulating the flow temperature, and the MPC using the compressor speed as the manipulated variable. We only consider the two MPC controllers for the experimental study without an additional benchmark test since we focus on the interface itself.
2.4. KPI Definition

We evaluate our results with different KPI definitions, which we explain in the following section:

Discomfort:
All building energy systems have a trade-off between discomfort and energy consumption. In our work, we calculate the total discomfort as follows:

$$\int_{t=0}^{t_{\text{end}}} |T_{\text{room}} - T_{\text{room, set}}| \, dt$$

(9)

Energy Consumption:
We consider for the energy consumption, the total electrical energy consumption of the heat pump:

$$W_{el, hp} = \int_{t=0}^{t_{\text{end}}} P_{el} \, dt$$

(10)

Seasonal Coefficient of Performance (SCOP):
To evaluate the heat pump's efficiency, we use the integrated COP of the heat pump over the day considered. To do so, we integrate the provided heat flow into the building $\dot{Q}_{sh}$.

$$SCOP = \frac{\int_{t=0}^{t_{\text{end}}} \dot{Q}_{sh} \, dt}{W_{el, hp}}$$

(11)

Compressor starts
Due to poor control parameter settings, heat pumps in the field can have many compressor starts, resulting in reduced efficiency. Additionally, compressor manufacturers specify a maximum number of starts to ensure a long service life. For this reason, we evaluate the amount of compressor starts for all use cases.

3. Results

This section presents the dynamic simulation results for the three control approaches (section 3.1) and the experimental comparison between both interfaces (section 3.2).

3.1. Simulation case study: MPC vs. heating curve

Figure 5 shows the benchmark case. The black lines show the upper and lower comfort bounds. Between 8 am and 4 pm, they are between 19 °C and 21 °C, else temperatures between 16 °C and 24 °C are within the bounds. For a reasonable comparison with the MPC approaches, the room temperature of the heating curve is set to 16 °C the night. The control of the volume flow behaves accordingly. We get similar room temperature trends in MPC and heating curve control.
It can be seen that the heating curve with the chosen setting can keep the room temperature within the given bounds. The heat pump turns on at around 3:00 am. The heat pump turns on and off frequently as the outdoor temperature rises. The heat pump turns off by lowering the temperature bounds at 4 pm. Since the additional control valve stops the volume flow into the underfloor heating system during low set temperatures, the heat pump can only control the flow temperature during heating hours (3 am – 4 pm; see Figure 4).

In Figure 6, the room temperature of the thermal zone is controlled with an MPC that sets the flow temperature setpoint. An internal PID-Controller of the heat pump controls the flow temperature. The MPC can keep the zone temperature within the comfort constraints. To reach the raised bounds at 8 o’clock, the MPC raises the flow temperature setpoint to its upper bound. Between 8 am and 4 pm, a discrepancy between the set and the actual flow temperature is observed. The difference results from frequent on-off cycling of the heat pump caused by the internal PID-Controller. The MPC lowers the flow temperature setpoint by lowering the temperature bounds.

Figure 7 shows the control of the zone temperature with an MPC that directly controls the compressor speed. The MPC is capable of keeping the zone temperature within the comfort constraints. The heat pump gets turned on at around 5 am. Before raising the temperature bounds, the MPC sets the compressor speed to its upper bound to fulfill the temperature bounds. Similar to the MPC with the flow temperature setpoint, the MPC lowers the set value during the day to minimize energy consumption. The discrepancy between the set and the actual heat pump modulation can be explained by the minimum compressor speed of 30 Hz. The compressor gets turned off if the MPC set value is below 30 Hz. Since the relative compressor speed can only
be between 0.33 and 1 and the set value range is between 0 and 1, the compressor can only follow the set fellow from 0.33 to 1.

![Figure 7: Simulation: Heating the thermal zone on a winter day using an MPC which controls the compressor speed.](image)

Table 1 shows the KPI evaluation of the three simulated control approaches. The consumed electrical energy is 29.38 kWh for the heating curve controller, which is the highest overall value. Both MPC approaches reduce electrical energy consumption. Controlling the flow temperature reduces the energy consumption by 20.25 %, and controlling the compressor speed directly reduces the energy consumption by 5.75 %. The highest discomfort of all control approaches is at 0.32 Kh with the MPC with flow temperature setpoint. The discomfort corresponds to a deviation of the temperature bounds of 0.32 K for one hour, which is negligible for the comfort of occupants.

The heat pump operates the most efficiently with the flow temperature MPC at a SCOP of 2.83. The heating curve controller achieves the lowest SCOP of 2.46. The number of starts for heating curve control and flow temperature MPC is 22 and 24, respectively. Both controllers yield a higher number of starts than compressor speed MPC, which is at 3. Summing up, directly controlling the compressor speed leads to fewer starts. Many compressor starts reduce the service life, but this study cannot measure it. According to the following case study, the heat pump's efficiency needs to be evaluated in real experiments.

3.2. Experimental case study: Integrating MPC into a real heat pump controller

This section demonstrates the successful integration of MPC on a real heat pump system. Figure 8 shows the MPC with flow temperature control. The heat pump first gets turned on at around 4 am, similar to the MPC, which controls the compressor speed. Due to the MPC raising of the flow temperature setpoint, the compressor speed rises until it operates at maximum speed.

With lowering the flow temperature setpoint, we observe several compressor starts between 9 am and 5 pm due to the internal PI controller, which turns off the heat pump if its output is below 0.33. On-off cycling happens if the flow temperature setpoint is too low to be kept with minimum compressor speed. The PI-controller turns off the heat pump, the flow temperature drops below the setpoint, and after the minimum off-time, the heat pump will be turned on again.

Table 2 shows the evaluated KPIs for the experiments with the real heat pump for the two MPC approaches. The electrical energy consumed is 8.15 % lower for the MPC with flow temperature control. The thermal discomfort for this approach is 3.77 Kh and 0.2 Kh for the compressor speed MPC. Table 2 gives an overview of these KPIs. The SCOP is similar to both approaches. Due to the behavior of the internal PI-controller, the flow temperature MPC has 18 starts. With direct control of the compressor speed, the starts are reduced to 2.
Figure 8: Real experiment: Heating of the thermal zone on a winter day using an MPC, which controls the flow temperature

Figure 9 shows the experimental results of the real heat pump using MPC controlling the compressor speed. The zone temperature and MPC setpoint curves are very similar to the simulated data in Figure 7. The heat pump’s compressor can keep the setpoints given by the MPC. Like in the simulations, the heat pump gets turned off at compressor speeds below 30 Hz, corresponding to an MPC setpoint of 0.33.

When the heat pump gets turned on, seen at around 4 am and 11 am, the compressor speed jumps. This starting behavior is given by the prescribed compressor startup program of the compressor’s manufacturer. This mode guarantees a safe operation within the highly dynamic starting procedure. After the dynamic starting mode, the heat pump switches to normal mode and accepts set values for compressor speed from the MPC. Starting procedures of heat pumps show real-world limitations, are challenging to model, and underline the importance of dynamic experimental tests. The following section discusses the explained results.

4. Discussion

In this section, we discuss the results from Section 3 in the context of the identified research gaps. The results show that the simulation and experimental studies provide reasonable results.

The first identified research gap concerns the high implementation effort for MPC. The data-driven MPC method chosen reduces the modeling effort. The results show that the modeling accuracy is sufficient. In the simulative and experimental case studies, the MPC controllers outperform the heating curve controller in energy consumption. The development of the process models requires either field test or simulative data but no physical equations. This work contributes to integrating MPC into practice by overcoming the need for reduced model development effort.

The literature did not investigate the potential of different system controller interfaces on the heat pump system. The results of this work prove the influence of available interfaces on the overall system performance. When comparing the results from Table 2, it is noticeable that the MPC with direct access to the compressor speed leads to lower discomfort (0.2 Kh to 3.8 Kh). If the set flow temperature is manipulated, the heat pump's internal controller calculates the control signal for the compressor. The control signal leads to high inaccuracies that the MPC cannot predict. In addition, the pre-setting of the flow temperature at low modulation increases the number of compressor starts (see Figure 8). As a result, the MPC with flow temperature pre-setting maintains the room setpoint temperature less accurately. If the MPC can control the compressor directly, the number of starts is reduced enormously (from 18 to 2).

One difference between the MPC's setpoint and the heat pump's conversion remains if the modulation setpoint is below 0.33 because the heat pump cannot convert frequencies lower than 30 Hz. Direct compressor control leads to improved comfort and efficient operation with fewer on/off cycles. However, the heat pumps' SCOP does not derive much between the interfaces. The differences are due to many compressor starts that reduce the average flow temperature. A low flow temperature leads thermodynamically to higher efficiency. Starting processes worsen the efficiency since additional losses occur during the compressor start (high overheating, high friction losses in the compressor). Both effects seem to balance each other out in the investigated experimental case study and should be investigated in more detail in the future.

Finally, purely annual simulative studies usually use simplified models to reduce computational effort. In the simulative case study, the calibrated model accurately describes the steady-state heat pump process. However, the differences between the experiment and simulation, especially in the discomfort, deviate strongly from each other. The differences are not due to MPC computing but due to differences in experimental and simulative heat pump operation. The influence of the compressor starts on the efficiency, and the flow temperature can hardly be represented by a simulation model. Therefore, the experimental data show the real-life behavior and the accurate system technology's influence. The HiL approach, with its dynamic, realistic, and repeatable boundary conditions, contributes to the integration of MPC into the practice.

5. Conclusion

This work contributes to integrating MPC with data-driven process models into practice using simulative and experimental case studies. In this paper, we apply the hardware-in-loop method to prove the functionality of MPC under dynamic, repeatable boundary conditions. We integrate a system controller into an energy system consisting of a self-developed heat pump test bench and a building performance simulation model coupled via a hydraulic test bench and a climate chamber. A conventional heating curve controller represents the benchmark control. The MPC controls the supply temperature or the heat pump's compressor speed exploiting the potential of different controller interfaces. We show that data-driven MPC controllers reduce the modeling effort and still lead to reasonable results outperforming conventional heat pump controller. In all case studies, the MPC reduces the system's energy consumption by up to 20.25 %. Direct access to the compressor frequency reduces the number of startups at from 18 to 2 for one specific day. The reduction of starts leads to a higher control quality and, thus, to low discomfort.

The BES consists only of a heat pump and building in this work. We will extend the system with a DHW tank and PV-System in future work.

Abstract

A two-phase ejector recovers the energy in the refrigerant cycles’ throttling process, improving the coefficient of performance (COP) of high-temperature heat pumps (HTHPs). This study investigated the effects of the mixing pressure on the performance of two-phase ejectors and ejector-assisted HTHPs. A 1D theoretical model of a two-phase ejector was built to predict the internal fluid dynamics and evaluate ejector performance. A thermodynamic model of an ejector-assisted HTHP was built to evaluate the COP of HTHPs and the volumetric heating capacity of low-global warming potential refrigerants. The results demonstrate that an optimum mixing pressure in a two-phase ejector provides the best performance of a two-phase ejector and ejector-assisted HTHP. The optimum mixing pressure was slightly lower than the evaporation pressure. At this pressure, the two-phase flow in the ejector was subsonic. For ejector-assisted HTHPs using low–global warming potential refrigerants at a sink temperature of 120°C, temperature lift of 40°C, and subcooling of 10°C, a two-phase ejector has an average ejector efficiency of 0.334, and the COP and volumetric heating capacity were improved by 7.2% and 7.3%, respectively.

1. Introduction

A high-temperature heat pump (HTHP) is one of the emerging solutions for decarbonization and electrification in industry and buildings. Current research focuses on HTHPs operating with electrically driven, single-stage vapor refrigerant compression cycles (VRCCs) [1]. A VRCC uses an expansion valve (EV) to reduce refrigerant pressure from the condenser to the evaporator, which is a throttling process associated with high energy loss. Using a two-phase ejector as an expander device to replace the EV could partially recover this energy loss, resulting in improved performance of the VRCC. A typical configuration of an HTHP operating with an ejector-expansion VRCC (EERC) is shown in Fig. 1(a). The configuration consists of a compressor, a condenser, an internal heat exchanger (IHX), a two-phase ejector, a separator, an evaporator,
and an EV. Figure 1(b) shows that the ejector provides an isentropic expansion process (i.e., process $4 \rightarrow 5'$), resulting in a larger specific enthalpy decrease than that associated with an isenthalpic expansion in an EV (i.e., process $4' \rightarrow 5'$). Additionally, the ejector works as a thermo-compressor, providing a higher suction pressure for the compressor (i.e., $p_1 > p_1'$). An EERC could improve the performance of HTHPs by increasing the specific heat absorption capacity in the evaporator and reducing the compression work in the compressor [2].

Using a two-phase ejector as an expander in EERCs was proposed in the 1930s. It became an exponentially increased research topic in HVAC and refrigeration (HVAC&R) systems in the 2010s [2, 3]. Two-phase ejectors have been employed in EERCs of transcritical CO$_2$ [4, 5] and subcritical, low-pressure refrigerants, such as R134a [6], R718 [7], R600a [8], R290 [9], and R410a [10]. For transcritical CO$_2$ EERCs with a high throttling loss, two-phase ejectors are attractive, increasing the cooling cycle coefficient of performance (COP) by 15%–30% [3]. For low-pressure refrigerant EERCs with a low throttling loss, a two-phase ejector is less effective, increasing the cooling cycle COP by 7%–20% [11]. The research on EERCs in HTHPs is limited. Popovac et al. [12] experimentally quantified the improved performance of an HTHP operating with R600 EERC and suggested that a two-phase ejector could improve the heating cycle COP by approximately 30% at a moderate temperature level ($T_{\text{sink}} = 80.4\,^\circ\text{C}$ and $T_{\text{source}} = 53.2\,^\circ\text{C}$). Bai et al. [13] theoretically assessed EERCs operating with low–global warming potential (GWP) refrigerants and demonstrated that an EERC of R1234ze(Z) could improve the heating cycle COP by at least 10.3% at $T_{\text{sink}} = 105\,^\circ\text{C}$ and $T_{\text{source}} = 30\,^\circ\text{C}$. Luo and Zou [14] theoretically showed that HTHPs with EERCs of R600 and R1234ze(Z) could reduce expansion losses by 10%–18% and improve the heating cycle COP by 8%–14% at $T_{\text{sink}} = 120\,^\circ\text{C}$ and $T_{\text{source}} = 80\,^\circ\text{C}$. Mateu-Royo et al. [15] theoretically demonstrated that an EERC could slightly improve the heating cycle COP and downsize the compressor.

The majority of theoretical research has employed the zero-dimensional model developed by Kornhauser [16]. Kornhauser’s model assumed the mixing process was under constant pressure, $p_{\text{M}}$, and the two-phase fluid was inhomogeneous at equilibrium. The model was built considering the conservation of mass, energy, and momentum with assigned efficiency for different sections within a two-phase ejector. The model required a specified $p_{\text{M}}$ as an input to predict the component-level performance of two-phase ejectors. Pressure $p_{\text{M}}$ is closely related to the ejector’s geometry, refrigerants, and operating conditions, which are difficult to determine experimentally [2]. For a mixing process within a constant area under a constant pressure, $p_{\text{M}}$ could be iteratively calculated from the relationship between the mass, flow area, and specific volumes of refrigerant [17-19]. However, the calculated $p_{\text{M}}$ was affected by the condensation shock wave and/or the nonequilibrium two-phase flow at the exit of the mixing chamber. In other literature, $p_{\text{M}}$ was guessed without justification. In transcritical CO$_2$, EERC for low-temperature refrigeration, $p_{\text{M, opt}}$ was assumed to be the evaporation pressure of secondary fluid (SF), $p_{\text{Evap}}$, by Deng et al. [20], or 95% of $p_{\text{Evap}}$ by Purjam et al. [21]. In EERC using R134a, R1234yf, and R1234ze(Z) for refrigeration, $p_{\text{Evap}}$ was assumed to be the saturated vapor pressure corresponding to a 5 K drop in the evaporation temperature, $T_{\text{Evap}}$, by Lawrence and Elbel [22] and Atmaca et al. [23]. Additionally, Kornhauser’s primary results showed that the maximum cooling cycle COP of EERC in refrigeration was achieved with an optimum mixing pressure, $p_{\text{M,out}}$, which gave the same velocity of the primary fluid (PF) and the SF before mixing. No evidence existed that the calculated or guessed $p_{\text{M}}$ was $p_{\text{M,out}}$, which could yield the maximum COP of the investigated EERC for refrigeration applications.
To fully explore the technical merit of using a two-phase ejector in an HTHP, selecting a reasonable value of $p_{\text{M, out}}$ is critical. This study analyzes the optimized mixing pressure of two-phase ejectors in HTHPs. An improved 1D thermodynamic model of a two-phase ejector was built with the real properties of refrigerants. The effects of mixing pressure on fluid dynamics within two-phase ejectors were investigated. The optimum mixing pressure was determined for the component-level performance of two-phase ejectors and the system-level performance of HTHPs. The technical merits of HTHPs with EERCs were explored for various low-GWP refrigerants.

2. Theoretical Model of a Two-Phase Ejector

A typical ejector consists of a primary nozzle, a suction chamber, a mixing chamber (including a converging section and a constant area section), and a diffuser, as shown in Fig. 2. The ejector works on the isentropic conversion process of potential work, contained in the PF flow, into kinetic energy. High-pressure PF accelerates into a high-speed jet and creates a low-pressure zone at the nozzle exit plane, which entrains the low-pressure SF vapor into the suction chamber. Depending on the initial state of the PF, the PF flow at the nozzle’s exit could be supersonic (e.g., in transcritical CO$_2$ cycles [24]) or subsonic associated with two-phase change (e.g., flashing evaporation or condensation). PF flow further accelerates and expands, creating a hypothetical throat at the section $y-y$, where the SF flow may be choked at its critical velocity. PF and SF mix in the constant area section of the mixing chamber under a constant mixing pressure, $p_{\text{M}}$. If the flow of completely mixed PF and SF is supersonic, a condensation shock wave occurs, resulting in a pressure lift. The static pressure of mixed PF and SF further increases in the diffuser by converting its kinetic energy into potential energy.

2.1. Governing Equations

In this study, an improved 1D thermodynamic model of a two-phase ejector was built, considering a constant pressure mixing process [16, 25]. Major assumptions adopted in the theoretical model include the following:

(1) The flow inside the ejector is 1D, steady, and adiabatic.

(2) The frictional and mixing losses are defined in terms of ejector component isentropic efficiencies, including $\eta_N$ for the primary nozzle, $\eta_S$ for the secondary flow, $\eta_M$ for the mixing process, and $\eta_D$ for the diffuser [26].

(3) Working fluid is in thermodynamic quasi-equilibrium condition (i.e., a homogeneous equilibrium model of two-phase flow [27]).

(4) The mixing PF and SF is initiated at the section $y-y$ and completed at the section $m-m$ under constant static pressure, $p_{\text{M}}$.

The governing equations in the thermodynamic model are built with the mass, momentum, and energy conservation across the ejector components. The state points of fluids in the following equations are presented by lowercase Roman numerals “i, ii, iii, …”, as shown in Fig. 2.

Fig. 2. Typical flow phenomena in a two-phase ejector [28]. (NXP stands for nozzle exit plane. MF represents the mixed PF and SF.)
The energy conservation of PF through an isentropic expansion process within the primary nozzle and the converging section of the mixing chamber is given by Eqs. (1) and (2):

\[ h_{iii} = (1 - \eta_N)h_i + \eta_N h_{iii,is}, \quad \text{and} \]
\[ V_{iii} = \sqrt{2(h_i - h_{iii})}. \]

The energy conservation of SF within the converging section of the mixing chamber is calculated with Eqs. (3) and (4):

\[ h_v = (1 - \eta_S)h_{iv} + \eta_S h_{v,is} \quad \text{and} \quad h_{v,is} = h(s_{iv}, p_v), \quad \text{and} \]
\[ V_v = \sqrt{2(h_{vi} - h_v)}. \]

The maximum value of \( V_v \) is limited to its local speed of sound, \( C_v \). If the flow of SF is choked, then Eq. (5) gives

\[ V_{v,max} = C_v. \]

The mixing process is under constant static pressure, represented by Eq. (6):

\[ p_{iii} = p_v = p_{vi} = p_M. \]

The moment conservation in the mixing process is given by Eq. (7):

\[ \phi_M(\dot{m}_{PF}V_{iii} + \dot{m}_{SF}V_v) = (\dot{m}_{PF} + \dot{m}_{SF})V_{vi}, \]

where \( \phi_M \) is the velocity coefficient accounting for the frictional loss in the mixing process, and \( \phi_M = \sqrt{\eta_M} \) [29].

The energy conservation in the mixing process is shown in Eq. (8):

\[ (\dot{m}_{PF} + \dot{m}_{SF}) \left(h_{vi} + \frac{1}{2}V_v^2\right) = \dot{m}_{PF} \left(h_{iii} + \frac{1}{2}V_{iii}^2\right) + \dot{m}_{SF} \left(h_v + \frac{1}{2}V_v^2\right). \]

If the mixed flow is supersonic or sonic (i.e., \( M_{vi} \geq 1 \)), a condensation shock will occur at the section s-s. The conservation of mass, momentum, and energy across a condensation shock wave are calculated by Eqs. (9), (10), and (11) [25]:

\[ \rho_{vii}V_{vii} = \rho_{vi}V_{vi}, \quad \text{and} \]
\[ p_{vii} + \rho_{vii}V_{vii}^2 = p_{vi} + \rho_{vi}V_{vi}^2, \]
\[ h_{vii} + \frac{1}{2}V_{vii}^2 = h_{vi} + \frac{1}{2}V_{vi}^2. \]

The thermodynamic state equations for the density and entropy after the condensation shock wave are given in Eqs. (12) and (13):

\[ \rho_{vii} = \rho(p_{vii}, h_{vii}), \quad \text{and} \]
\[ s_{vii} = s(p_{vii}, h_{vii}). \]

If the mixed flow is subsonic (i.e., \( M_{vi} < 1 \)), Eq. (14) applies:

\[ V_{vii} = V_{vi}, p_{vii} = p_{vi}, \quad \text{and} \quad s_{vii} = s_{vi} = s(p_{vii}, h_{vii}). \]
The energy conservation within the diffuser is given by Eqs. (15) and (16):

\[ h_{\text{viii}} = h_{\text{vii}} + \frac{1}{2} V_{\text{vii}}^2, \]  

\[ h_{\text{viii,ls}} = h_{\text{vii}} + \eta_D \frac{1}{2} V_{\text{vii}}^2. \]  

The static pressure and quality of the two-phase fluid discharged from the ejector are given in Eqs. (17) and (18):

\[ p_{\text{viii}} = p(h_{\text{viii,sf}}, s_{\text{viii}}) \]  

\[ s_{\text{viii}} = s_{\text{vii}} \]  

\[ x_{\text{viii}} = x(p_{\text{viii}}, h_{\text{viii}}). \]  

Assuming the discharged two-phase fluid could be fully separated in the separator, the fluid loop in an EERC requires Eq. (19):

\[ x_{\text{viii}} = \frac{m_{\text{PF}}}{m_{\text{SF}} + m_{\text{PF}}} = \frac{1}{1+\omega} \]  

where \( \omega \) is the ratio of the mass flow rates of SF, \( m_{\text{SF}} \), and to that of PF, \( m_{\text{PF}} \), as shown in Eq. (20):

\[ \omega = \frac{m_{\text{SF}}}{m_{\text{PF}}}. \]  

The flow conditions in the ejector are characterized by the Mach number, \( M \), and \( M = V/C \). The speed of sound of the two-phase flow, \( C \), is given in Eq. (21) [21]:

\[ C = \frac{1}{(1-\alpha) \sqrt{\frac{1}{\rho_l c_l^2} + \frac{\alpha}{\rho_v c_v^2} + \frac{\alpha (1-\alpha) \rho_l}{\rho_v c_v^2}}}, \]  

where \( \alpha \) is the void fraction of the two-phase flow, and \( \rho \) is the density. The subscripts \( l \) and \( v \) are for the saturated liquid and vapor phases of refrigerants. In a homogeneous two-phase flow, the void fraction is given by Eq. (22):

\[ \alpha = \frac{x \rho_l}{(x \rho_l + (1-x) \rho_v)} \]  

where \( x \) is the vapor quality of the two-phase fluid.

### 2.2. Calculation Procedure

The two-phase ejector was operated with specified inlet temperature and static pressure of PF and SF, denoted as \( T_i, p_i, T_{iv}, \) and \( p_{iv} \). In investigated ejector-assistant HHHPs, inlet PF was subcooled liquid, and inlet SF was saturated vapor.

\[ T_i = T_{\text{sink}} - \Delta T_{\text{sc}} \]  

\[ p_i = p(T_{\text{sink}}, x = 1) \]  

\[ T_{iv} = T_{\text{source}} = T_{\text{sink}} - \Delta T_{\text{lift}}, \]  

where \( T_{\text{source}} \) is the sink temperature, \( \Delta T_{\text{sc}} \) is the subcooling temperature of PF from the IHX, and \( \Delta T_{\text{lift}} \) is the lifted temperature of HHHPs. The mixing pressure, \( p_M \), is the saturated vapor pressure of SF at an equivalent temperature of SF before mixing, \( T_M \), given in Eq. (24):

\[ T_M = T_{\text{Evap}} - \Delta T_M, \]  

where \( T_{\text{Evap}} \) is the saturated vapor temperature of SF and \( \Delta T_M \) is the lift temperature of HHHPs.
where $\Delta T_M$ is the assumed temperature drop of saturated SF before the mixing process.

The calculation procedure for solving the two-phase ejector model is shown in Fig. 3. These governing equations were solved iteratively in the Engineering Equation Solver (EES, F-Chart software). Component efficiencies of two-phase ejectors were assumed with constant values: $\eta_N = 0.8$, $\eta_S = 0.8$, $\eta_M = 0.9$, and $\eta_D = 0.8$ [18]. For a specified $p_M$, the model could predict the pressure and quality of discharged two-phase fluid from the two-phase ejector, $p_{viii}$ and $x_{viii}$.

Fig. 3. Flow chart of solving the two-phase ejector model.

### 3. Thermodynamic Model of an Ejector-Assisted HTHP

A thermodynamic model of an HTHP with EERC was built by applying the mass and energy conservation within each component [15, 30], as summarized in Table 1. The theoretical model was solved using EES with its built-in thermophysical properties of the refrigerants. The system performance of HTHPs was evaluated with selected refrigerants under specified operating parameters of $T_{sink}$, $\Delta T_{in}$, and $\Delta T_{SC}$. The system assumed the approach temperature and the pressure drops in the evaporator/condenser were negligible.

3.1. Compressor

A piston compressor was used in the investigated HTHP for a heating capacity of ≤800 kW. The compressor could provide the maximum discharged temperature of 150°C using hydrofluoroolefins (HFOs) [31]. The volumetric and isentropic efficiencies of piston compressors, represented as \( \eta_{vol} \) and \( \eta_{is} \), were predicted using Pierre’s correlations in Eqs. (25) and (26) [32, 33]:

\[
\eta_{vol} = 1.04 \left( 1 + 0.15 \frac{T_{suc} - 18}{100} \right) \cdot \exp \left( -0.07 \frac{p_{disch}}{p_{suc}} \right), \quad (25)
\]

\[
\left( \frac{\eta_{vol}}{\eta_{is}} \right) = \left( 1 - 0.1 \frac{T_{suc} - 18}{100} \right) \cdot \exp \left( -2.40 \frac{T_{disch} + 273.15}{T_{suc} + 273.15} \right) + 2.88, \quad (26)
\]

where \( T_{suc} \) and \( T_{disch} \) are refrigerant temperatures in degrees Celsius, and \( p_{suc} \) and \( p_{disch} \) are pressures at the compressor’s inlet and outlet, denoted by state points 1 and 2 in Fig. 1(b), respectively.

The power consumption of the compressor, \( W_{Comp} \), is calculated by Eq. (27):

\[
W_{Comp} = \frac{\dot{m}_{3g} (h_{2,12} - h_{1,12})}{\eta_{is} \eta_{em}}, \quad (27)
\]

where \( h_{2,12} \) is the enthalpy of discharged refrigerant after an isentropic compression process, and \( \eta_{em} \) is the electromechanical efficiencies of compressor; \( \eta_{em} = 0.95 \).

3.2. Internal Heat Exchanger

An IHX is employed in HTHPs to ensure a dry compression process in the compressor and improve the COP of HTHPs [34]. An IHX exchanges the heat between high-pressure vapor and low-pressure liquid. Refrigerant vapor entering the IHX is saturated at the discharged pressure of the ejector. The enthalpy of superheated vapor leaving the IHX is determined from the energy balance between the liquid and vapor refrigerant in the IHX. In this study, the subcooling temperature of refrigerant leaving the IHX, \( \Delta T_{SC} \), was specified as an input in the theoretical model of the two-phase ejector, which should be large enough to ensure the superheating of vapor at the compressor outlet.

3.3. Two-Phase Ejector

The component-level performance of the ejector was evaluated by the entrainment ratio, \( \omega \), defined in Eq. (20), and the pressure lift ratio, \( \Pi \), which is defined in Eq. (28) as the ratio of the ejector’s discharged pressure, \( p_{disch} \), to the inlet pressure of SF, \( p_{in} \):

\[
\Pi = \frac{p_{disch}}{p_{SF,in}} = \frac{p_{disch}}{p_{in}} = \frac{p_{12}}{p_{in}}, \quad (28)
\]
Elbel and Hrnjak [35] proposed the ejector efficiency, \( \eta_{\text{EJT}} \) as an applicable efficiency metric to evaluate the trade-off between \( \alpha \) and \( \Pi \). \( \eta_{\text{EJT}} \) is the ratio of the actual amount of work recovered by the ejector, \( W_r \), and the total work recovery potential for an isentropic process, \( W_{r,\text{max}} \), given by Eq. (29):

\[
\eta_{\text{EJT}} = \frac{W_r}{W_{r,\text{max}}(\frac{C=h_B-C(h_A)}{C'=\rho\cdot T})}
\]  

(29)

where \( h_A \) and \( h_B \) are the enthalpy of the PF at the ejector’s discharged pressure via isenthalpic and isentropic expansion processes, respectively. The entropy of SF flow before and after an isentropic compression process are \( h_C \) and \( h_D \), respectively. For the investigated ejector-assisted HTHP in this study,

\[
h_A = h_4,
\]

\[
h_B = h(p = p_B, s = s_A),
\]

\[
h_C = h(p = p_B, s = s_{12}),
\]

\[
h_D = h_{12}.
\]  

(30)

### 3.4. Performance of Ejector-Assisted HTHPs

The system-level performance of ejector-assisted HTHPs is evaluated by its heating cycle COP, given in Eq. (31):

\[
\text{COP}_{\text{EHTHP}} = \frac{Q_{\text{sink}}}{W_{\text{comp}}}
\]  

(31)

The refrigerants for the ejector-assisted HTHPs were evaluated by the volumetric heating capacity (VHC) [36]. A higher value of VHC is desired for a smaller compressor displacement rate to deliver a specified capacity, as shown in Eq. (32):

\[
VHC = \eta_{\text{vol}} P_1 (h_2 - h_3).
\]  

(32)

### 3.5. Low-GWP Refrigerants

Low-GWP refrigerants promising for HTHPs were selected to evaluate the merit of ejector-assisted HTHPs, as listed in Table 2. These refrigerants can be categorized into hydrocarbon (HC), hydrochlorofluorocarbon (HCFO), and HFO. R245fa is R-245fa is a hydrofluorocarbon (HFC) and set as a reference refrigerant because of its wide use in current HTHPs.

### 4. Results and Discussion

The ejector-assisted HTHPs were operated at \( T_{\text{sink}} = 120°C \), \( \Delta T_{\text{lift}} = 40 \) K, and \( \Delta T_{\text{SC}} = 10 \) K. The component isentropic efficiencies of a two-phase ejector were \( \eta_S = 0.8 \), \( \eta_S = 0.8 \), \( \eta_M = 0.9 \), and \( \eta_D = 0.8 \). The effects of the
mixing pressure, $p_M$, on the component-level performance of a two-phase ejector was predicted by the theoretical model with various equivalent temperature drops of SF (i.e., $\Delta T_M$ in Eq. (25)). For R1336mzz(Z), $p_M$ in the two-phase ejector almost linearly decreased from 429.2 kPa to 235.0 kPa as $\Delta T_M$ increased from 0.1 K to 21.4 K.

### 4.1. Effects of the Mixing Pressure

#### 4.1.1. Component-level performance of two-phase ejector

With the decrease of $p_M$, the velocity of PF and SF flows increased, and the velocity of SF flow increased more significantly than that of PF flow, as shown in Fig. 4(a). This difference is because the enthalpy change of SF (saturated vapor) is much larger than that of PF (low-quality two-phase fluid) through an isentropic expansion process across the same pressure drop. The $p-h$ diagram of R1336mzz(Z) shows that the isenthalpic and isentropic lines are nearly parallel in the low-quality two-phase region, and the slopes of isenthalpic lines are much smaller than those of isentropic lines in the high-quality two-phase region. With the decrease of $p_M$, the discharged pressure of ejector, $p_{viii}$, increased to the maximum value of 456 kPa, giving the maximum pressure lift ratio, $\Pi_{\text{max}}$. After that maximum, $p_{viii}$ linearly decreased.

From the velocity and the static pressure of PF and SF before the mixing process, four unique points could be identified as: the maximum pressure lift ratio, $\Pi_{\text{max}}$; no pressure lift effect, $\Pi = 1$; the same velocity of PF and SF, $V_{\text{SF}} = V_{\text{PF}}$; and a choked SF flow, $M_{\text{SF}} = 1$. The effects of $p_M$ on the component performance of two-phase ejectors are shown in Fig. 5. The trends of $\omega$ and $\eta_{\text{EJT}}$ related to $p_M$ are similar to that of $\Pi$. At the optimum mixing pressure, $p_{M,\text{opt}} = 424.7$ kPa with $\Delta T_M = 0.6$ K, the maximum values of $\omega_{\text{max}} = 0.733$, $\Pi_{\text{max}} = 1.059$, and $\eta_{\text{EJT, max}} = 0.333$ were achieved. At $p_M = 358.2$ kPa (with $\Delta T_M = 6.8$ K), $\Pi = 1$ and $\eta_{\text{EJT}} = 0$. Further reducing $p_M$, the ejector could not provide a compression effect because of the overexpansion of PF in the primary nozzle. At $p_M = 349.4$ kPa (with $\Delta T_M = 7.7$ K), $V_{\text{SF}} = V_{\text{PF}}$, $\Pi < 1$, and $\eta_{\text{EJT}} < 0$. These values indicate that selecting $p_M$ for $V_{\text{SF}} = V_{\text{PF}}$ is not beneficial for the performance of two-phase ejectors. When $p_M$ was reduced to 235 kPa (with $\Delta T_M = 21.4$ K), $p_M$ was sufficiently low to accelerate the SF flow to $M_{\text{SF}} = 1$, and the PF flow was subsonic, with $M_{\text{PF}} = 0.77$. At this $p_M$, the mixed PF and SF flow at the section $m-m$ was subsonic; thus, a condensation shock wave did not occur [37]. Further reducing $p_M$ may accelerate the PF flow to supersonic, but the performance of the two-phase ejector would extremely deteriorate.

---

**Fig. 4.** Effects of the mixing pressure on the gas dynamic properties in a two-phase ejector: (a) velocity and (b) static pressure.

**Fig. 5.** Effects of the mixing pressure on the two-phase ejector’s performance: (a) entrainment ratio, (b) pressure lift ratio, and (c) ejector efficiency.
4.1.2. System-level performance of ejector-assisted HTHPs

The system-level performance of an ejector-assisted HTHP is closely related to the component-level performance of a two-phase ejector. The maximum values of COP and VHC were achieved with $\eta_{EJT,\text{max}}$ at $p_{M,\text{opt}}$, as shown in Fig. 6. The reference values of COP and VHC, represented as $COP_{\text{ref}}$ and $VHC_{\text{ref}}$, are for HTHPs with an EV.

$$COP_{\text{max}} = 6.29$$ and $$VHC_{\text{max}} = 3,272 \text{ kJ/m}^3$$ were achieved at $p_{M,\text{opt}}$, corresponding to the improvement of $\Delta COP_{\text{max}} = 7.01\%$ and $\Delta VHC_{\text{max}} = 7.63\%$ for R1336mzz(Z). Replacing an EV with a two-phase ejector becomes unfavorable in HTHPs when the ejector cannot provide the compression effect (i.e., $\Pi \leq 1$).

Fig. 6. Effects of the mixing pressure on the performance of an ejector-assisted HTHP: (a) COP and (b) VHC.

4.2. Effects of the Refrigerants

The performance of two-phase ejectors and ejector-assisted HTHPs with selected refrigerants under specified operating conditions (i.e., $T_{\text{sink}} = 120^\circ\text{C}$, $\Delta T_{\text{lift}} = 40$ K, and $\Delta T_{\text{SC}} = 10$ K), as shown in Fig. 7. Similar to R1366mzz(Z), the mixing pressure had an optimum value for the maximum values of $\eta_{EJT}$, COP, and VHC, as summarized in Table 3. The averaged value of $\eta_{EJT}$ was $0.334 \pm 0.005$, improving the performance of HTHPs by $\Delta COP = 7.2\% \pm 0.9\%$ and $\Delta VHC = 7.3\% \pm 0.7\%$. This work demonstrates that replacing an EV with a two-phase ejector improves the COP of HTHPs and requires more compact compressors than basic HTHPs, which is consistent with previous studies [11]. The contribution of the two-phase ejector in the COP improvement of HTHPs with low-GWP refrigerant is $5.79\%–8.47\%$, which is much lower than moderate-temperature HPs with transcritical CO$_2$ ($\Delta COP = 15\%–30\%$ [3]). Compared with R245fa, two-phase ejectors contribute to lower improvements of COP and VHC with the selected low-GWP refrigerants, except for the improved COP with R600. R600 presented the highest COP improvement of $8.47\%$ and the highest VHC values of $6,090 \text{ kJ/m}^3$.

For HTHPs under specified operating conditions, $p_{M,\text{opt}}$ was approximately $98.4\% \pm 0.2\%$ of $p_{\text{Evap}}$, which was slightly larger than $95\%$ of $p_{\text{Evap}}$ for a transcritical CO$_2$ EERC refrigeration system [21]. $\Delta T_M$ for $p_{M,\text{opt}}$ was $0.7^\circ\text{C} \pm 0.1^\circ\text{C}$, which was much smaller than $\Delta T_M = 5$ K for EERC refrigeration using R134a, R1234yf, and R1234ze(E) [22, 23]. A higher value of $p_{M,\text{opt}}/p_{\text{Evap}}$, associated with a lower $\Delta T_M$, for two-phase ejectors in HTHPs may be because of the high operating temperature of low-pressure refrigerants and the ejector components’ isentropic efficiencies adopted in the theoretical model. Additionally, this study demonstrated that $p_M$ for $V_{SF} = V_{PF}$ does not give the maximum COP of ejector-assisted HTHPs. This result disagrees with Kornhauser’s primary analysis, which claimed that $p_{M,\text{opt}}$ was for $V_{SF} = V_{PF}$ [16]. In a supersonic ejector, the same velocities of PF and SF in the mixing process theoretically results in minimal kinetic energy loss associated with the velocity difference [38]. However, this effect may not be significant in a two-phase ejector because of the subsonic flow combined with a two-phase transition process.
Fig. 7. Ejector-assisted HTHPs with different refrigerants: (a) ejector efficiency, (b) COP, and (c) VHC.

5. Conclusions

The ejector-assisted HTHP used a two-phase ejector to replace an EV, improving energy efficiency and reducing the compressor size. These improvements closely relate to the component-level performance of two-phase ejectors. This study investigated the effects of mixing pressure on the component-level performance of two-phase ejectors and the system-level performance of ejector-assisted HTHPs. A 1D theoretical model was built to predict the fluid dynamic properties of refrigerants within the two-phase ejector and evaluate the ejector’s performance. A thermodynamic model of ejector-assisted HTHP was built to evaluate the COP and VHC of HTHPs. Low-GWP refrigerants were selected for the ejector-assisted HTHPs. The effects of the mixing pressure on the component-level performance of two-phase ejectors and the system-level performance of ejector-assisted HTHPs were investigated under specified operating conditions: \(T_{\text{sink}} = 120^\circ\text{C}, \Delta T_{\text{lift}} = 40\text{ K}, \text{ and } \Delta T_{\text{SC}} = 10\text{ K}\). The main conclusions are as follows:

1. An optimum mixing pressure exists in a two-phase ejector, which gives the maximum performance of the two-phase ejector and ejector-assisted HTHP under specified working conditions.
2. The optimum mixing pressure in a two-phase ejector for HTHPs is slightly lower than the evaporation pressure of SF.
3. At the optimum mixing pressure, the two-phase flow in a two-phase ejector is subsonic. Choked flow and condensation shock waves do not occur.
4. A two-phase ejector improves the performance of HTHPs with low-GWP refrigerants. But, the improvement of COP is less than that of transcritical \(\text{CO}_2\) HTHPs.

Some limitations of this primary study need to be addressed in future studies. The developed 1D theoretical model of a two-phase ejector adopted constant values for the ejector component isentropic efficiencies. Particularly, the energy loss owing to the difference in the velocity of PF and SF was not considered in the isentropic efficiency of mixing process. These isentropic efficiencies are closely related to the working fluids, the ejector’s geometry, and operating conditions. Computational fluid dynamics analysis needs to be employed to determine these isentropic efficiencies. This study provided a comprehensive analysis of the optimum
mixing pressure for ejector-assisted HTHPs operated with specified parameters. The effects of HTHPs operating parameters on the merits of two-phase ejectors needs to be investigated.

Abstract

In this work, the energetic behavior of compressor types was investigated and an evaluation method was developed to compare them under variable load profiles and locations. The numerous compressor maps, locations and load profiles lead to a very large number of possible combinations. For the efficient evaluation a freely available compressor tool has been developed which compares the different compressor types. The core of the tool is a database with compressor polynomials of more than 1400 compressors from different manufacturers. The same compressor types from different manufacturers were grouped together to represent an average energy performance. Compressor characteristic maps were created which visualize the behavior of each compressor type as well as their application limits and control range. An evaluation method is used to determine the seasonal energy efficiency of the different compressor types depending on the location, load profile and application. The method is based on several operating points, which are weighted according to their energetic share of the annual consumption. Based on the maps, the seasonal efficiency of the compressor types is determined and ranked.

Keywords: Compressor types, compressor characteristic map, seasonal efficiency

1. Introduction

The benefits of refrigeration technologies towards a sustainable energy system are undisputed. The market share of refrigeration machines and heat pump is increasing rapidly. The shortage of skilled workers is therefore becoming a major problem for the industry. On behalf of the Swiss Federal Office of Energy, we developed a freely available tool [4] to support planners in the selection of the optimal compressor type. The focus of this investigation is on air-conditioning and commercial refrigeration applications.

The aim of this work is an energetic comparison of different compressor types based on the data provided by the manufacturers. The performance data of compressors are provided in the form of polynomials and are regulated in the EN 12900 [1] standard. The behavior of the compressors can be summarized in compressor maps. Compressor maps are often created for turbo compressors in the form of shell curves [5][6][7]. However, compressor maps in refrigeration technology are usually not available.

In this study, compressor maps for different compressors were created based on the performance data of the compressor polynomials.

The seasonal comparison of refrigeration machines is regulated in EN 14825 [2]. Here, the seasonal efficiency is determined based on several operating points, which are weighted according to their energetic share. The energy weighting is based on hourly frequencies of ambient temperatures and load profiles. In this study, the SEER evaluation method was adapted to compressors. This allows a seasonal assessment of...
compressor types based on data provided by the manufacturers. For this purpose, compressor maps are combined with load profiles and weather data.

2. Compressor characteristic maps

The representation of compressor performance data is defined in the EN 12900 [1] standard. Compressor polynomials can be used to determine cooling capacity $Q_0$, electrical power consumption $P_{el}$ and refrigerant mass flow $\dot{m}$ as a function of evaporating temperature $T_0$ and condensing temperature $T_c$. The compressor polynomials are only valid for a specific frequency, overheating and subcooling. Therefore, several polynomials are required for each compressor to represent the compressor map. Table 1 shows an overview of the collected polynomials.

The coefficients of the compressor polynomials are available in the design tools of the manufacturers. Manufacturers who do not provide their compressor data could not be considered in this study. For turbo compressors are no performance polynomials according to EN 12900 available, therefore only individual operating points are given. These were calculated using the manufacturers' design tools.

Additional quantities such as Coefficient of Performance COP, final compression temperature $T_2$ and isentropic compressor efficiency $\eta_{is}$ can be calculated directly from the given compressor polynomials.

2.1. Database (compressor polynomials)

The application of the refrigeration machine has a strong impact on the evaporating temperature of the plant. Therefore, three different applications with different design points are considered in this study. Depending on the application, various refrigerants and design capacities were investigated. Table 2 shows an overview of the selections considered.

Any combination of application, refrigeration capacity and refrigerant for each compressor type represents a selection. For each selection, compressor data from several manufacturers are collected according to the parameters shown in Table 1. In total, more than 1400 compressors were considered. Figure 1 shows the collected data for semi-hermetic propane reciprocating compressors with a design capacity $Q_{0,\text{design}}$ of 50 kW ± 30% from various manufacturers.
In Figure 1 the cooling capacity $\dot{Q}_0$ and the Coefficient of Performance $COP$ of each compressor as a function of the condensing temperature $T_c$ at various frequencies are illustrated. The evaporating temperature $T_0$ is constant according to the design point. The deviations of $\dot{Q}_0$ at the maximum frequency with $T_c = 45 \, ^\circ C$ are due to the capacity range considered ($\dot{Q}_0_{design} \pm 30\%$). It should be noted that the frequency range may differ depending on the manufacturer. Additionally, the operating limit $T_{c,min}$ of each compressor is taken into account.

2.2. Neutralization

The aim of this study is to compare different types of compressors. To prevent direct comparison between manufacturers, neutralization is applied. In the following, it will be shown how this neutralization is implemented. The compressor data from different manufacturers are combined into one average compressor with each manufacturer equally weighted. This resulting compressor represents the average behavior of the compressor type in the specific selection. Figure 2 shows the compressor characteristic map for the neutralized compressor. This compressor map is based on the twelve individual compressors shown in figure 1.
In Figure 2 the compressor characteristic map of a semi-hermetic propane reciprocating compressor with a $Q_{\text{design}}$ of 50 kW for air conditioning applications ($T_0 = 5 \, ^\circ\text{C}$) is shown. The curve of the cooling capacity $Q_0$ at different frequencies shows the control range at variable condensing temperatures $T_c$. The left end of the characteristic diagram corresponds to the average operating limit. The right diagram shows the course of the $\text{COP}$ at different frequencies.

The compressor maps are the basis for seasonal efficiency considerations. However, they also allow an assessment of conceptual considerations when planning a plant. For example, the effects of oversized refrigeration systems or compressors can be easily estimated from the compressor map.

### 2.3. Comparison of different compressor maps

A total of 70 compressor maps were created during the investigation. These maps are located in the appendix of the final project report [3]. To show the differences between the compressor types, sizes or refrigerants used, the compressor maps were also compared. This comparison illustrates the deviations in efficiency, operating limits, and control range. Therefore, this comparison is a very comprehensive resource. Figure 3 is pointing out the deviation of different compressor types with a 2 kW design capacity and the refrigerant R513A. Further comparisons for other selections can be seen in the final report [3].
The selection in Figure 3 compares compressor types in medium temperature application \( T_0 = -10 \, ^\circ\text{C} \). Due to the small design capacity \( \dot{Q}_0_{\text{design}} \) selected, no turbo or screw compressors are available. The hermetic piston and scroll compressors don’t have capacity control, the compressor map therefore merges into one curve.

At the design point \( T_c = 45 \, ^\circ\text{C} \), the cooling capacity \( \dot{Q}_0 \) of the reciprocating compressor and the scroll compressor is almost identical. If the condensing temperature \( T_c \) is reduced, the cooling capacity \( \dot{Q}_0 \) of the reciprocating compressor increases significantly more than the one of the scroll compressor. As a result of re-expansion, the volumetric efficiency of the reciprocating compressor increases more in comparison to the scroll compressor if a small pressure differential is applied. Therefore, mass flow of the reciprocating compressor and thus capacity \( \dot{Q}_0 \) increase over-proportionally at low condensing temperatures \( T_c \).

The internal pressure ratio is particularly characteristic for the behavior of the scroll compressor. This can be seen in the curve of the isentropic compressor efficiency \( \eta_{\text{i}} \). If the pressure ratio of the system and the internal pressure ratio of the compressor match, high efficiencies are achieved. If the compressor is operated at a different pressure ratio, the efficiency is increasingly reduced. When selecting a scroll compressor, it is therefore important to ensure that the internal pressure ratio is at an energetically relevant operating point.

3. Seasonal energy efficiency evaluation method (aCOP)

The seasonal energy efficiency ratio SEER is a seasonal assessment of chillers and is defined in EN 14825. However, due to the different system boundaries as shown in figure 4, the ratio cannot be used to evaluate compressors. For the evaluation of compressor types, the ratio aCOP (annual coefficient of performance) is defined. The methodology of the aCOP is very much based on the existing ratio (SEER) of chillers in part-load operation and is an energetic analysis. The aCOP is calculated according to Eq 1.

\[
aCOP = \sum_{i=1}^{5} w_i \cdot c_i \cdot COP_i
\]
To compare different chillers, EN 14825 tests chillers under identical inlet and outlet temperatures in the evaporator and condenser. The temperatures and load profiles are defined to determine a seasonal behavior. The aCOP applies the same methodology to the system boundary compressor. Different compressors are compared under the same evaporating and condensing temperatures.

To calculate the annual coefficient of performance aCOP the compressor maps are combined with load profiles and hourly frequencies of ambient temperatures. This ratio is based on five operating points. The COP of the compressor $\text{COP}_i$ is determined from the compressor map. The energetic share of the annual consumption $w_i$ is calculated from the load profile and the hourly frequency of the ambient temperatures. If the cooling capacity of the compressor cannot be adapted to the cooling demand due to the limitations of the capacity control, the COP at the operating point is reduced with a type-dependent cycle factor $c_i$. In this study, several load profiles and Swiss locations were investigated. The impact of location and load profile are shown in Figure 5.

Figure 6 shows the influence of load profile and location on the weighting of the individual operating points. The location has an impact on the frequency of ambient temperatures $T_{\text{amb}}$. This can be seen from the heights of the bars. The load profile shows the cooling capacity $Q_0$ in relation to the ambient temperature $T_{\text{amb}}$. The weather data are taken from the data portal IDAweb of the Federal Office of Meteorology and Climatology MeteoSwiss. The hourly average temperature of the years 2015–2020 is used.

3.1. Compressor performance

To determine the coefficient of performance $\text{COP}$ of the compressor from the compressor map, the cooling demand $Q_{\text{dem}}$, evaporating temperature $T_0$ and condensing temperature $T_c$ has to be defined. The cooling
demand and evaporating temperature are given due to the load profile and application. The condensing temperature depends on the ambient temperature $T_{\text{amb}}$ and the operating limit $T_{c,\text{min}}$ of the compressor. Thus, the operating point of the compressor may vary depending on the compressor type. Table 3 shows the correlation between the ambient temperature $T_{\text{amb}}$ and the condensing temperature $T_c$ regarding the operating limit $T_{c,\text{min}}$ of the compressor.

<table>
<thead>
<tr>

<td>45</td>
<td>10</td>
<td>45</td>
</tr>
</tbody>
</table>

The temperature difference $\Delta T$ between ambient temperature $T_{\text{amb}}$ and theoretical condensing temperature $T_{c,\text{theoretical}}$ is not constant for all operating points. This is because the temperature differences $dT$ in the heat exchangers become smaller in part-load operation. The defined temperature differences correspond to an application with dry cooler. If the theoretical condensing temperature $T_{c,\text{theoretical}}$ is smaller than the compressor operating limit $T_{c,\text{min}}$, the condensing temperature $T_c$ will be adjusted. The impact of the compressor map on the operating point is shown in Fig. 6.

Figure 6 shows the differences between theoretical conditions and operating conditions. The theoretical conditions (A-E) resulting from the ambient temperatures $T_{\text{amb}}$ and the cooling demand $Q_{\text{dem}}$ based on the load profile (blue). The operating conditions (1-5) are resulting from the combination of compressor map and theoretical conditions. The operating conditions (red) are therefore depending on the operating limits and control range of the compressor. Thus, the operating points of the compressor types may differ at the same ambient temperatures.

3.2. Operating mode

The cycling factor $c_t$ is determined from the combination of load profile and compressor map. If the cooling demand $Q_{\text{dem}}$ is within the compressor map, the compressor can modulate and adapt the compressor capacity $Q_{\text{comp}}$ to the cooling demand. If the cooling demand is less than the cooling capacity at minimum frequency, the compressor goes into on-off operation. This short cycling has a negative influence on the efficiency. The operating mode thus has an influence on the efficiency of the compressor and is considered by a cycling factor $c_t$. The cycling factor $c_t$ depends on the compressor type and the difference between the
cooling demand $Q_{\text{dem}}$ of the consumer and the cooling capacity of the compressor $Q_{\text{comp}}$ and is calculated according to the equations 2 and 3.

$$c_i = \frac{f_{\text{load}}}{f_v \cdot f_{\text{load}} + (1 - f_v)}$$  \hspace{1cm} (2)

$$f_{\text{load}} = \frac{\dot{Q}_{\text{dem}}}{Q_{\text{comp}}}$$  \hspace{1cm} (3)

The calculation of the cycling factor $c_i$ is very similar to EN 14825. First, according to equation 3, the load factor $f_{\text{load}}$ is calculated from the cooling demand $\dot{Q}_{\text{dem}}$ and the capacity of the compressor $Q_{\text{comp}}$. The load factor $f_{\text{load}}$ can take values between 0 and 1 and becomes smaller the more the compressor is short cycling. Subsequently, the cycling factor $c_i$ can be calculated according to equation 2. For this, the load factor $f_{\text{load}}$ and the reduction factor $f_v$ of the compressor type are required. The reduction factor can be determined using Table 4.

**Table 4. Reduction factor compressor types**

<table>
<thead>
<tr>
<th>Compressor Type</th>
<th>$f_v$</th>
</tr>
</thead>
<tbody>
<tr>
<td>Rolling piston</td>
<td>0.9</td>

<td>Reciprocating</td>
<td>0.9</td>
</tr>
<tr>
<td>Screw</td>
<td>0.85</td>
</tr>
<tr>
<td>Turbo</td>
<td>0.8</td>
</tr>
</tbody>
</table>

As shown in Table 4, the reduction factor $f_v$ depends on the compressor type. This is since the influence of the on-off operation on the efficiency varies depending on the compressor type. A turbo compressor has very high speeds and therefore requires energetically demanding switch-on and switch-off routines. For this reason, the differences in compressor types are addressed in the reduction factor $f_v$. It should be mentioned that the values of the factors were defined in consultation with experts. In further investigations, the values can be validated and optimized.

### 3.3. Energetic weighting

The concept of energy weighting is already shown in Figure 4. Each operating point covers a range of ambient temperatures $T_{\text{amb}}$. The weighting of the operating point is the ratio of the cooling load in the temperature range to the annual cooling load and is calculated according to equation 3.

$$w_x = \frac{\sum_{x_{\text{min}} = x_{\text{max}}}^{x_{\text{max}}}(h_i \cdot \dot{Q}_{\text{demand}})}{\sum_{h_i = 40}^{49}(h_i \cdot \dot{Q}_{\text{demand}})}$$  \hspace{1cm} (4)

The weighting factors are depending on the load profile as well as the location. The location defines how many hours a year a certain ambient temperature $h_i$ occurs. The load profile determines the cooling demand $\dot{Q}_{\text{dem}}$ at a certain ambient temperature. The cooling load corresponds to the product of cooling demand and frequency at a specific ambient temperature. The sum of all weighting factors is always 1. The temperature ranges of the operating points are shown in table 5.
4. Results

4.1. Compressor characteristic maps

In this study, manufacturer-neutral compressor maps were created for different compressor types, refrigerants, and sizes. The characteristic compressor maps can be used regardless of the presented evaluation method (aCOP) and show their seasonal behavior. Based on the information presented, such as the operating limits, control range or efficiencies, many conceptual impacts can be estimated. In particular, the comparison of compressor maps as shown in Figure 7 clarify the differences between compressor types.

Figure 7 shows the deviation between a displacement compressor (screw) and a fluid machine (turbo). In particular, the trend of the cooling capacity $Q_0$ as a function of the condensing temperature $T_c$ is most interesting. Cooling demand decreased in many applications as ambient temperatures dropped. Turbo compressors can modulate the cooling capacity $Q_0$ to a much greater extent as the condensing temperature $T_c$ drops. It should be noted that the compressor data of the turbo compressors do not consist of polynomials according to EN 12900.

4.2. Seasonal energy efficiency evaluation method (aCOP)

The presented evaluation methodology combines compressor maps with load profiles and weather data from locations and allows an energetic comparison of compressor types. Due to the large number of applications,
refrigerants, cooling capacities, load profiles and locations investigated, a very large number of results have been obtained.

For the efficient evaluation of a specific plant, a compressor tool has been developed which compares compressor types on the basis of a few parameters and supports the selection of the optimum compressor type by providing further additional information. The tool can be downloaded free of charge from the Federal Office for Energy [4]. Figure 8 shows an example of the evaluation of a selection.

Fig. 8. Example results compressor tool

Figure 8 shows the ranking of R513A compressors with a cooling capacity of 20 kW in an air conditioning application. Only scroll and reciprocating compressors are available in this capacity range. The ranking is made according to the average aCOP. This is calculated according to equation 1. The aCOP average is determined from all compressors in the selection. In addition, the aCOP of the best and worst compressor of the selection (low – best) as well as details of the individual operating points are shown. The results of the tool were randomly checked by the experts who accompanied the project.

5. Conclusion

The created compressor maps are a tool to estimate conceptual considerations. The representation of the seasonal behavior in combination with the control range and the operating limit allow a very comprehensive comparison. This is especially helpful for prospective professionals to better understand the differences in compressor types.

Some of the compressor manufacturers were in the process of converting their product line to the refrigerants studied. Therefore, it is possible that certain compressor data were not yet available at the time of data collection and are therefore not shown. The data basis for the creation of the compressor maps should therefore be updated later. In addition, further distinctions (e.g. three-phase asynchronous motors or permanent magnet motors) could be made to further subdivide the maps in order to better represent differences between series.

The polynomials provided by the manufacturers allow very extensive comparisons regarding the seasonal efficiency of compressors. The evaluation method developed in this thesis adapts the methodology of the SEER to a compressor and allows a seasonal comparison based on different weather data and load profiles. Both the operating limits and the control range of the compressor are taken into account.

The operating limit of a chiller is defined by the most restrictive component. For compressors with a large operating range, it is therefore possible that the operating range is reduced by other components (e.g. expansion valve). This was not considered in this study and can be improved in further investigations.

Especially for large refrigeration capacities, several compressors are often operated in parallel. This increases the operational reliability due to redundancies and increases the control range of the refrigeration machine. In a next step, the evaluation method should be extended so that circuits with several compressors can also be evaluated.
The results show that in particular the desired refrigerant as well as the required refrigerating capacity strongly limit the available compressor types. The tool developed in this work checks which compressor designs are available for a given refrigeration capacity and refrigerant. Subsequently, the available compressor types are compared based on the defined location and load profile according to the method defined in this paper. The result is a ranking of the available compressor types according to aCOP.

The results of the tool were reviewed by the experts. To identify errors in the data acquisition (compressor polynomials) or evaluation method (aCOP), additional checks (e.g. by manufacturers) are useful.

Abstract

Thermal energy storage (TES) offers a unique storage solution wherein heat is stored for later use to thermally condition an application. Heat pumps (HPs) move heat from relatively cold to a relatively hot with an input of work. Integrating TES into a HP system adds a third temperature body, and the HP can be selectively coupled to operate between any two bodies: a constant temperature application, a temporally fluctuating ambient temperature, or a constant temperature TES. Since the HP-TES system enables operation under different conditions depending on the pair of temperature bodies, changes in efficiency and capacity can be expected. Thus, TES can shift HP operation to more favorable conditions to deliver heat to the application. Consequently, TES increases the apparent capacity of the HP which might enable a nominally smaller HP to be used effectively for an application. This paper outlines a method by which TES can reduce the size of a HP without sacrificing heat delivered to the application. The method is demonstrated for a building cooling application which realized a reduction in nominal HP size from 3 tons to 2.4 tons.

Keywords: thermal energy storage; heat pump;

1. Introduction

Thermal energy storage (TES) is posed to be a critical technology for the Energy Transition. TES can benefit many everyday applications and services, but its relevance and performance is dependent on the temperature at which energy is stored. Analogous to electrical energy storage (EES) which might be characterized by its voltage, TES is characterized by its storage temperature. However, unlike EES which can have its voltage transformed to higher or lower values, TES can only transfer heat down a temperature gradient from relatively hot to relatively cold. However, by integrating TES into a heat pump (HP) system, heat may be upgraded to move up a thermal gradient with an input of work. This opens the possibilities for TES to be deployed for a wide variety of applications without needing quite specific storage temperatures (e.g., a cooling application can effectively utilize a TES storage temperature higher than the application temperature). The TES analyzed in this report is assumed isothermal, but real systems might have small TES temperature changes or internal temperature gradients during use.

Fig. 1 shows the possible HP-mediated modes that the HP-TES system can take for thermally conditioning an application. A conventional HP might operate only between the application and the ambient, providing heating to the application when the ambient temperature is low and cooling when the ambient temperature is high, simply speaking. For simplification, the ambient in an infinitely large temperature body whose temperature can fluctuate in time, is unaffected by the operation of the HP, and thermally interacts with the application. The efficiency of the HP to thermal condition the application is inversely correlated to the temperature difference between the application and the ambient, typically. Adding TES to a HP system provides a third temperature body with which to operate the HP. At any one time, the HP may only couple to two of the three temperature bodies.

Fig. 1. Heat exchange between three temperature bodies in a HP-TES system.

If the TES is at a different temperature than the ambient, it may provide more advantageous HP operating conditions with which to heat or cool the application. Discharging mode is when the TES is used to provide thermal conditioning to the application and this mode nominally reduces the available energy stored within the TES. Simply speaking, operating in discharging mode is advantageous when the temperature difference between the application and TES is more favorable than the difference between the application and ambient for the thermal conditioning needed. For example, if the application requires cooling and the TES is at a lower temperature than the ambient, it may be more favorable to operate the HP in discharging mode than in conventional mode. If the ambient temperature experiences time-varying fluctuations, there may be an optimal time to operate in discharging mode based on the ambient temperature oscillation. However, the TES has finite energy storage capacity and once it is depleted, it must be returned to its original state before another discharging event can occur. In this system, this charging event is accomplished by thermally coupling the TES to the ambient via the HP, and the HP adds heat to or withdraws heat from the TES, depending on what is needed, to return the TES to its original state. Again, if the ambient temperature presents cyclic fluctuations and the TES temperature is constant, there may be an optimal time to charge the TES when the HP is most effective. Thus, HP-TES systems may shift bulk energy demand for peak heating and cooling loads of an application.

Another value proposition for HP-TES systems is the potential to downsize a HP. Typically, a HP is sized for the most extreme heat load the application might experience, often called the design condition. But most conditions experienced by the application are less extreme than the design condition and thus the HP is oversized for most of its regular use. If instead TES is designed to be utilized during the most extreme conditions by providing more favorable HP operating conditions, a smaller HP, more appropriately sized for a less extreme condition, can be used effectively. In essence, the TES increases the apparent capacity of the HP by providing more favorable HP operating conditions during extreme conditions and thus the requisite heat delivered to the application is met with a nominally smaller HP.

Some published research has examined HP sizing with integrated TES. However, most studies focus on the sizing of the TES storage capacity to meet the thermal loads of a certain event while fewer leverage the TES to reduce HP size. A summary of the reports found in literature follows, first those that include HP sizing then those that exclusively focus on TES capacity sizing. Many also report on the TES storage temperature, but this is often predetermined or chosen from a narrow set of preselected temperatures. It is
observed that the approaches to integrate TES into a HP system differ significantly between studies, and the criterion by which the value of TES or downsized HP vary. Many studies focus on building technologies and systems, but HP-TES can be used in many applications.

Renaldi et al. (2017) performed a cost optimization of an integrated HP system to meet indoor heating demands and domestic hot water production in the United Kingdom [1]. The authors explore four HPs that were modeled using regression fits from manufacturer data and six TES capacities each modeled with two storage temperatures, 35°C and 50°C. The TES is modeled as a typical domestic hot water tank which was used for either space heating through radiators and underfloor heating, or for providing domestic hot water. The authors reported HP-TES as compared to gas boilers and concluded that the HP-TES system is not cost effective, even when subsidized. The authors include a baseline HP system without TES in a summary figure, and it is observed that the TES can reduce the operational cost of the HP by approximately 50% with the largest TES size studied. However, the baseline HP and the HP in the HP-TES system are identical, therefore it is inferred that the authors found no advantage or mechanism by which the TES reduces the HP size. Furthermore, the authors mention that smaller HPs can lead to increased cost by way of increased energy consumption from auxiliary backup heating systems if the smaller capacity cannot meet all the heating demands even with TES. In the scenario studied, no HP downsizing potential was viable.

Aljehani et al. (2018) evaluated a 4-6°C TES system for air conditioning [2]. The TES was coupled to the HP refrigerant loop and the duct air via an ethylene glycol loop. The HP was used to charge the TES, and the temperature difference between the air and TES allowed for direct discharging with a nonzero amount of work to circulate the ethylene glycol. The authors explain that in the conventional system, a 5 kW compressor is needed to meet the thermal loads during the six hour peak, but that it is oversized during off-peak hours. With the integrated TES system, a 2.5 kW compressor was sufficient in meeting peak loads and this size was sufficient for off-peak. Thus, the authors demonstrate a 50% reduction in HP compressor size with the inclusion of TES. Simulations then show that this system can reduce electricity consumption by 30%.

Lyu et al. (2022) evaluated the size of an air source HP and of a water tank TES unit for a residential house in Beijing, China [3]. The building model was built in TRNSYS based on measurement data. The water storage tank is modeled between 0.06 – 4.5 m³, though this is not explicitly related to energy storage capacity. The TES temperature is studied with two setpoint temperatures: 45°C during the hottest 12 hours of the day and 35°C during the coldest 12 hours of the day. The HP size is varied from 80% of the HP sized for the design heating load of the building, and all could meet the thermal needs of the building with TES. The authors indicate that HP capacities lower than 80% of the design conditions led to an unacceptable loss of thermal comfort even with large TES. In addition, the authors investigated the startup losses associated with HP cycling. The authors explain that steady HP capacity may not be achieved until several minutes after startup, based on measurement data. Thus, some efficiency loss is observed during the transient startup period. The authors hypothesize that the larger HPs will have shorter operational times and therefore startup losses are more significant and will accumulate with repeated short cycling events. Comparatively the smaller HPs have longer operational times which leads to fewer startup events and therefore less accumulated startup losses. During startup, the TES acts as a buffer tank to compensate for the reduced capacity as described by Meng et al. (2021) [4]. Furthermore, the TES can be used to absorb excess heat during steady HP operation, prolonging its operating time and limiting losses due to short cycling. Thus, Lyu et al. (2022) conclude that even small TES can reduce HP startup losses compared to lone HP systems. Furthermore, Lyu et al. (2022) do not observe significant energy savings with the smaller HP and therefore conclude that the size of the HP has little effect when TES is present. Critically, however, the successful use of a smaller HP is enabled by the presence of the TES. And they note that a smaller HP can reduce the upfront investment. Findings indicate that the large TES sizes can lead to higher energy savings, upwards of 18%.

Marini et al. (2019) performed an analysis for the potential of HP-TES to replace existing gas boilers in the UK for space heating and domestic hot water [5]. Data from several residential building were collected operating with the existing gas equipment. A model was then built in TRNSYS to simulate each building with HP-TES equipment, over 400 scenarios in total. A process was used to select an appropriate HP size based on [6] such that the HP-TES thermal service provided to the building matched as closely as possible to the historical data. The HP selection process included information about each house analyzed, the load shifting strategy based on available utility tariffs, and the TES capacity modeled as a hot water tank with a setpoint temperature of 60°C. The authors show that larger TES systems required larger HPs – contrary to the hypothesis proposed that TES adds capacity and thus reduces HP size. However, little discussion was given to the HP selection process as the analysis focused on whether the HP-TES can meet or exceed the thermal conditioning service as compared to the extant gas equipment. It is speculated that the combination of large TES size and relatively high TES temperature requires a large HP to fully recharge. Furthermore,
the approach to mirror historical heat loads with the HP-TES led to a bias towards big systems as there was little opportunity for the load shift flexibility of the HP-TES to be explored. From the data, a minimum TES size could be determined based on the building characteristics, the occupants’ idiosyncratic behavior, and the utility tariff. The authors conclude that sizing such HP-TES systems might be specific to certain building and occupant characteristics, and that operational costs to maintain the same level of thermal comfort are likely the largest motivator for HP-TES systems.

Alimohammadisagvand et al. (2016) performed a cost optimization of a TES operating with a ground source HP for space heating in Finland [7]. The temperature of TES was evaluated between 55-95°C and the size the TES system varied between 0.3-1.5 m³, but it is not said how TES physical size correlates to energy storage capacity. The HP and TES selected in this study are based on available products. The authors find that the smallest TES size led to the minimum life cycle cost. Moreover, the authors note that increasing the TES temperature does not lead to increased performance if the TES discharging capacity is sufficient for the application. The optimal TES size was determined by a cost minimization; there is no objective function which would size the TES to the expected heat loads or usage. The authors report the delivered energy from the TES. Unsurprisingly with this metric, the smallest TES unit delivered the lowest amount of energy therefore having the smallest impact of all systems analyzed. Moreover, this study evaluated a ground source HP which are not greatly influenced by the ambient conditions and often have more consistent operation compared to air source HPs. Therefore, without a cost objective related to load shift enabled by the TES, such as a time-of-use or other time varying utility tariff, or a HP that undergoes significant performance changes, it is unsurprising that a small TES tank was found to be cost optimal.

The previous studies evaluate specific building technologies in specific climates to ascertain HP sizing or requisite TES capacity. Many studies focus on operational or life cycle cost to determine an optimal solution. And it is well understood that consumer facing products heavily factor cost into success and deployment. However, the approaches used in determining the equipment size and TES temperature vary considerably between studies and result in some conflicting conclusions. A more methodical approach for determining the potential of TES and its effect on HP size is warranted.

This paper explores the potential of an isothermal TES system to reduce nominal HP size and presents a methodology by which HP and TES size, and TES temperature can be determined for an application. First the method is explained in general terms as it might apply to any application. Then the method is demonstrated using empirical HP data for a building cooling application.

2. Methodology

The method by which TES can reduce HP size is shown here using general terms such that it can be applied to any application. Fig. 2 shows the process flow for determining the downsizing HP for an application in generalized terms. The follow sections provide more detail to how this process is utilized for an application. In Section 2.1, the method is explained as to provide heating to the application, but an identical approach can be used for cooling applications, curtly discussed in Section 2.2.
2.1. Heating Application

For a heating application it is assumed that a HP provides all heating and no backup heating systems are used. First, the design condition, or design day temperature, $T_{HDD}$, and associated design heat load on the application, $\dot{H}_{H,D}$, are determined. For buildings, this could be determined from ACCA Manual J, ASHRAE Standards, or through building energy modeling. Other applications might require unique calculation procedures to determine heating loads against some design conditions. It is uncommon to determine the heating loads for all conditions and commonly, even for real systems. The heating load curve, $\dot{H}_H$, is thus a linear interpolation between the design conditions and the application’s balance point temperature, $T_{BP}$. For applications with special considerations, the heating load might yield a nonlinear curve, but this would be specific to that application and circumstances. But to keep the method general, intermediate heating loads at some ambient temperature, $T_o$, between $T_{BP}$ and $T_{H,D}$ the curve is interpolated on the load curve, $\dot{H}_H(T_o)$.

For a heating application, the HP hot side is connected to the application temperature body, $T_{app}$, which is often at a higher temperature than $T_{BP}$. The heat might be delivered with some approach temperature above the application temperature, $T_{app}^+$ (the approach temperature denoted as a plus sign for brevity). The notation
for HP capacity will be $\dot{Q}(T_{\text{cold side}}, T_{\text{hot side}})$. A subscript $H$ will indicate HP heating, a $C$ will indicate cooling. Additional subscripts will identify the HP design conditions.

The ACCA Manual S includes a methodology for sizing the HP to the design conditions of a building [8]. Other methodologies for sizing the HP might be used, including those that are “tricks of the trade” of contractors, but generally, the HP is sized to meet the design day conditions with some safety factor, $f_s$. The capacity of the design day HP, $DDHP$, is sized for these conditions: $\dot{Q}_{\text{H,DD}}(T_{\text{H,DD}}, T_{\text{app}}) = f_s \dot{H}_{\text{H,DD}}$

Next, either a smaller HP or a new design day temperature is selected – these are intrinsically linked. If a smaller HP is selected, its maximum capacity, $\dot{Q}_{\text{H,NDD},*}$, will identify the new design day temperature, $T_{\text{H,NDD},*}$, to meet the thermal conditioning needs at this temperature. Or if a new design day temperature is identified, the same HP sizing procedures and standards as before may be used to identify a properly sized, presumably smaller, $\text{NDDHP}$. The result of both processes yield a $\text{NDDHP}$ and $T_{\text{H,NDD},*}$ such that $\dot{Q}_{\text{H,NDD}}(T_{\text{H,NDD},*}, T_{\text{app}}) = f_s \dot{H}_{\text{H,NDD}}$. This process can be done iteratively based on available HP devices and the conditions experienced by the application. Once the $\text{NDDHP}$ and $T_{\text{H,NDD},*}$ are determined, the TES temperature, $T_{\text{H,TES},*}$, is identified as the operating temperature at which the $\text{NDDHP}$ can supply the heating capacity equal to the design day heat load, $\dot{Q}_{\text{H,NDD}}(T_{\text{H,TES},*}, T_{\text{app}}) = f_s \dot{H}_{\text{H,DD}}$. For simplicity, the TES will be used for discharging only when the ambient temperature, $T_o$, is less than $T_{\text{H,NDD},*}$, and despite the safety factor included in its sizing. The safety factor will be dropped from further discussion and equations.

The ambient temperature is a function of time, $T_o(t)$, and may take a periodic waveform. Thus, to determine the time spent discharging during a single event, $t_{\text{H,dis}}$, information about the amount of time and the magnitude by which the ambient temperature is below $T_{\text{H,NDD}}$ is needed for each discharging event. This information will be specific to the application, location of the system, and the previous decisions made to determine $T_{\text{H,NDD}}$. An energy balance is then performed such that the time spent discharging at the constant $\text{NDDHP}$ discharging heating capacity, $\dot{Q}_{\text{H,NDD}}(T_{\text{H,TES},*}, T_{\text{app}})$, is equal to the cumulative heating loads from the ambient during this time, $T_o(t)$, below $T_{\text{H,NDD}}$. Eq. 1 This ignores temperature fluctuations or gradients in the application or the TES as these are considered small compared to the ambient temperature fluctuations. Also note that Eq. 1 is calculated for each discrete discharging event, not cumulatively.

$$t_{\text{H,dis}} \cdot \dot{Q}_{\text{H,NDD}}(T_{\text{H,TES},*}, T_{\text{app}}) = \int_0^{t_{\text{H,-}}} \dot{H}_H(T_o(\tau)) \, d\tau \text{ when } T_o < T_{\text{H,NDD}}$$

(1)

When the ambient temperature returns above the new design day temperature condition, $T_o \geq T_{\text{H,NDD}}$, the $\text{NDDHP}$ may spend some time heating the application normally, $t_{\text{heat}}$, such that the cumulative heating delivered by the $\text{NDDHP}$ equals the sum of the heating loads from the ambient conditions. To determine $t_{\text{heat}}$, the amount of time, $t_{\text{H,dis}}$, and magnitude by which $T_o(t) \geq T_{\text{H,NDD}}$ is needed for the period immediately succeeding a discharging event and before the next discharging event. Unlike in Eq. 1, the heating capacity of the $\text{NDDHP}$ is not constant as it couples between the time-varying ambient and application. Eq. 2 shows the energy balance of the NDDHP to meet the heat loads from the ambient in conventional mode.

$$\int_0^{t_{\text{heat}}} \dot{Q}_{\text{H,NDD}}(T_o(\tau), T_{\text{app}}^+) \, d\tau = \int_0^{t_{\text{H,+}}} \dot{H}_H(T_o(\tau)) \, d\tau \text{ when } T_o \geq T_{\text{H,NDD}}$$

(2)

Any time not spent directly heating the application can be used to charge the TES, $t_{\text{H,chg,available}} = t_{\text{H,dis}} - t_{\text{heat}}$. As the TES is discharged for heating the application, the TES experiences a cooling load from the $\text{NDDHP}$ and receives some amount of cooling energy for the duration of discharging, depleting the stored energy by an amount $E_{\text{H,dis}}$. Eq. 3. The TES must receive an equal amount of cumulative heating energy to fully charge, $E_{\text{H,chg}}$, for the next discharging event, Eq. 4.

$$E_{\text{H,dis}} = t_{\text{H,dis}} \cdot \dot{Q}_{\text{C,NDD}}(T_{\text{H,TES},*}, T_{\text{app}}^+) \text{ when } T_o < T_{\text{H,NDD}}$$

(3)

$$E_{\text{H,chg}} = \int_0^{t_{\text{H,chg,min}}} \dot{Q}_{\text{H,NDD}}(T_o(\tau), T_{\text{H,TES}}) \, d\tau \text{ when } T_o \geq T_{\text{H,NDD}}$$

(4)

Equating Eqs. 3 & 4 informs of the minimum time required to fully charge the TES after a discharging event, $t_{\text{H,chg,min}}$, based on the ambient conditions and where $t_{\text{H,dis}}$ is determined from Eq. 1. The charging procedure must satisfy the two constraints: 1) $E_{\text{H,chg}} = E_{\text{H,dis}}$, and 2) $t_{\text{H,chg,min}} \leq t_{\text{H,chg,available}}$. Failure to satisfy both is ultimately attributed to a lack of available time to complete the charging process before the
next discharging process occurs which is related to the ambient conditions, and the combination of the new design day conditions and the capacity of the NDDHP.

For an application that experiences irregular periodic thermal heat loads from the ambient, the minimum energy storage capacity of the TES for heating the application, $E_{\text{H,TES}}$, should be equal to the maximum energy discharged, $E_{\text{H,dis, max}}$, in any one discharging event as determined by solving Eq. 3 for all events. A factor of safety might be added to the minimum determined TES capacity to provide additional resilience against extreme heating events.

This method might be done iteratively or with several different parameters to determine an array of feasible HP-TES systems for this application. Due to the relationship between the NDDHP capacity, TES temperature, and new design day temperature, decisions might percolate throughout the analysis and affect the result in unexpected ways. Furthermore, the availability of HPs might be limited or TES storage temperatures might be offered in discrete selections based on available TES materials or technologies. Therefore, if designing a HP-TES system some concessions might need to be made to the availability of products.

### 2.2. Cooling Application

The process for a cooling application follows the same approach as described by the heating application in Section 2.1. Dual heating and cooling applications are reserved for future work. To summarize the cooling application, like in the heating application, a design day condition, $T_{\text{C,DD}}$, is determined by conventional means based on the application. The design day heat loads are determined, and a linear heat load curve is drawn between the design conditions and the balance point temperature, $T_{\text{BP}}$, to calculate the heat loads as a function of ambient temperature, $H_{\text{C}}(T_0)$. Note that for many applications, the balance point temperature might be the same for both heating and cooling. The DDHP is selected by conventional means. The NDDHP and $T_{\text{C,NDD}}$ are determined – these are intrinsically linked and choosing one will affect the other. The maximum TES temperature, $T_{\text{C,TES}}$, is identified by the conditions at which the NDDHP can provide the maximum heat load experienced by the application, $Q_{\text{C,NDD}}(T_{\text{app}},T_{\text{C,TES}}) = H_{\text{C,DD}}$.

Fig. 3 demonstrates the approach graphically for a cooling application: 1) The design day heat load and temperature are determined. 2) A HP is selected to meet this design day load. Here, empirical HP compressor data is used to identify a suitable device, a nominal 3 ton HP. The published compressor map is used to plot its capacity as a function of condensing temperature which is related to outdoor temperature by a designated approach temperature. 3) A smaller HP is selected, a nominal 2.4 ton HP. Its capacity is determined from published compressor map information. Where its capacity intersects with the application’s heat load curve is the temperature which describes the new design day conditions, $T_{\text{C,NDD}}$. 4) Where the NDDHP capacity is equal to the original design day heat load identifies the TES temperature necessary to provide thermal conditioning during the most extreme ambient conditions. Though this application and heat load curve is fictional, the HP compressor data is real and could be used in a similar way to size and design a HP-TES systems.

Like was explained for the heating application, the HP is responsible for cooling the application such that its time spent cooling multiplied by the HP discharging cooling capacity is equal to the heat loads experienced by the application from the ambient, Eq. 5. When the ambient temperature exceeds the $T_{\text{C,NDD}}$, discharging mode is activated, Eq. 6, as the NDDHP does not have enough capacity at these conditions to provide the necessary heat.

\[
 t_{\text{c,dis}} \cdot Q_{\text{C,NDD}}(T_{\text{app}},T_{\text{C,TES}}) = \int_0^{t_{\text{c,+}}} H_{\text{C}}(T_0(\tau))d\tau \text{ when } T_0 > T_{\text{C,NDD}} \\
 \int_0^{t_{\text{c,cool}}} Q_{\text{C,NDD}}(T_{\text{app}},T_0(\tau))d\tau = \int_0^{t_{\text{c,-}}} H_{\text{C}}(T_0(\tau))d\tau \text{ when } T_0 \leq T_{\text{C,NDD}}
\]
Fig. 3. Generalized HP downsizing with TES based on empirical HP data. 1) The outdoor design day temperature \(T_{C,DD}\) is determined for the application which determines the maximum heat load acting on the application. 2) A DDHP is identified to meet this maximum heat load at the \(T_{C,DD}\) condition. 3) A smaller NDDHP is identified. The intersection of its capacity with the heat load curve indicates the new design day conditions \(T_{C,NDD}\). This can be done in reverse; \(T_{C,NDD}\) identified and a NDDHP sized for this condition. 4) The temperature at which the NDDHP capacity equals the maximum heat load at the DD conditions indicates the TES temperature \(T_{C,TES}\) necessary to provide thermal conditioning at temperatures between \(T_{C,NDD}\) and \(T_{C,DD}\).

Contrary to the heating application, the TES receives a heating load during discharging. Therefore, the delivered heat to the application is less than the heat stored in the TES; the efficiency of the HP implicitly affects the TES storage capacity which in turn is affected by the TES temperature. The energy depleted from the TES during discharging is shown in Eq. 7. After the discharging event, the TES is charged by coupling the TES to the ambient via the HP, Eq. 8. When charging, the HP still must provide cooling to the application if needed, but any time not spent directly cooling the application can be used for charging the TES, \(t_{C,chg,available} = t_{C,dis} - t_{cool}\). And likewise, the charging procedure must satisfy the two constraints: 1) \(E_{C,chg} = E_{C,dis}\), and 2) \(t_{C,chg,min} \leq t_{C,chg,available}\) for every discharge and charge cycle.

3. Demonstration of HP-TES Sizing

Fig. 3 only demonstrated the HP selection process, and the relationship between the NDDHP capacity, the new design conditions, and the TES temperature. However, to size the TES system and determine if the NDDHP is capable of supplying all thermal conditioning needs including conventional and charging modes, data on the fluctuating ambient temperature is needed. To demonstrate the approach outlined in Section 2.2 for a cooling application, the process is followed for a building application in Phoenix, Arizona. Typical Meteorological Year version 3 (TMY3) data is used [9]. The TMY3 data presents the median temperature for each hour of the year for building thermal energy simulations. In this analysis, the TMY3 data was interpolated and extrapolated to each minute of the year using Akima spline technique.

Fig. 3 shows the heat load curve for this building and two HP capacity curves calculated from empirical HP compressor data. The nominal 3 ton HP would be selected by conventional means for this building; this is the DDHP. Commonly for a building application, the DDHP is sized for the 0.4% design condition. The ASHRAE 0.4% design conditions for Phoenix is an ambient dry bulb temperature of 110.2°F (43.4°C). Using the interpolated 2020 TMY3 data, the 0.4% design temperature was identified as 45.2°C. For consistency with the dataset, the calculated 0.4% design condition from the TMY3 data is used. This building is assumed to experience a 9.3 kW net heat load at the 0.4% design condition. The balance point temperature is assumed as 12.8°C where it experiences 0 kW net heat load.
The 2.4 ton HP in Fig. 3 is the next model size smaller in the same family of HPs by the manufacturer; this is the NDDHP for this application. The NDDHP capacity intersects the heat load curve at 41.8°C, thus any ambient temperatures above this temperature will discharge using the TES: \( T_{C,NDD} = 41.8°C \). This temperature corresponds to the 3% design condition based on the TMY3 data. The TES temperature necessary to provide the necessary capacity at the design conditions is identified as 32°C.

Fig. 4 shows the TMY3 dry bulb temperature data, and 0.4% and 3% design conditions for Phoenix. Using the TMY3 data, all discharging events (when the outdoor temperature is greater than \( T_{C,NDD} \)) are identified. Then using Eq. 5, the time spent discharging is determined during each event is determined and the energy depleted from the TES found using Eq. 7. These are shown as green pins in Fig. 4 with the energy depleted from the TES for each discharging event on the right vertical axis. The maximum TES storage capacity is found to be 80.3 kWh for the discharging event on July 13 between 9:47am and 5:13pm – nearly 7.5 hours.

For reference, if the density and phase change enthalpy of water/ice used, the volume of this TES is about 1 cubic meter or about slightly smaller than a typical domestic refrigerator; if the density and phase change enthalpy of sodium sulfate decahydrate (which has a melting temperature of 32.4°C), the volume of this TES would be approximately 1.5 cubic meters [10]. Note, the published compressor maps only include cooling capacity, thus as a proxy for heating capacity (i.e., heat going into the TES and depleting its stored energy), the cooling capacity plus the electrical power consumed by the compressor was used. It is understood that this might not perfectly represent the heating capacity at the condenser, but from a crude energy balance, this method sufficed.

Between each discharging event, the time required to cool the application in conventional mode was found from Eq. 6, which then informs on the available time to charge the TES. Note, these calculations do not include optimal HP timing to take advantage of diurnal ambient temperature extrema, but future versions and more rigorous simulations can include these considerations. Then by calculating Eq. 7 and comparing to the energy depleted from the previous discharging event, the feasibility of the NDDHP to fully recharge the TES was determined. For the conditions outlined, the NDDHP with TES can meet all thermal loads to cool the application and recharge the TES between discharging events, thus all discharging event pins in Fig. 4 are green.

As discussed, the performance of the HP is affected by the TES temperature for both charging and discharging. While a colder TES temperature is advantageous for discharging in cooling applications, it may present a larger temperature gradient for the HP to charge depending on the ambient temperature fluctuations. Fig. 5 shows the same building simulation in Phoenix, AZ except where the TES temperature is 25°C, only 7°C lower than in Fig. 4. Here, the necessary TES capacity is reduced to 77.1 kWh because there is a more favorable temperature gradient to cool the application. However, there are three events in which the NDDHP fails to fully recharge the TES between discharging events as shown by the red pins in Fig. 5. Thus, this combination of NDDHP, \( T_{C,NDD} \), and \( T_{C,TES} \) is not feasible for this application. This highlights the sensitivity
of designing such HP-TES systems, and the interplay between the TES temperature, HP capacity, and ambient temperature conditions.

Fig. 5. A building cooling application modeled for Phoenix, AZ with a 2.4 ton HP and 25°C TES, identical conditions compared to Fig. 4 except for a colder TES. With the colder TES, the smaller HP cannot fully recharge the TES after each discharging event. This demonstrates the sensitivity of the HP-TES system; a colder TES provides more favorable cooling during discharging but presents too large a lift for the small HP to recharge.

Lastly, Fig. 6 shows the same building configuration with an even smaller NDDHP, nominal 2 ton capacity. From Fig. 6A, the $T_{C,NDD}$ is determined to be 38.1°C (a 6% design condition) and the required $T_{C,TES}$ is equal to 15°C. However, this NDDHP proves to be far too small to be effective even with the TES; there are discharging events over 12 hours long which leaves insufficient time to recharge the TES between discharging events with the smaller HP capacity as shown by the numerous red pins in Fig. 6B. This shows there are practical limits to downsizing with a HP-TES system. A HP-TES system with these conditions would need at least 170 kWh of storage to keep the system operational, bridging the gap between discharging events. During the height of the cooling season, the HP would be running continuously to either cool the building (conventional or discharging) or charge the TES, but it is still insufficient in supplying the necessary thermal loads.

Fig. 6. A building cooling application modeled for Phoenix, AZ with a 2 ton HP and 15°C TES. The HP-TES allows for the system to be sized to the 6% design condition. The TES discharging events are the red and green pins. This HP proves to be too small for the application as the HP cannot fully recharge the TES before the next TES discharging event, evidenced by the red pins.

4. Discussion and Conclusion

This report presents a methodology by which a HP might be downsized when TES is integrated. Data on the specific application, its conventional operating conditions and heat loads, and climate-specific temperature
fluctuations are needed. If this information is known for the HP-TES system to be installed, the TES temperature and its storage capacity can be determined as it relates to the smaller HP size. This report indicates the feasibility of HP compressor downsizing with empirical data but is not comprehensive. The approach can serve as a guideline for other applications or specific uses of HP-TES systems.

This procedure might be performed iteratively to identify an array of possible design conditions, HP equipment, and TES temperatures. HP sizes and TES storage temperatures might be available in discrete options, and thus the design of such systems is subject to these discrete variables. Once a HP-TES system is designed using the methodology outlined here, it might be evaluated in more rigorous simulations to determine the real-world feasibility of such HP-TES systems. Furthermore, more advanced HP-TES control strategies might enable more intelligent use of the TES. For example, simultaneous charging and conventional modes can more effectively utilize excess HP capacity and reduce short cycling, and forecasting heat loads might allow for a TES system to carry partial charges between discharging events while still providing the thermal conditioning necessary. Future work will also evaluate dual heating and cooling applications, and seek to identify HP-TES systems that benefit both modes.

The method was demonstrated on an example building cooling application in Phoenix, AZ with TMY3 weather data. It was shown that the HP could be downsized from a 3 ton system to a 2.4 ton system when TES was added. Furthermore, the TES enabled the HP to be sized based on the 3% design condition (compared to the 0.4% design condition). The HP-TES was shown to be sensitive to the TES temperature as the performance of the HP is affected by this temperature for both charging and discharging; a lower TES temperature is advantageous for cooling during discharging but presents a steeper thermal gradient to charge and thus the smaller HP capacity might be incapable of fully recharging the TES between discharging events.

HP-TES can be valuable for system retrofits. As global temperatures continue to rise due to anthropogenic climate change and thus the prevalence of air conditioning continues to grow, this methodology shows that integrating TES can increase apparent HP capacity. Therefore, adding TES to extend HPs might be a viable solution in applications where the HP is now undersized due to the locally changing climate. Thus, rather than replacing the HP, retrofitting with TES can extend its useful life and avoid costly system upgrades.

HP-TES systems are posed to play a critical role in the future of energy. The potential of HP-TES to reduce energy use and shift demand might be specific to the target application and its setting. Nevertheless, this analysis presents the opportunity for HP-TES to be designed more intelligently and reduce unwanted oversized systems. More work to realize these devices in real-world research settings.

Abstract

The application of high-temperature heat pump (HTHP) in the pulp and paper industry can promote a more efficient and sustainable use of waste energy. In particular, the paper aims to perform a preliminary feasibility study for the upgrade of heat extracted from the wastewater aiming to increase the circularity of pulp and paper production through a combination of technological innovation. In the analysed case study a 1.3 MW th tailored cascade HTHP is designed to supply heat at 120°C at the thermal dryer while cooling the wastewater from 42°C to 28°C. The proposed solution generates several benefits: i) reduction of sludge mass associated with higher heating value for use as secondary fuel; ii) energy saving (i.e. the heating demand of the thermal dryer is not covered by the steam produced by the existing CHP plant) and consequent recovery of waste heat and CO\textsubscript{2} and pollutants emission reduction; iii) wastewater cooling without cooling tower operation, with a consequent reduction of fan power consumption up to 44 kW; iv) reduction of oxygen demand during the wastewater treatment due to temperature decreasing before aerobic stage, with a further power consumption reduction of the air fan. The preliminary techno-economic analysis shows a negative NPV at year 20 for both HTHP integration strategies analysed, that is completely fed by the power produced by the existing natural gas CHP unit or partially fed by a 0.54 MW el peak PV plant. Despite the contribution to emissions reduction, that is 1,989 ton/year of equivalent CO\textsubscript{2} with PV plant and 1,613 ton/year of equivalent CO\textsubscript{2} without PV, the economic sustainability cannot be guaranteed in the conditions examined. The preliminary sensitive analysis highlights a relevant impact of incentives intensity and duration and of the COP of HTHP.

1. Introduction

Industrial production processes account for a considerable share of the overall pollution in Europe due to their emissions of greenhouse gases and air pollutants, discharges of wastewater and the generation of waste. The Industrial Emission Directive (IED) aims to achieve a high level of protection of human health and the environment taken as a whole by reducing harmful industrial emissions across the EU [1], in particular through better application of Best Available Techniques (BAT). Increasing energy efficiency and renewable energy in industrial processes is part of the IED and it is also coherent with the Clean energy for all European package (CEP) strategy [2], recently updated after the Covid-19 pandemic through the NextGenerationEU [3] and RePowerEU [4] initiatives. The European industrial sector represents one quarter of the EU28’s final energy consumption with 260 Mt\textsubscript{o}e in 2019 [5], while waste heat sources exist in all industries with a total amount of 300 TWh/year in the EU. Figure 1 shows the distribution of EU28’s final energy consumption in the industrial sector for 2019 (based on data extracted from [6]). Chemical and Petrochemical industry ranks first with 20.78% of the whole consumption, while non-metallic minerals (which includes the Ceramic industry in the

Eurostat classification), Pulp and Paper, and Food industries are, respectively, at the second (13.63%), third (13.05%) and fourth (11.6%) places.

Fig. 1. Distribution of final energy consumption in EU28's industrial sector in 2019 (based on data extracted from [6]).

Industrial process heat accounts for more than two-thirds of total energy consumption in industry, and half of this process heat demand is at low to medium temperatures (i.e. lower than 400°C). Figure 2 shows for each temperature range the final energy consumption share for industrial process heating (based on data extracted from [6]). While more than 85% of heating demand in the iron and steel industry (the industrial sector with the largest final energy consumption) occurs at temperatures over 500°C, Chemical and Petrochemical, Ceramic (included in non-metallic minerals), Food, and Pulp and Paper industries have a relevant heating demand in the range 100-200°C. Furthermore, a good match with the waste heat potential is found in these sectors [7].

Fig. 2. Industrial final energy consumption for process heating: classification by industrial sectors and by temperature ranges in 2019 (based on data extracted from [6]).

The so-called “heat upgrade technologies” such as traditional heat pumps, mechanical vapour recompression heat pumps, absorption heat pumps and absorption heat transformers allow low-temperature heat (i.e. ambient heat, waste heat or renewable heat) to be upgraded to higher temperatures [8]. Heat upgrade technologies are promising solutions for increasing industrial processes efficiencies and decreasing greenhouse gas (GHG) emissions. In traditional heat pumps the recovered heat vaporizes the working fluid in the evaporator, which is compressed to a higher temperature by electrical power. The working fluid is condensed and expanded in a valve, and then the cycle repeats. In mechanical vapour recompression (MVR) heat pumps the pressure and thus also the temperature of waste gases are increased by a compressor, thereby allowing the heat to be re-used. The most common type of vapour compressed by MVR is steam. MVR heat pumps are widely used in specific industrial applications like in evaporator and distillation installations, in seawater desalination and industrial wastewater treatment plants [9,10]. Absorption heat pumps (AHP) and heat
transformers (AHT) are thermally activated heat upgrading technologies in which the compression of the working fluid is achieved in a solution circuit consisting of a generator, an expansion valve, a solution pump and an absorber. The difference between AHP and AHT is that in an AHT, thermal energy required to vaporize the working fluid in the evaporator is supplied at a higher temperature than that of the heat required for separating the working fluid pair in the generator. In the Sustainable Development Scenario of [11] both electrically and thermally driven heat pumps are considered to be a potentially economically viable solution for heat supply at temperature ranges of up to 400°C. However, accordingly to both IEA HPT Annex 35 [12] and 58 [13] findings the commercially available heat pumps are limited to supply temperatures below 100°C, while the availability of systems capable of higher supply temperatures or high-temperature heat pumps (HTHPs) is limited. In particular, HTHPs integration in existing processes still need to be demonstrated at relevant scale in the medium temperature range (90-150°C) to improve market confidence [14].

In 2020, more than 85 million tons of paper and board and 36 million tons of pulp has been produced in the EU. The leading producing countries are Germany, Sweden, Italy, Finland and France. The turnover for the production of pulp, graphic paper, hygiene paper, packaging paper and special papers is expected to be around EUR 90 billion, with an added value of EUR 20 billion and investments of EUR 4.5 billion, directly providing 178,000 jobs in 891 mills and indirectly 3 million jobs along the forest and paper chain [15]. Pulp and paper mills are highly complex, and involve various process steps to transform the wood into the final product, including wood preparation, pulp production, chemical recovery, bleaching and papermaking. In 2019, the European Pulp and Paper industry consumed 380 TWh of primary energy [15], with drying accounting for up to 70% of the fossil energy use. The sector has reduced its CO₂ emissions by 24% since 1991 thanks to improvements in energy efficiency and the reduction of fossil fuel consumption (from 54.6% in 1991 to 37.6% in 2019) by replacement with biofuels (mostly black liquor) [16]. The Confederation of European Paper Industries (CEPI) has elaborated a roadmap [17] to decarbonize by 80% the European forest fibre and paper industry in 2050 compared to 1990. This will represent a decrease of 37 Mton of CO₂ per year in 2050 compared to 2015 and 32% of the reduction will be achieved through higher energy efficiency and the introduction of emerging and breakthrough technologies, including HTHPs. While there is potential for a high impact of HTHPs in the pulp and paper industry [18,19], several barriers (including regulatory ones to implementation, low fossil-fuel prices, adaptation to the industry processes, high investment cost, lack of knowledge and trust) hinder a wider adoption of HTHPs [20]. The first step for the market uptake of HTHPs in the pulp and paper industry is the preliminary techno-economic evaluation of the HTHP integration in existing facilities. Nevertheless, literature about HTHP application in the pulp and paper industry is limited.

To cover the literature gap about HTHP application in pulp and paper industry, the paper illustrates the design of a 1.3 MW th cascade HTHP to supply heat at 120°C at the thermal dryer of sewage sludge treatment plant of a pulp and paper industry while cooling the wastewater from 42°C to 28°C. The design is optimized to guarantee i) the use of sustainable working fluids and ii) the highest COP. Environmental and economic impact assessments are performed to evaluate CO₂ saving, net present value and payback time of the proposed solution. The sustainability impact of techno-economic parameters on the environmental and economic performances is estimated through a sensitivity analysis.

2. Case study description

The case study is based on a pulp and paper recycling plant located in the North of Italy. The plant, which covers an area of about 290,000 m² and employs about 100 workers, currently produces 400,000 tons per year of recycled paperboard. 200,000 Sm³ of natural gas are daily consumed to supply both electricity and heat to the industrial processes through a gas turbine unit with a nominal power of 21.5 MW el, a recovery boiler with post-combustion for the nominal production of 135 ton/h of steam at 49 bar g and 440°C, and a counter-pressure steam turbine with an electrical power output of approximately 10.44 MW el. The high-pressure steam is sent to the steam turbine which has i) a medium pressure bleed of 105 ton/h of steam at 10 bar g and 275°C for the paper drying machines and ii) a low-pressure discharge of 30 ton/h of steam at 3.5 bar g and 210°C. This steam, after appropriate temperature and pressure adjustments, is destined for the low-pressure processes of the plant. The plant also includes a wastewater and sludge treatment facility. The wastewater treatment plant has the objective of reducing both pollutants and temperature of the water that after being treated is discharged in a superficial water body. The treatment includes both aerobic and anaerobic digestion, which generates 6,000 Sm³ per day of biogas plus sludge. The sludge is currently dewatered mechanically, reaching a water content of about 50-60%. The relatively high water content of the sludge increases disposal costs and does not allow energy recovery.
3. HTHP integration into pulp and paper industry processes

The first concept was to introduce a new thermal sludge dryer operating in the temperature range 80-120°C to reach a sludge humidity of 5% after treatment. The energy requested for sludge drying process is estimated in 1.3 MW th, that corresponds to a yearly heat demand of 10,920 MWh (i.e. by considering about 8,400 hours of operation per year). The reduction of sludge humidity is beneficial since i) it reduces the mass to be disposed and ii) it increase the lower heating capacity of the sludge, which can be used as secondary fuel. Nevertheless, thermal drying is usually not cost-effective if realized by consuming natural gas. So, sludge thermal drying is not commonly performed in pulp and paper industry facilities [21]. Moreover, due to legislative obligations, the wastewater has to be discharged at a temperature lower to 30°C. In the specific plant the targeted discharge temperature is currently reached by cooling towers, that generate waste heat and high water consumption [22]. Therefore, the second concept was to use the heat content of wastewater as heat source for a HTHP able to dry the sewage sludge, thus generating a combined effect of wastewater cooling and sludge heating.

The identified solution is a cascade HTHP to supply heat at 120°C at the thermal dryer while cooling the wastewater from 42°C to 28°C (see the process flow diagram PFD in Figure 3). A secondary circuit has been foreseen between the HTHP and the wastewater to avoid direct contact and possible fouling of the HTHP evaporator. The configuration generates several benefits for the pulp and paper industry: i) reduction of sludge mass associated with higher heating value for use as secondary fuel; ii) energy saving (i.e. the heating demand of the thermal dryer is not covered by the steam produced by the existing CHP plant) and consequent recovery of heat waste and CO₂ and pollutants emission reduction; iii) wastewater cooling without cooling tower operation, with a consequent reduction of fan power consumption up to 44 kW; iv) reduction of oxygen demand during the wastewater treatment due to temperature decreasing before aerobic stage, with a further power consumption reduction of the air fan.

![Fig. 3. Process flow diagram of the suggested integration of HTTP in pulp and paper industry.](image)

The cascade HTHP is a 1.3 MW th customized solution offered by a renowned heat pump manufacturer. The size of the HTHP has been identified on the basis of available commercial components and based on heat demand for sludge drying on site. The cascade HTHP (see Figure 4) consists of two separate cycles, called “low temperature” and “high temperature” cycles, interconnected through a cascade heat exchanger. Each of the two cycles will employ two screw compressors in parallel to share the flowrate since the maximum capacity of commercial compressors is not sufficient to cover heat demand. The cascade heat exchanger acts as a condenser for the “low-temperature” cycle and as an evaporator for the “high-temperature” cycle. The pre-selected refrigerants are R1234ze(E) and R1233zd(E), respectively. The heat sink fluid is water, which is pumped from the end-user and recirculates back to it: the water enters the condenser at 80°C and exits as superheated water at 120°C. The economizers play a key role in optimizing heat flows among low and high temperature cycles and contribute to guarantee a relatively high COP despite the large temperature lift requested by the end-user. The expected COP of the whole system is 2.4, but it can be higher (up to 3.5) if the cooling effect on wastewater is considered as positive side effect.
4. Feasibility study and preliminary techno-economic and environmental assessment

The assessment of HTHP integration into industrial processes requires a detailed techno-economic analysis to justify the investment in a real application. Furthermore, the reduction of the existing environmental impacts should be estimated as well since it can generate benefits from both economic and social community perspectives. The following methodology is proposed for the preliminary assessment. First of all, it is necessary to clearly define the scenarios under assessment. While in the new scenario sewage sludge drying and wastewater cooling are both reached through the integration of HTHP, the existing scenario needs some adaptation to make a proper comparison. In fact, in the current scenario the wastewater is cooled by cooling towers, which are not effective in reaching the expected temperature of 28°C for wastewater discharge in the superficial water body all over the year, especially in summertime. Therefore, in the paper the comparison is made between the cooling effect of the HTHP and the cooling effect that a traditional air-to-water chiller would have to reach the same wastewater output temperature. Figure 5 resumes the two scenarios; the HTHP integration scenario includes also the option of HTHP feeding by renewable electricity (i.e. PV plant), which will be discussed below.
The comparison among the two scenarios is performed by considering two different parameters: the net present value (NPV), measured in Euros, and the payback time (PT), measured in years. The NPV is computed as in Equation 1, where \( t \) (years) is time, \( n \) (number of years) is the time period considered for the investment evaluation (which will be assumed equal to both depreciation and technical life time of plants for treatment simplicity purpose), \( i \) (\%) is the discount rate, \( F_t \) (Euro) is the net cash flow at year \( t \). The contribution of tax is not taken into account to simplify the economic assessment.

\[
NPV = \sum_{t=0}^{n} \frac{F_t}{(1+i)^t}
\] (1)

The net cash flow \( F_0 \) at \( t=0 \) corresponds to the starting investment: the simplifying hypotheses of full investment payment and plant operation start in the same year (\( t=0 \)) are also assumed. The net cash flow for period \( t > 0 \) was computed taking into account the main costs \( C_t \) and revenues \( R_t \) components, as highlighted in Equation 2.

\[
NPV = -F_0 + \sum_{t=1}^{n} \left[ R_t (1+i)^t - C_t (1+i)^t \right]
\] (2)

Revenues \( R_t \) include i) natural gas consumption saving in sludge drying process due to HTHP integration, ii) power consumption saving in wastewater cooling due to HTHP integration, iii) emission of new energy efficiency certificate, and iv) CO\(_2\) emission certificate saving, both caused by a reduction in natural gas consumption. In this preliminary economic assessment, the benefits related with lower power consumption for the wastewater treatment due to lower air flow rate demand caused by wastewater temperature reduction before entering the anaerobic digester are not taken into consideration. Energy efficiency certificate can be accounted as revenues only for the first 7 years of HTHP operation, accordingly to the Italian procedure [23]. On the other hand, costs \( C_t \) account for i) missed revenues due to electricity not sell to the grid operator while being self-consumed by the HTHP, and ii) operation and maintenance costs of the HTHP integration (not including the sludge dryer, which is the same for both scenarios). Equation 3 and Equation 4 define, respectively, how \( R_t \) and \( C_t \) have been computed: \( E_{th} \) is the yearly heat demand requested for sludge drying (MWh/year), \( c_{ng} \) is the cost of natural gas (\( \text{€/MWh} \)), \( \eta_{th} \) is the thermal efficiency of the existing CHP plant (\%), \( \eta_{el} \) is the electric efficiency of existing CHP plant (%), COP is the efficiency of the HTHP (%), \( E_{el} \) is the yearly cooling energy demand for wastewater cooling (MWh/year), \( c_{el} \) is the electricity selling price (\( \text{€/MWh} \)), EER is the efficiency of the traditional air-to-water chiller considered for the comparison with HTHP cooling effect (%), \( N_{sec} \) is the yearly number of energy efficiency certificate (#/year), \( c_{sec} \) is the market value of one energy efficiency certificate (\( \text{€/sec} \)), \( t_{CO_2} \) is the yearly saving of equivalent CO\(_2\) emission (ton of eq CO\(_2\)/year), \( c_{CO_2} \) is the trading emission cost of CO\(_2\) (\( \text{€/tCO_2} \)), \( C_{O&M} \) is the operation and maintenance cost of the HTHP integration. The yearly natural gas saving \( V_{ng} \) (Nm\(^3\)/year) can be computed as in Equation 5 and is equal to about 781,610 Nm\(^3\).

\[
R_t = E_{th} \cdot c_{ng} \cdot \left( \frac{\eta_{el} - \eta_{th}}{\text{CO}_{2} \cdot \eta_{el}} \right) + E_{el} \cdot c_{el} + N_{sec} \cdot c_{sec} + t_{CO_2} \cdot c_{CO_2}
\] (3)

\[
C_t = E_{th} \cdot c_{el} \cdot \left( \frac{1}{\text{CO}_{2}} \right) + C_{O&M}
\] (4)

\[
V_{ng} = \left[ E_{th} \left( \frac{\eta_{el} - \eta_{th}}{\text{CO}_{2} \cdot \eta_{el}} \right) + E_{el} \left( \frac{1}{\text{CO}_{2} \cdot \eta_{el}} \right) \right] \cdot \frac{1,000}{LHV} \cdot \frac{273.15}{298.15}
\] (5)

Discount rate \( i \) 5%
Inflation rate \( e \) 2%
HTHP lifetime \( n \) 20 years

Figure 6 shows the NPV based on the values included in Table 1. The NPV is computed with and without incentives: the results clearly show how incentives are crucial to make the investment more profitable. Nevertheless, NPV is negative anyway by considering or not incentives. Therefore, the tuning of incentives duration and intensity is crucial accompanying energy efficiency actions like HTHP integration in industrial processes. The reduction of CO\(_2\) emission during the HTHP lifetime is relevant, being about 32,260 ton. If initial investment \( F_0 \) is divided per ton of CO\(_2\) avoided in 20 years, we obtain a value of 34.6 € per ton of CO\(_2\), which is lower than trading emission costs of CO\(_2\). So, incentives are apparently well-designed. Indeed, the high selling price of electricity is the parameter that does not allow to make the investment profitable. So, the main barrier to HTHP integration is the high revenues that electricity selling can generate even by power production through natural gas combustion in CHP units.

![Fig. 6. NPV with and without considering incentives.](image)

But since March 2021 a strong variation in both natural gas cost and electricity selling price has led to enormous stress on the energy market, substantially changes may be expected on the cost framework and related investment NPV and payback time. Table 2 summarizes natural gas cost and electricity selling price variation in 2021. Figure 7 shows how NPV varies by considering the different costs and prices (the NPV is computed with incentives). No relevant results can be reached in terms of investment profitability, since the high selling prices of power produced by natural gas CHP units. Discussion on how disincentivize power
production by fossil fuel combustion is an open question which has implication on both environmental and economic sustainability of electricity market [26].

Fig. 7. NPV by considering incentives and with different natural gas cost and electricity selling prices.

The logic consequence of the techno-economic assessment is to prefer HTHP operation fed by renewable energy locally generated. In this case, the requested investment is higher, but the cost related to missing power selling as in Equation 4 can be avoided or, at least, reduced. Renewable energies availability is strongly related with local resources, and so it is highly site specific. When biomass and hydropower are not available in large amount, wind and solar energies are the most common renewable resources available at any site. But both solar and wind sources are characterized by being unpredictable and variable over time (both daily and seasonally) [27]. In the site of the pulp and paper industry under analysis only solar energy can be considered as a sustainable resource, and so photovoltaic (PV) can be taken into account to reduce the carbon footprint of HTHP operation.

Optimization of PV plant and battery storage requires complex modelling taking into account technical, economic and environmental concerns [28]. Since the scope of the paper is only to show how to foster HTHP application in industrial processes, a preliminary assessment of the impact of PV installation is given by considering a size of about 0.54 MW el peak. This configuration simplifies the analysis since no storage is needed and ideally all the electric energy is consumed by the HTHP. Based on the industrial site location, it is expected a mean annual production of 596 MWh. The specific cost of PV plant is assumed equal to 1000 €/kW peak installed [29]. Figure 8 shows the NPV (with and without incentives) in the case of HTHP integration and 0.54 MW el peak PV installation to make HTHP operation less dependent from natural gas consumption. The NPV is computed by considering energy values as in March 2021. The partial switch from natural gas to PV decreases natural gas consumption while increasing CO₂ emission saving, that are, respectively, about 857,679 Nm³/year and 1,770 ton of CO₂ per year. The increased CO₂ emission reduction also has positive effect in terms of higher number of energy efficiency certificate release, that are 703 per year. But NPV at year 20 is still negative (-490,000 €). Finally, if the initial investment for HTHP plus PV plant is divided per ton of CO₂ avoided in 20 years, we obtain a value of 46.8 € per ton of CO₂, which is in line with the value of trading CO₂ emission certificate considered in Table 1.
Due to the innovative design of the HTHP, also the COP of the HTHP needs to be assessed. Figure 9 shows how the NPV is influenced by relatively small COP variation (±8%). The variation has large potential influence on NPV; the increasing of COP generates a NPV increasing at year 20 up to about 0.5 million €, with a payback time up to 7 years. The impact of incentives is high, since without incentives the investment would be negative. A 7 years payback time investment may be perceived as risky since over such a long period variation in the framework conditions (like natural gas and electricity prices, inflation rate, incentives’ values) is likely to occur, having potential negative impact on NPV estimation. Therefore, it is essential to pay attention to the COP of the HTHP integration, since an apparently negligible efficiency reduction or increasing can have a huge impact on the economic sustainability of the investment.

5. Conclusions

The paper analyses the application of a HTHP in a pulp and paper industry localized in Northern Italy. In particular, the paper introduces an innovative cascade HTHP to simultaneously generate heat for sludge drying and cool wastewater before wastewater anaerobic digestion treatment section. The temperature lift from the heat source to the heat sink allows to reach a COP limited to 2.4 by applying state-of-the-art technologies. The initial hypothesis is to feed the HTHP with the electricity locally generated by the existing natural gas CHP unit. The HTHP integration in the industrial process produces a more efficient use of the energy. In fact, about 1,613 ton of CO₂ equivalent emission per year can be avoided through the described approach. Nevertheless, the economic sustainability of the HTHP integration is hindered by the high selling price of electricity produced by the existing CHP unit, and that is no longer sold but self-consumed. Despite the rocketing of natural gas
price in 2021 (and still on going in 2022), the connection among natural gas and electricity price makes difficult to predict the existence of a combination of prices able to make the investment profitable.

The solution is to combine the HTHP integration with local renewable power generation. In the paper the realization of a PV plant able to produce the peak power requested by HTHP is considered. The yearly power production is limited to 13% of HTHP power demand, which generates insufficient benefits in terms of NPV increasing. Once again, despite the energy efficiency performance reached by the system (1.770 ton of equivalent CO₂ emission avoided per year), the economic sustainability of the HTHP integration cannot be achieved. Through an optimization of the PV plant, to be coupled with batteries for energy storage, it would be possible to gain positive NPV and sustainable payback time. Such a configuration will be assessed in a following paper. Nevertheless, it is relevant to highlight how incentives intensity and duration play a key role in the promotion of energy efficiency actions. Finally, COP of the HTHP can strongly affect economic performance of the integration process: in fact, by reaching a COP increase of only 8%, it would be possible to have payback time of 7 years with a NPV at year 20 of about 0.5 million €.

Abstract

The objective of this study is evaluation of the nZEB in a cold region in Japan equipped with an open-loop groundwater source heat pump (GWHP) system and radiant ceiling panel (RCP) system from both the energy conservation and the thermal environmental points of views. Firstly, the annual energy consumption was calculated based on the recorded measurements. The results indicated that this building could reach the ZEB-ready level in Japan. The primary energy consumption can be decreased by approximately 67\% compared to that of the reference building by applying this system. Secondly, the indoor thermal comfort was evaluated based on the physical measurements and survey questionnaire. The results showed that the suspended RCP system could achieve comfortable indoor thermal conditions during the year. The indoor temperature was maintained within the range of 22–26 °C. Finally, energy conservation and the thermal comfort of the continuous operation methods for heating were compared to those of the intermittent operation method. Benefits of the continuous operation method were proved that a stable indoor thermal environment was maintained, and the \textit{COP} and \textit{SCOP} of the GWHP system were increased by 12\%.

1. Introduction

Presently, buildings account for approximately 36\% of the total energy consumption and 40\% of the energy-related greenhouse gas emissions worldwide [1]. Zero energy building (ZEB) or net zero energy building (nZEB) [2] have been proposed to reduce energy consumption. In Japan, the Society of Heating, Air-Conditioning, and Sanitary Engineers (SHASE) released the definition of ZEB and the evaluation method for ZEBs in 2015. ZEBs are defined as buildings that can reduce the annual net primary energy consumption to zero through renewable energy, highly efficient systems, and controlling the building load through advanced architectural designs (Figure 1). The Ministry of Economy, Trade, and Industry (METI) then issued a national definition of ZEB with four stages to promote its widespread use: ZEB (100\% decrease in primary energy consumption), nearly ZEB (75\% decrease), ZEB-ready (50\% decrease) and ZEB-oriented (40\% or 30\% decrease) [3] - [5]. On the other hand, radiant heating and cooling (RHC) systems are typically used to achieve ZEB and are accepted worldwide. Specifically, the radiant ceiling panel (RCP) system is a widely used RHC system, that can directly use renewable energy, such as geothermal heat and solar heat, to heat or cool indoor air [6]. In this study, the open-loop groundwater source heat pump (GWHP) is combined with the RCP system.

The objectives of this study are evaluation of the nZEB in a cold region in Japan equipped with an open-loop groundwater source heat pump (GWHP) system and a radiant ceiling panel (RCP) from both the energy conservation and the thermal environmental point of view. Firstly, the annual energy consumption was evaluated. The results showed that this building could reach the ZEB-ready level. The primary energy consumption can be decreased by approximately 67\% compared to that of the reference building. Secondly, the indoor thermal environment and comfort were evaluated from both measurement and questionnaire. It was

clarified that the suspended RCP system could achieve comfortable indoor thermal conditions during the year, and it contribute energy conservation due to the high performance of the heat pump chiller.

2.1 Building characteristics

The present study was undertaken in a newly constructed two-storey office building, located in Sapporo (latitude: 43°03'00"N, longitude: 141°21'00"E; 32 m above sea level), Hokkaido, Japan. The floor area of this building is 1949.58 m². Sapporo falls under the subarctic region, characterized by a mild summer and cold winter. The cold season lasts for 3.5 months from December to March, with an average daily low temperature of -5 °C and an average daily high temperature of 0.8 °C (climate data in 2020).

In this building, the ground floor includes parking, the main entrance, equipment rooms, and meeting and reception spaces. The second floor is primarily the workplace, with two large office rooms. Almost all company employees work there during the day. As shown in Figure 2, eight strings of 112 photovoltaic polycrystalline modules are installed on the south wall. To reduce heat loss, the building envelopes are well-insulated and covered with polystyrene foam plates. Table 1 summarizes the structure and heat transmission coefficients of each element. The windows use pairs of Low-E pair glass with argon gas. The area ratio of the window to the wall is 0.09 for the south and east sides, 0.04 for the west side, and 0.02 for the north side. The heat loss coefficient of this building was estimated to be 0.9 W/(m²·K), which was calculated based on the heat flow rate and the total floor area. The suggested value is 1.6 W/(m²·K) in the Hokkaido region in Japan. Thus, it represents that this building has excellent insulation performance.

Fig. 2 South view and south elevation of the target nZEB.

2.2 HVAC systems

As illustrated in Figure 3, the radiant ceiling panel (RCP) system heats or cools two office rooms on the second floor. The outdoor-air handling units are used for the central ventilation system, which supplies fresh
processed air to the workspaces through displacement ventilation. The building also uses passive stack ventilation during summer. Figure 4 shows the combined open-loop GWHP system, RCP system, and outdoor-air handling units for the second floor. The groundwater is pumped up from a water well and its temperature is almost constant at 12 °C throughout the year. The temperature of the water supplied to the RCP system is set as 18 °C in the summer and 32 °C in the winter. Free-cooling, which the groundwater directly exchanges heat between RCP and outdoor-air handling though plate type heat exchangers, is adopted during summer (Figure 4 (a)). In winter (Figure 4 (b)), a heat pump (maximum heating output capacity of 45 kW; MCRV-P450E; Mitsubishi Electric) operates and supply hot water to the RCPs, AHU and a water storage tank. The building energy management system (BEMS) controls and monitors all system components and records a total of 167 measuring points every second.

Fig. 3 HVAC systems in the target nZEB.
2.3 Indoor space and radiant Ceiling Panels (RCP) for heating and free cooling

The target office has a large open-space office, denoted as Office 1 (457.39 m²), where all staff sit together without partitions. In this office, the east wall is the internal wall, connected with another office and the stairwell. The west, south, and north walls are well-insulated exterior walls. The south windows (2.2 m × 1.3 m) use roller blinds that cover all window areas to prevent sunlight exposure during mid-day. In contrast, the west and north windows (1.4 m × 0.5 m) are exposed without shading. The thermal time constant of the target building, which represents the building’s ability to retain heat, was calculated as 89.7 h based on the thermal mass and heat loss. As shown in Figure 5, radiant ceiling panels are suspended 1.4 m beneath the ceiling and 2.7 m above the floor, covering over 50% of the ceiling area. Each ceiling panel consists of five concave aluminum segments, with a serpentine water pipe fixed on the upper surface. The system is divided into two parts (RCP Group 1 and Group 2), which are independently controlled using different water supply circuits, as shown in Figure 6.
3. Annual energy consumption

Figure 7 shows changes of the monthly average indoor air temperature and electric energy consumption of each part, including air conditioning, ventilation, lighting, hot water, elevator, and power generated by solar PV during 2019. From the breakdown pie chart of the annual energy consumption, it is understood that the energy consumption of the air-conditioning system accounted for 48% of the total annual energy consumed as 61,306 kWh/y, and more than 60% of that from December to March.

Figure 8 is comparisons of primary energy consumptions between for the reference building, design stage and actual measured ones in 2019 and 2020. When primary energy was calculated, conversion coefficients from electric energy to primary energy in energy-saving standards was used as 9,970 kJ/kWh during the day and 9,280 kJ/kWh in the night.
4. Evaluation of the Groundwater source heat pump system (GWHP)

Table 2 summarizes the operation status and performance of the groundwater heat source heat pump system (GWHP) in the second year of operation. The stand-alone COP of the water-cooled chiller used as a heat pump was 4.11, the SCOP including the primary well water pump and circulation pump was 3.62, the SCOP including the secondary circulation pump and radiant panel circulation pump was 3.28, and the SCOP of the entire heat source system including the external controller was 3.12. The SCOP of the entire heat source system including the external controller was 3.12. The SCOP of the entire heat source system was 26% lower than the COP of the heat pumps alone. This value is in the general category because the energy consumption of the well pump is large in the groundwater heat source utilization system, but the target should be 20% or less when aiming for ZEB.

</tbody>
</table>

The detail operating conditions of GWHP is shown in Figure 9. It can be seen that the temperature at a representative point in the room is stable at around 24°C ± 2°C per year, regardless of whether the room is free cooled in the summer, heated in the middle of the year, or heated in the winter. This room temperature stability is characteristic of an exterior-insulated building with high thermal insulation and huge heat capacity of the concrete construction. However, if the room temperature can be controlled at 22°C for heating in winter and 26°C for cooling in summer, energy savings of approximately 10% over the current level can be expected, based on the temperature difference between the inside and outside.
5. Evaluation of vertical room temperature profile

The vertical temperature distribution in the room (6 measuring points; just below the ceiling, 0.1 m below the ceiling, FL +1.8 m, +1.0 m, +0.1 m, and just above the floor) was measured. The daily and period-averaged vertical temperatures at 10 a.m. and noon on weekdays from February 1 to February 12, 2020, including the coldest day, are shown in Figure 10. It is understood that the temperature difference between the upper and lower temperatures at FL+0 m to 1.8 m in the human activity zone is ±0.5 K at noon (the temperature directly above the floor is 23.0 to 23.4°C), except on Monday, but the temperature near the floor is 1.0 K lower than the average temperature at 10 am (the lowest temperature directly above the floor is 22.0 to 23.4°C), more than ±1.0 K. This is the range in which a temperature difference is felt at the foot on the floor. This can be improved by starting the heating earlier every morning or by using continuous heating.
6. Evaluation of continuous heating operation

6.1 Energy conservation

Continuous heating operation was tested in order to compare the energy consumptions and indoor thermal environment with those of intermittent heating operation in the period with similar weather conditions in winter as shown in Table 3.

The results are shown in Fig. 11. In the continuous2 test, the evaporation temperature of the heat pump was set to 7 °C, and the circulation pump speed was controlled by an inverter, which gives the temperature difference between the supply and return temperatures of the heat pump circuit was 4 K to 5 K. As a result, both COP and SCOP were improved up to 12%. The heating operation time was 22 hours per day. The COP of the heat pump machine was 4.16, and SCOP was 3.70, both 12 % higher than the values in intermittent operation. This result indicates that in an externally well insulated building and huge heat storage capacity, continuous heating can lead the reduction of energy consumption and increasing the thermal comfort by setting the proper circulation pump flow rate and the heat pump evaporation temperature.

The results of the questionnaire survey are shown in Figure 12 for the daily distributions of thermal sensation, and comfort sensation. The average percentages of respondents who answered "cold" or "slightly cold" during the continuous and intermittent operation periods were 18% and 25%, respectively, which were 7% lower for the continuous operation period. Despite the better thermal sensation in continuous operation, the daily energy consumption of the two types was 129 kWh and 139 kWh, respectively. It is true that the power consumption of auxiliary equipment such as well water pumps and circulation pumps increase almost in proportion to the operation time as the operation time increases, but since the heat pump chiller itself operated in a highly efficient compressor speed band, the power consumption of the heat source including the auxiliary equipment power is also reduced. As a result, the SCOP (including power consumption of primary side pumps) of continuous operation was 12% higher than that of intermittent operation. On the other hand, it can be seen in the lower figures that the percentage of respondents who answered "slightly uncomfortable" was 9% in continuous operation, while it was 12% in intermittent operation. The average percentage of respondents who answered "comfortable" or "slightly comfortable" was 48% and 35%, respectively. This means clearly that the continuous operation gives the higher comfort level.

![Fig. 12 Daily distributions of thermal sensation (1) and comfort sensation (2).](image-url)
7. Conclusions

The building performance of the nZEB in a cold region in Hokkaido equipped with an open-loop groundwater source heat pump (GWHP) system and a radiant ceiling panel (RCP) was evaluated from both the energy conservation and the thermal environmental points of view. The primary energy consumption can be decreased by approximately 67% compared to that of the reference building by applying this system. It was shown this building could reach the ZEB-ready level from the measurement. The results showed that the suspended RCP system could achieve comfortable indoor thermal conditions during the year. The indoor temperature was maintained within the range of 22–26 °C. Finally, both energy consumption and thermal comfort of the continuous heating was compared to those of the intermittent operation. More stable indoor thermal environment was maintained and the COP and SCOP of the GWHP system was increased by 12%.

Abstract

During the past few years, Ground Source Heat Pump (GSHP) systems have attracted great attention because of the ability to improve the efficiency compared to air source heat pumps (AHSP), especially in cold climates. This paper aims to evaluate the performance of a GSHP system with series-connected solar PVT collectors for a Multi Family House (MFH) in the heating-dominated region of Oslo, Norway. The system efficiency has been obtained by a detailed simulation of the system model for 50 years using TRNSYS software. The results indicate that using the PVT collectors can significantly influence the Seasonal Performance Factor (SPF) of the system by maintaining the ground temperature compared to the case without PVT. In addition, a parametric study has been carried out to investigate how much the number of the boreholes can be reduced by adding PVT to the system while maintaining the same SPF as a standard GSHP. Hybrid systems combining GSHP and PVT collectors have the potential to contribute to the decarbonization of the MFHs in dense urban areas and to achieve Zero Energy Buildings (ZEB) in Europe.

Keywords: Solar assisted heat pump; Ground source heat pump; PVT; Solar energy; Thermal energy storage

1. Introduction

The building sector accounts for approximately 40% of the world’s energy consumption [1]. Furthermore, space cooling, space heating and Domestic Hot Water (DHW) takes a large proportion of buildings energy consumption, commonly 40-60%, depending on the climate and the type of the building [2]. Also, improving the life standards results in increasing the energy consumption of the buildings during the next years. Therefore, energy saving and further developing the current Heating, Ventilation and Air Conditioning (HVAC) systems play an important role in decreasing the world’s total energy consumption.

Heat pump is an energy efficient technology which can be used for heating and cooling purposes. This technology is of interest since it consumes less electricity and primary energy compared to traditional heating systems, such as electric heaters and boilers. There exist different types of heat pumps based on the heat source of this system, such as air-source [3], water-source [4] and ground-source heat pumps [5]. Air-source heat pumps are the most common types in Norway and the main advantage of these heat pumps is the lower electricity consumption in comparison with direct electric heaters. They can be used for both cooling and heating and operate even while the ambient temperature is as low as -20 °C. The performance of these systems strongly depends on the ambient temperature, since by decreasing the source-side temperature of the heat pumps, the electrical energy consumed by the compressor increases considerably, which results in reducing the coefficient of performance (COP) of the whole system [6]. Therefore, using another source of thermal...
energy which can provide relatively higher and constant temperature during the year is beneficial for enhancing the system performance [7].

Ground Source Heat Pumps (GSHP) can be considered as a good solution, since these systems benefit from the high quantity of thermal energy, which is stored in the ground, and can compensate the low ambient temperature [8, 9]. Solid ground, seawater, soil ground and groundwater can be used as the heat source of GSHP systems. In Norway, the majority of GSHP installations are indirect closed-loop systems utilizing vertical boreholes in crystalline rock [10]. Using this technology, the effect of outdoor air temperature fluctuations on the performance of the system will be reduced, since the ground temperature remains relatively constant throughout the year. One of the main limitations regarding the use of GSHP systems for a region dominated by heat extraction is decreasing ground temperature after a couple of years. Depending on the borehole size and the heating demand, the average temperature of the soil may decrease by 0.5 to 1 °C each year, which results in decreasing the COP of the system after a few years [11]. This reduction in ground temperature can be reduced by increasing the borehole depth and borehole number. It should be noted that increasing the borehole depth is associated with considerable rise in drilling costs and also, increasing the number of boreholes requires large area. The thermal load of Multi Family Houses (MFH) is dominated by heating in Norway. The vast majority of MFHs are located in highly dense locations of urban areas where land for drilling a large borehole field may not be available. Therefore, another solution for maintaining the ground temperature throughout the lifespan of the GSHP should be considered.

One of the methods for overcoming this problem is using the solar heat for regenerating the boreholes by storing the absorbed solar energy during the summer. In this research, the aim is to study the performance of a Solar-Assisted Heat Pump (SAHP) system in heating dominant regions with high latitude, such as Norway. During the conversion of the solar radiation into electricity using a PV module, the surface temperature of the panel increases, which leads to decrement of solar panel efficiency. Therefore, cooling the surface temperature of the panel, which can be conducted using water or air, is necessary to maintain the efficiency. Hence, the concept of PVT collectors has been introduced to enable the potential of reducing the panel temperature to keep the electrical efficiency at a satisfactory level and at the same time, absorb the thermal energy from the received solar radiation by the collector. In other words, these collectors are a hybrid between photovoltaic (PV) and solar thermal panels, which produce electricity and heat, respectively.

Noro et al. [12] studied the energy and economic performance of using PVT panels coupled with an electric compression heat pump to provide space heating in different climates. The results of this study show that up to 65% reduction in primary energy can be achieved by using this hybrid system and also, the discounted payback of the investment can be around 10 years. Lazzarin et al. [13] investigated the effect of using a hybrid system of GSHP-PVT for a refurbished building and optimized the sizing of the system by considering five alternatives, increasing the solar field from 20 m² to 60 m² and reducing the ground field from 500 m to 300 m. The dynamic simulation of this study reveals that the most efficient alternative for this system is the case with 60 m² PVT combined with boreholes of 300 m. Sommerfeldt et al. [6] carried out a parametric study of the technical and economic performance of GSHP-PVT system for a MFH located in Sweden. The results of this study show that using PVT modules can result in reducing the borehole length by 18% and maintaining the SPF of the system compared to the case without PVT.

In this work, PVT collectors are used for the thermal regeneration of the boreholes while they are not operated for heating purposes. TRNSYS, which is a dynamic simulation software, is used for simulating the PVT-GSHP system. The main objective of this paper is to investigate the energy performance of GSHP system combined with glazed and unglazed PVT collectors for a MFH in Oslo. The heating system provides both Space Heating (SH) and Domestic Hot Water (DHW) and is designed in such a way that producing DHW is prioritized over SH when both demands occur at the same time. Moreover, a sensitivity analysis has been carried out to study the effect of using different number of boreholes. The performance of a GSHP with a reduced number of boreholes combined with PVT collectors (to compensate the temperature reduction after some years of operation) is compared to a standard GSHP without PVT.
2. Model description

In this work, the simulation of a GSHP system for providing SH and DHW for a MFH is presented. The simulated building is a four-story MFH with net floor area of 420 m² per each floor which has the characteristics of a Norwegian building constructed between 1991 to 2000, i.e., generation 5 in [14]. The heating system designed for this building includes a combined PVT-GSHP system and direct electric heaters for covering the peak load. The simulation is carried out using the dynamic simulation software, TRNSYS 17, with time step of 2 min for the whole period of the study, which is 50 years.

In order to recharge the extracted heat from the ground a series/regenerative system is used, where the PVT loop is connected to a plate heat exchanger on the evaporator side of the heat pump. In this configuration, when the heat pump is on, the PVT boosts the borehole loop temperature and when the heat pump is off, the PVT regenerate the ground. The schematic overview of the system is shown in Figure 1.

![Fig. 1. Base scheme of PVT+GSHP in series/regenerative mode.](image)

The meteorological data has been obtained from Meteonorm Software. The Norwegian standard for calculation of energy needs and energy supply (SN-NSPEK 3031: 2021) [15] has been used to define the internal gains by people, lights and equipment, infiltration rate, ventilation rate and Domestic Hot Water (DHW) demand. Since the building is located in a heating dominant region, there is no need for cooling and only heating is required. Based on Norwegian standards, the set point temperature for heating the residential buildings is 20 °C for the night and 22 °C during the day and 55 °C for DHW. Figure 2 shows the hourly variation of heat generated by internal gains and heating demand for DHW according to [15].

![Fig. 2. Hourly variation of a) heat generated by internal gains and b) heat required for DHW.](image)
The yearly simulation gives an annual and specific energy demand for heating of the building by 179 MWh/year and 107 kWh/(year.m²), respectively. Figure 3 shows the monthly SH and DHW demand during the year. Also, the maximum power required for providing both SH and DHW is 104 kW.

Simulations has shown that a HP covering 70% of the peak power results in a large energy coverage factor. Therefore a water-to-water single-speed heat pump with total heating capacity of 69.44 kW has been chosen. The HP is expected to cover approximately 90% of the energy demand of the building and the remaining comes from direct electric heaters, which can cover the peak load. Three different layouts have been used to provide the required heat for the building, including the standard GSHP system, GSHP-glazed PVT and GSHP-unglazed PVT. The heating system provides both SH and DHW and is designed in such a way that producing DHW is prioritized over SH when both demands occur at the same time. In this study, the baseline model comprises 12 single U-shape and water-filled non-grouted boreholes of 200 m depth with spacing of 20 m. The PVT collectors used for the study have the PV efficiency of 17.02% at reference condition with a temperature coefficient of -0.0041 (1/K). Two different numbers of PVT collectors have been used which correspond to area of approximately 50 m² and 100 m².

In the standard GSHP layout without PVT, only heat extraction from the boreholes occurs, which results in reducing the borehole temperature after some years of operation. In GSHP-PVT layout, the recharge of the ground temperature occurs when the outlet temperature from the PVT collector is high enough to be able to recharge the borehole. In this study, the PVT circuit turns on when the temperature difference between the outlet of the PVT and inlet of the plate heat exchanger is higher than 6 K. Also, two different modes for GSHP with PVT systems have been used. In downstream mode, the outlet flow from the borehole enters the plate heat exchanger and absorbs thermal energy from the PVT loop, and then enters the evaporator side of the HP. In upstream mode, the flow direction in BH loop has been reversed and the outlet of the BH flows directly to the evaporator side of the HP and then, the outlet from the HP flows into the plate heat exchanger to be recharged by the PVT loop.

The Key Performance Indicators (KPIs) used for assessing the performance of the system are as follows:

\[
SPF = \frac{Q_{H, HP}}{E_{Comp}}
\]  

\[
SPF_4 = \frac{Q_{SH} + Q_{DHW}}{E_{Comp} + E_{Aux} + E_{Pumps}}
\]

Where SPF is the Seasonal Performance Factor for the HP, \(Q_{H, HP}\) and \(E_{Comp}\) are heat delivered by the condenser and electricity consumed by the HP, respectively. SPF₄ is the performance factor of the whole system which is equal to the ratio between the heat delivered for SH and DHW over the electricity consumed.
by the HP, auxiliary heaters and the pumps in the system. SPF also takes into account the thermal losses of the two hot-water storage tanks.

3. Results and discussion

In this section, the results from the long-term performance analysis of the combined GSHP-PVT system are presented. Figure 4 shows the electricity consumption of each component in the standard GSHP system. Based on this chart, since the HP system cannot cover all the heating demand of the building, a significant amount of electricity is consumed by the auxiliary heaters to cover the peak load in January, February and December. The amount of energy consumed by the peak load system increases after some years of operation, since the heat provided by the HP decreases gradually with the decreasing ground temperature.

Figure 5 shows the average BH temperature ($T_m$) of the standard GSHP system with 12 BHs. In this system, since there are no other energy resources to recharge the extracted thermal energy from the BHs, a significant reduction in the average BH temperature can be seen. This reduction can result in a considerable reduction in the performance of the HP system. Figure 6 shows the yearly variation of SPF and SPF of the same system with and without PVT collectors in the period of 50 years. Based on this figure, it can be seen that the SPF and SPF decrease as a result of decreasing the outlet BH temperature, but in case of using PVT collectors, since a part of extracted heat from the ground can be recharged, less reduction in SPF and SPF is observed.
The reason for reducing the SPF of the system after some years of operation can be better seen in Figure 7. According to this figure, the percentage of heat provided using the HP reduces as the result of reducing the BH temperature. This reduction results in increasing the percentage of the heat provided using the peak load system, which subsequently leads to decreasing the SPF of the system.

In Figure 6, the GSHP-PVT system has downstream layout with unglazed PVT collectors. Since the glazed PVT collector has higher thermal efficiency, the same case study has been investigated using the glazed collectors to study the effect of BH temperature reduction and consequently reduction in SPF and SPF using these PVTs. It should be noted that since the glazed PVT collectors typically can produce higher temperatures, the electrical efficiency of these collectors is lower. Therefore, the choice between the glazed and unglazed collectors highly depends on the priority of thermal or electrical energy production.
Fig. 6. Yearly variation of SPF and SPF4 of GSHP and GSHP-PVT systems with 50 m$^2$ and 100 m$^2$ collector area.

Fig. 7. Yearly variation of HP and auxiliary system energy coverage of GSHP and GSHP-PVT systems with 50 m$^2$ and 100 m$^2$ collector area.
In order to investigate the effect of using each system layout on the ground heat extraction, 5 different cases are compared: standard GSHP, GSHP with glazed or unglazed PVT collectors with downstream or upstream layouts. Figure 8 shows the monthly variation of heat extraction/rejection from/to the BH field in different cases with 12 BH and 100 m² PVT collectors. According to this chart, the net amount of heat extraction in upstream layout from the BH is insignificantly lower than that of downstream configuration. The reason for this difference can be explained by the difference between the inlet temperature to the BH. In upstream layout, the outlet flow from the evaporator side of the HP flows into the plate heat exchanger and extracts energy from PVT loop and then enters the BH, while in downstream flow, the outlet from the HP directly flows into the BH without being recharged by PVT loop. Also, it can be observed that using glazed PVT collectors, more thermal energy can be injected into the ground compared to the cases with unglazed PVT, which results in having lower net energy extraction from the BH during the year. Therefore, it can be concluded that the upstream layout using glazed PVT collectors has lower BH temperature reduction compared to other cases.

![Average extraction/rejection from/to BH](image)

Fig. 8. Monthly variation of heat extraction/rejection from/to BH in different cases with 12 BH and 100 m² PVT collectors.

Table 1 shows the SPF and SPF₄ of the standard GSHP, GSHP with glazed and unglazed PVT for both downstream and upstream layouts. In this table the reduction in system performance after 50 years of operation can be observed. According to the table, approximately 6.6% reduction in SPF of GSHP system without PVT collectors can be seen from the first to the last year of operation. As explained earlier, this reduction is due to the reduction in the BH temperature. In case of using PVT collectors, since a part of the extracted heat from the BH can be regenerated, less reduction in SPF and SPF₄ can be seen. For instance, the downstream case with 100 m² of glazed PVT shows only 4.1% reduction SPF after 50 years.

Also, it can be concluded that the percentage of the reduction in SPF and SPF₄ in cases of using upstream layout is slightly lower than that of downstream, since in this configuration, the amount of net heat extraction from the BHs is slightly lower than that of downstream. However, the system performance in downstream cases is higher than that of upstream layout. The reason for this statement is the higher inlet temperature of the flow which enters the evaporator side of the HP. As clearly shown in figure 1, in downstream flow, the outlet flow from the BH first enters the plate heat exchanger and absorbs the thermal energy from PVT loop and then, flows into the HP, while in upstream flow, the outlet flow from the BH directly enters the HP.

Also, it can be seen that the system performance in cases with glazed PVT collectors is slightly higher than the cases with unglazed PVT. As explained earlier, glazed PVT collectors have better thermal efficiency because of a layer of air gap between the cover glass and PV cell, which acts as a layer of insulation. Therefore,
it can be expressed that for this system, the downstream layout using the glazed PVT collectors can show better performance, in terms of thermal efficiency, compared to the other investigated cases.

Another interesting fact from this table is that by using PVT collectors, a smaller BH field can be used while achieving the same performance than a standard GSHP (without PVT). For instance, the SPF of the standard GSHP system with 12 BHs in the first and last year of operation is 3.8 and 3.55, respectively, which is close to that of downstream case with 50 m² glazed PVT collectors with 10 BHs, which varies from 3.8 to 3.58 after 50 years. By comparing these two cases, it can be concluded that using PVT collectors can compensate the reduction in BH temperature and it can also help the system to have smaller BH fields for a same thermal performance (here a reduction of 16%).

Another parameter which has been studied, is the electricity production using the PVT collectors. Figure 9 depicts the monthly electricity production of 100 m² PVT collectors and the annual solar production using glazed and unglazed collectors are 12.6 MWh and 13.5 MWh, respectively. In conclusion, while the glazed PVT collectors improve the thermal performance compared to unglazed PVT, they reduce the electricity production. In future work, this balance between electricity used by the GSHP and the electricity generated by the PVT should be investigated.

4. Conclusions and future works

In this study, the long-term performance analysis of a combined system of GSHP-PVT with different layouts, downstream and upstream, and glazed and unglazed PVT collectors over the period of 50 years is investigated. The results of this study confirm that using PVT collectors can significantly impact the amount of heat extracted from the BH fields. Also, it can be concluded that the upstream flow results in lower temperature reduction in the BH filed compared to downstream flow. Furthermore, the results show that the downstream flow with glazed PVT collectors can exhibit better thermal performance in comparison with the other investigated cases.

One of the most interesting results obtained by this study is using PVT collectors in GSHP systems to reduce the size of the BH fields. For instance, the SPF of the standard GSHP system with 12 BHs over the period of 50 years is approximately similar to that of the downstream case with 50 m² glazed PVT collectors with 10 BHs. As the future works, it is worth studying the techno-economic performance of these systems to evaluate the gains in life cycle costs, including investment costs. In other words, it should be clarified that how much gain, in terms of investment costs, can be achieved by adding PVT collectors to the system and reducing the BH size.

Abstract
Heat pumps are widely used in Swedish single-family houses for space and water heating applications, of which the most common is air-to-water heat pumps. Today, there is an increase in the variability and uncertainty of electricity production due to an increment in the share of electricity generation by intermittent energy sources. Hence, as opposed to the conventional power system operation, there is variability and uncertainty in electricity consumption and production. One possible way of addressing the challenge of balancing the power system is by using heat pumps as a flexibility resource. In this regard, this study quantifies the flexibility potential by developing and integrating a mathematical model of an air-to-water heat pump with the thermal model of a building with a standard way of space heating i.e., radiator heating. The result from this study will provide an estimate of flexibility levels from space heating, in terms of varying levels of reduced electricity consumption as a function of indoor temperature, during different outdoor ambient temperatures. Furthermore, the result of this study helps in employing suitable measures for demand-side-management to support the power system during severe problems.

1. Introduction
The role of electricity is significant for social and economic development. In Sweden, increasing emphasis to reduce greenhouse gas emissions has resulted in a transition of electricity production from conventional fossil fuel-based power plants towards renewable-based power plants\textsuperscript{[1]} i.e., the share of electricity production from wind and solar is increasing. However, the electricity production from these sources is highly intermittent in nature. As a result, in the current power system, there is variability as well as uncertainty in both electricity consumption and production, as opposed to the conventional power system. Hence, one of the major challenges is to ensure the balance between the electricity supply and consumption for hassle-free operation of the power system, especially during power deficit conditions.

Currently, in the scientific literature, a holistic approach is adopted to address the challenge of ensuring the balance between electricity production and consumption in the current as well as future power systems. Most of the technologies like fuel cells and converters aim at making the electricity production side much stronger. However, they have limitations and involve high investment costs \textsuperscript{[2],[3]}. On the other hand, several studies focus on reducing electricity consumption during power deficit conditions, often known by the terms demand-side-management and flexibility studies.

Focusing on the total electricity consumption in Sweden, 58 \% of it is from the residential and service sector \textsuperscript{[4]}. Moreover, the total electricity consumption in single-family residential buildings is around 4 to 4.5 times higher compared to the multifamily dwellings \textsuperscript{[5]} and mostly electricity is used for space as well as water heating applications, with an air source heat pump as the most common type \textsuperscript{[6]}. The air source heat pumps
are mainly of two types namely, air-to-air and air-to-water heat pumps. Another category of air source heat pump is the exhaust air heat pump (mainly air-to-air but air-to-water also available). This could be used for providing additional heating based on the insulation level and the needs of the building [7]. As water-based heating with radiators is the most common in Sweden, a single-family residential building equipped with an air-to-water heat pump, will be the focus of this article for quantifying the flexibility potential. In this study, flexibility refers to the reduction in the electricity consumption for space heating, to support the electric power system during power deficit conditions.

To use an air to water heat pump as a flexible load, it is important to have information regarding its performance, indicating the quantity of heat delivered, temperature at which heat is rejected, speed and electricity consumption of the compressor, during different outdoor ambient temperatures. Unfortunately, the heat pump manufactures will provide the relevant information only at standard Air Conditioning and Refrigeration (ARI) conditions, where the performance will be optimized. In this regard, in most of literature dealing with demand side management and flexibility studies, the model of air source heat pumps is simplified, where Coefficient of Performance (COP) is only considered as a constant value or as function of outdoor ambient temperature. Furthermore, the variable speed heat pump is assumed to be perfectly modulating between 0 and 100% as the limitations posed by the operating envelope of the compressor in terms of speed and condensor temperatures are not accounted [8][9][10].

Thus, with this background, the purpose of this article is to quantify the potential for flexibility from space heating in a building equipped with an air-to-water heat pump, by obtaining the heat pump’s performance, considering the compressor’s rating, and operating envelope during different outdoor ambient temperatures to fulfill different heating requirements in the building. The main contribution of this study is that the flexibility quantification serves as valuable information to ensure resilient operation of the electricity grid during power deficit conditions.

2. Methodology

This section describes the method to quantify the heat delivered by a variable speed air-to-water heat pump as a function of condensor and evaporator temperatures together with the speed of the compressor and outdoor ambient temperature, using vapour compression heat pump cycle. This will be followed by the description of the method to obtain the thermal model of a building.

2.1. Vapour compression heat pump cycle

The main components of a heat pump and its operation based on the actual vapour compression cycle, represented on a pressure-enthalpy diagram is shown in figure 1. The four processes involved in this cycle are heat absorption by the refrigerant in the evaporator, compression of the refrigerant by the compressor, heat rejection by the refrigerant in the condensor and the expansion of the refrigerant in the expansion valve.

![Figure 1: Vapour compression heat pump cycle](image)

The procedure for evaluating the heat delivered and COP is as follows:
• The pressure in the evaporator is determined using the information of the temperature at which evaporation occurs and the quality (100% for saturated vapour (1s)) of the refrigerant.
• The temperature for superheating (ΔT_{sh}) is assumed to be 5K. The enthalpy ‘h₁’ is determined using the details of the superheated temperature of the refrigerant and the pressure in the evaporator (pressure is assumed to be constant in the evaporator). Also, the entropy and density are determined at the same condition.
• The process of compression is assumed to be isentropic. So, the entropy of the compressed vapour is assumed to be same as that of the vapour at the outlet of the evaporator.
• The pressure in the condensor(pressure is assumed to be constant in the condensor) is determined using the information of the temperature at which condensation occurs and the quality (0 for saturated liquid (3s)) of the refrigerant.
• The temperature of the compressed vapour is determined using the details of pressure in the condensor and entropy and entropy of the compressed vapour.
• The mass flow rate of the refrigerant in \( \frac{(kg)}{s} \) is calculated as
  \[
  \dot{m} = \frac{V_{dis} \rho_s f \eta_{vol}}{10^6}
  \]
where, ‘\( V_{dis} \)’, ‘\( \rho_s \)’, ‘\( f \)’ and ‘\( \eta_{vol} \)’ are the compressor displacement volume \( \left( \frac{cc}{rev} \right) \), density at suction \( \left( \frac{kg}{m^3} \right) \), compressor speed (Hz) and the volumetric efficiency respectively\[11\].
• Using the information of the entropy and temperature of the compressed vapour, the enthalpy ‘\( h_2 \)’ \( \left( \frac{kJ}{kg} \right) \)is determined. The work done by the compressor to perform the compression is calculated using
  \[
  W_{comp} = \frac{\dot{m}(h_2 - h_3)}{\eta_{isent.speed}}
  \]
where, ‘\( \eta_{isent.speed} \)’ is the isentropic efficiency of the compressor for a given speed.
• The temperature for subcooling (\( \Delta T_{sc} \)) is assumed to be 5K. The enthalpy ‘\( h_3 \)’ is determined using the details of the temperature at which the refrigerant is sub cooled completely and the pressure in the condensor.
• The heat delivered at the condensor (kW) and the COP is calculated as
  \[
  COP = \frac{\text{Heat delivered}}{\text{Work done by the compressor}} = \frac{\dot{m} (h_2 - h_3)}{W_{comp}}
  \]
2.2. The compressor’s operating envelope

The compressor is the heart of a heat pump. Manufactures of compressors will provide the operating envelopes indicating the conditions within which the compressors can operate safely, and performance is guaranteed. Before analyzing the vapour compression heat pump cycle, it is important to check if the operating point lies within the operating envelope, otherwise that operating point cannot be used, since the safe operation is not guaranteed outside the envelope.

2.3. Thermal dynamics in the building

With the knowledge of the physical and thermal properties of the building, the thermal mass (C) and the thermal resistance (R) are estimated. A simple way of modelling the thermal dynamics in a building, is in the form of an electric circuit, comprising of a resistance and a capacitance connected in series, powered by a heating system modelled as a current source. The ambient temperature which is an external condition is represented as a voltage source and is shown in figure 2.

The terms ‘\( C_{tot} \)’ and ‘\( R_{tot} \)’ are the total thermal mass and thermal resistance of a building respectively. ‘\( P_{heat} \)’ and ‘\( T_{amb} \)’ are the heat from the heating system and external ambient temperature respectively. The temperature of the room is represented by the voltage ‘\( T_r \)’ across the capacitor.
3. Case study

This section deals with a brief description of the data considered for the modelling of a variable speed, air-to-water heat pump. This will be followed by a description of the thermal and physical properties of the building, for establishing its thermal model.

3.1. Air to water heat pump

The technical data of a variable speed compressor without enhanced vapour injection, from Copeland Emerson technology is considered for the validation of the model developed. The working fluid considered is the refrigerant ‘R410a’. The relevant data together with the operating envelope considered for this study is provided in Table 1 and figure 3 respectively [12]. The operating envelope for this study, adapted for heating application, is considered based on two reasons, the first reason is that the minimum compression ratio should be greater than or equal to 2.3. This assumption is based on the experimental result obtained for Emerson’s scroll compressors in [13] and [14]. The second reason is that for heating application, the condenser temperature should be at least 30°C.

3.2. Physical and thermal properties of the building

A single-family residential building in Gothenburg constructed between 1961 and 1975 with an average U-value (rate of heat transfer for climate shell) of $W/m^2K$ and thermal mass of $MJ/K$ is considered. The building is assumed have a floor area 125 m² and equipped with water radiators for space heating. Sanitary ventilation of $0.35 l/s m^2$ is also accounted. The maximum supply temperature to the radiators is 55°C. The heating to this building will be provided from an air-to-water heat pump equipped with a variable speed ZPV030 compressor discussed above.
4. Results

This section deals with the assumptions made for the analysis and validation of the results obtained from the steady state model of an air-to-water heat pump with ZPV030 and ZPV038 Copeland Emerson scroll compressors. Furthermore, it also deals with the quantification of the flexibility levels from space heating in a single-family residential building dealt with in section 3.2, equipped with an air-to-water heat pump having ZPV030 scroll compressor.

4.1. Validation of simulation result from the air source heat pumps with ZPV030 and ZPV038 scroll compressors @ARI 60 Hz

The following are the assumptions made in the model developed:

- The volumetric efficiency $\eta_{vol}$ of the compressor is 83%.
- The isentropic efficiency $\eta_{isent}$ is 65% at design conditions, considering the aspects of losses [15].
- For air source heat pumps, the temperature difference between evaporator and outdoor ambient temperature is between 50°C and 80°C [16]. In this study, a temperature difference of 80°C is considered.
- The condenser temperature $T_{cond}$ required to heat the water to a desired temperature, is calculated as:

$$T_{cond} = T_{return} + \frac{T_{supply} - T_{return}}{1 - e^{-\left(\frac{\Delta T_{log,cond}}{\Delta T_{log,cond}}\right)}}$$

where, $T_{return}$, $T_{supply}$ are the return and supply temperatures of the water from and to the heating circuit respectively. $\Delta T_{log,cond}$ is logarithmic temperature difference of the heat exchanger and is assumed to be 4K.
- The isentropic efficiencies ($\eta_{isent}$) during different compression ratios for the Emerson’s scroll compressor considered by comparing and analyzing the data available in [13] and [14], is shown in table 2.

</tbody>
</table>

Figure 3: Operating envelope of scroll compressor adapted for the study [12]
The variation in isentropic efficiency with respect to the speed ($f$) of the compressor is estimated [17] as

$$\eta_{\text{isent, speed}} = \eta_{\text{isent}} \left( -0.08 \left( \frac{f}{f_{60}} \right)^2 + 0.1411 \left( \frac{f}{f_{60}} \right) + 0.9337 \right)$$

where, '$f_{60}$' is the frequency of the compressor at 60 Hz.

The simulation result is compared with the data provided in Table 1 and the observations are tabulated in Table 3. It is observed that the simulation result matches well with the data provided (@ARI 60Hz, i.e., 7°C evaporator temperature and 55°C condensor temperature).

4.2. The COP as a function of outdoor ambient temperature and condensor temperature for an air to water heat pump with ZPV030 scroll compressor

The condensor temperature as a function of outdoor ambient temperature and COP for an air source heat pump under study is shown in figure 4. It is observed that for a given condensor temperature, as the outdoor ambient temperature increases, COP increases. It is interesting to observe that, at lower outdoor ambient conditions, the heat pump should be complemented with electric heating to deliver desired heat at high temperatures.

![Figure 4: Condensor temperature as a function of outdoor ambient temperature and COP](image)

4.3. The COP and speed as a function of heat delivered and outdoor ambient temperature for supplying water at 55°C, 45°C, and 30°C.

The maximum supply temperature to the panel radiator considered for the analysis is 55°C. However, depending on heating requirements during different outdoor ambient temperatures, the supply temperature of the water to the radiator can vary. In this regard, for the representation purpose, supply water temperatures of 30°C, 45°C and 55°C are selected. The COP and the speed as a function of heat delivered and outdoor ambient temperature, for supplying water at temperatures 55°C, 45°C and 30°C are shown in figure 5.
The COP and amount of heat delivered increases with an increase in ambient temperature, as the temperature of the source increases. Furthermore, for a given ambient temperature, the heat delivered increases with a reduction in the supply temperature of the water.

The change in COP at a given condenser temperature and ambient temperature, for delivering different heat loads is due to the variation in isentropic efficiency at different compressor speeds. It is also observed that the speed of the compressor is limited as the power consumption exceeds the rating of the compressor. However, as the supply temperature of the water is reduced, the heat pump can be operated at higher speeds.

Figure 5: Heat delivering capability of the heat pump to deliver hot water at 55°C, 45°C and 30°C
4.4. Flexibility offered by the residential building by reducing the indoor temperature from 20°C to 18°C during different outdoor ambient temperatures

The outdoor ambient temperatures of -5°C, 0°C and 5°C are selected.

4.4.1. Flexibility offered by the residential building by reducing the indoor temperature from 20°C to 18°C during outdoor ambient temperature of -5°C

To maintain indoor temperature at 20°C, when the outdoor ambient temperature is -5°C, around 4.6 kW of heat is required. This heat is obtained by setting the supply temperature of the water in the radiators to 39°C with appropriate mass flow rate to achieve the return water temperature of 29°C. The COP and speed of the heat pump at this condition is 2.89 and 46 Hz respectively. This is shown in figure 6.

Figure 6: Thermodynamics in the building during outdoor ambient temperature of -5°C

When the indoor reference temperature is changed to 18°C, there is no heating required for nearly 1.33 hours. After 1.33 hours until reference indoor temperature is reset, the heating requirement gradually increases for maintaining the indoor temperature at the desired level. During this period, it can be observed in figures (6c) and (6d) that, as the supply temperature of water increases, the COP reduces accordingly. When the new steady state has been reached, it is noticed that COP is 3.1 and is higher compared to the COP required for maintaining the indoor temperature at 20°C.

When the indoor reference temperature is reset to 20°C, it can be observed in figures (6b) and (6c) that there is a spike in electricity consumption due to spike in heating requirement. At outdoor ambient temperature of -5°C, the heat pump cannot heat the water to 49°C. In this situation, the heat pump heats the water to 42.5°C and electric heater is used for heating the water up to 49°C. Correspondingly, it is observed that there is a sudden dip in the COP to 2.53 (to heat water to 42.5°C). As the heat requirement reduces and the supply...
temperature of water reduces, COP improves gradually, heating from electric heater also reduces and a new steady state is reached.

For 1.33 hours, no electrical energy is consumed by space heating, which corresponds to taking 2.13 kWh less electricity from the power grid, and this can be viewed as the flexibility service offered from the building. Furthermore, by continuing to maintain the indoor temperature at 18°C, the strain on the grid during power deficit conditions can be reduced as it is reflected in terms of reduced electricity consumption i.e., higher COP. However, when the temperature is reset to 20°C, initially there is a spike in electricity consumption.

4.4.2. Flexibility offered by the residential building by reducing the indoor temperature from 20°C to 18°C during outdoor ambient temperature of 0°C

When the outdoor ambient temperature is 0°C, around 3.6 kW of heat is required to maintain indoor temperature at 20°C. This is achieved by setting the supply temperature of the water in the radiators to 37°C with appropriate mass flow rate to achieve the return water temperature of 27°C. The corresponding COP and speed of the heat pump is 3.41 and 30.5 Hz respectively and is shown in figure 7.
heat electric heater is used for providing extra heat of 1.6 kW. Correspondingly, it is observed that there is a
sudden dip in the COP to 2.53 (to deliver heat of 8.2 kW). As the heat requirement reduces and the supply
temperature of water reduces, COP improves gradually, heating from electric heater also reduces and a new
steady state is reached.

For 2.16 hours, no electrical energy is consumed by space heating, which corresponds to taking 2.38 kWh
less electricity from the power grid, and this can be viewed as the flexibility service offered from the building.
Furthermore, by continuing to maintain the indoor temperature at 18°C, the strain on the grid during power
deficit conditions can be reduced as it is reflected in terms of reduced electricity consumption i.e., higher COP.
However, when the temperature is reset to 20°C, initially there is a spike in electricity consumption.

4.4.3. Flexibility offered by the residential building by reducing the indoor temperature from 20°C to 18°C
during outdoor ambient temperature of 5°C

Around 2.7 kW of heat is required to maintain indoor temperature at 20°C, when the outdoor ambient
temperature is 5°C. This is realized by setting the supply temperature of the water in the radiators to 35°C with
appropriate mass flow rate to achieve the return water temperature of 25°C. The COP and speed of the heat
pump obtained at this condition is 4 and 19.5 Hz respectively. This is shown in figure 8.

![Diagram](8a): Variation of indoor temperature

![Diagram](8b): Heat delivered by the radiators, electric heater in the
heat pump, the heat pump and electricity consumed

![Diagram](8c): Supply and return temperatures of the water in the
radiator together with the temperature of water supplied by
heat pump

![Diagram](8d): The variation in the speed and COP of the heat pump while
maintaining desired indoor temperature

Figure 8: Thermodynamics in the building during outdoor ambient temperature of 5°C

When the indoor reference temperature is changed to 18°C, there is no heating required for nearly 3.5
hours. After 3.5 hours and some time before the reference indoor temperature is reset, around 2.1 kW of
heat is provided as it is the minimum heat which the heat pump can provide at this condition. This heating
is then gradually increased to 2.2 kW. During this period, the observations in figures (8b) and (8c) with respect to supply temperature of the water in radiators is similar to as discussed in section 4.4.1.

When the indoor reference temperature is reset to 20°C, it can be observed in figures (8b) and (8c) that there is a spike in electricity consumption due to spike in heating requirement. Correspondingly, it is observed that there is a sudden dip in the COP to 3.12. As the heat requirement reduces and the supply temperature of water reduces, COP improves gradually, heating from electric heater also reduces and a new steady state is reached.

For 3.5 hours, no electrical energy is consumed by space heating, which corresponds to taking 2.49 kWh less electricity from the power grid, and this can be viewed as the flexibility service offered from the building. Furthermore, by continuing to maintain the indoor temperature at 18°C, the strain on the grid during power deficit conditions can be reduced as it is reflected in terms of reduced electricity consumption i.e., higher COP. However, when the temperature is reset to 20°C, initially, there is a spike in electricity consumption.

5. Discussion

The result obtained in section 4 is consolidated in table 4. It can be observed that the flexibility in terms of power is high when the outdoor ambient temperature is ~5°C compared to 5°C. On the contrary, the flexibility in terms on energy is high during when the outdoor ambient temperature is 5°C compared to ~5°C. Furthermore, by maintaining the reference indoor temperature to a low value, the amount of energy offered as flexible service would be high, considering the contribution from several residential buildings. This can help the electricity grid to be more resilient by avoiding situations which can lead to severe problems during power deficit conditions.

The future scope of this work involves assessing the flexibility based on different types of single-family residential building i.e., U-value and thermal mass, followed by the different types of heat pumps used. Furthermore, the heat pump technology i.e., with or without enhanced vapour injection, affects the flexibility result, as the heat delivering capability and COP would be high in the latter case. Also, considering the electric heating element used for complementing the heat pump of fixed type, greatly affects the result from flexibility studies focused on shorter time scales.

General classification of heat pumps solutions for multi-family buildings

Marek Miara*

*Fraunhofer Institute for Solar Energy Systems ISE, Heidenhofstrasse 2, 79110 Freiburg, Germany,

Abstract

The paper documents the results of the IEA HPT Annex 50 “Heat Pumps in Multi-Family Buildings for Space Heating and DHW” and it is based on the final report of the Annex 50. The active Annex group consisted of seven countries (Austria, Denmark, France, Germany, Italy, Netherlands, and Switzerland). The working group has succeeded in creating a general classification of heat pumps solutions for multi-family residential buildings. The solutions have been defined in a standardized way according to eight representative categories. Overall, 13 solutions have been identified, ranging from a fully centralized to a completely decentralized system (each-room solution). The solutions have been grouped into five “families”, each grouping specific sub-solutions. In parallel to the theoretical classification of solutions, the Annex collected numerous case studies representing implementation of heat pumps in multi-family buildings. The cases show a wide variety of possibilities for use of heat pumps, depending on the energetical standard of the building, its number of apartments, heat source and further characteristics. For each case study, a corresponding theoretical solution has been defined. All these elements reflect the holistic approach of the Annex, which encompasses the definition, categorisation and the practical implementation of heat pump solutions.

Keywords: multi-family buildings; classification of solutions, centralized systems, decentralized system

1. Introduction

The goal was never so clear. We must stop, or at least significantly reduce, the use of fossil fuels. The most important argument to do that is the mitigation of consequences of the climate change. The newest IPCC report [1] does not leave any illusion – the life on our planet as we known it and are used to, will no longer be possible. The consequences of “business as usual” would be dramatic.

In light of the above considerations, the perception of heat pumps by the policy- and lawmakers has changed significantly in favour of heat pumps as a solution for the decarbonisation of heating in the housing sector. New strategies to reach climate neutrality point to heat pumps as the key solution [2, 3].

Most heat pumps installed in Europe are dedicated for single family houses. To reach the climate protection goals, heat pumps must be installed also in multi-family buildings. The analyses provided in the final report of Annex 50 [4] show clearly that one of the major barriers of a broader application of heat pumps in multi-family buildings is a deficit of knowledge. Both on the side of owners of the buildings or apartments, as well as investors.

New domestic buildings are often constructed with a building envelope and heating system designed for low energy consumption and the potential to use new renewable energy technologies, such as heat pumps. For multi-family buildings, the challenge of applying heat pump technologies and renewable energy is more complex. The aspect of ownership varies among member countries of the IEA HPT Implementing agreement. While in some countries multi-family houses are often owned by local cities, communities, or housing corporations, in other countries ownership is private and divided into individual apartments. There are even combinations of ownership by housing corporations and private owners in one building. This implies extra challenges at organizational, financial and implementation level.

*Marek Miara. E-mail address: marek.miara@ise.fraunhofer.de
Annex 50 was covering a comprehensive range of topics which relate exclusively to multi-family buildings. A variety of key aspects for usage of heat pumps in multi-family buildings has been considered within this Annex. The outcome allows to better understand the technical and non-technical barriers, comprehensively presents different theoretical solutions of heat pumps implementation in multi-family buildings and visualises numerous case studies with their practical implementation. The connection of theory and the real implementation was an important factor during the whole work within the Annex.

2. National situations

In Europe, the market for heat pumps (HPs) in residential buildings has been steadily growing for several years in most countries [5]. However, this overall trend does not reflect various situations in different types of buildings. Whereas in new individual houses HPs are the most spread solution, their market in multi-family buildings (MFB), both new and existing, remains low.

The first task of Annex 50 was to collect and analyse data from the participating countries with a view to identifying country-relevant characteristics of buildings, their technical aspects and legal regulations relevant for application of heat pumps in MFB.

The shares of individual and collective housing are quite similar among the countries and encompass from 45 to 50% of dwellings in multi-family buildings. In almost all countries, most of multi-family buildings are composed of less than 10 flats; 6 to 8 in average.

In all countries, the multi-family buildings stock is almost equally distributed between owners and tenants, with a slight majority of owners. In all countries participating in the Annex 50, the residential building stock is quite old, with an average share of 52-60% of buildings built before 1970. The main consequence is that space heating constitutes the largest part of energy consumption with a share of about 65%. For old multi-family buildings (<1970), it represents a yearly heating demand of 120-150 kWh/m².

Apart from the age of the buildings and an average number of appartements, also the energy carriers for providing the heating needs varied in analysed countries (Figure 1). Natural gas is the main energy source for heating in multi-family buildings in most analysed countries. In France and Switzerland there is a significant share of direct electrical heating. Denmark is the country with the biggest share of district heating (followed by Austria). Switzerland is the exception with more than 50% of oil heating systems.

![Fig. 1. Energy carriers for providing heating and domestic hot water production in selected European countries](image)

3. Translating complexity

The diversity of multi-family buildings is significantly higher than in the case of single-family buildings. This results in more numerous and complex solutions which can be implemented for covering the heating demand and domestic hot water needs. Consequently, the choice of the most appropriate solution is a much more difficult task.
In the first attempt, the working group tried to create possibly exhaustive categorisation taking into account of various perspectives, such as level of centralisation, heat sources, type of hot water production, energy standard of a building, size, etc. The visual result of this endeavour represents Figure 2 (it is not the intention to show the content of the classification but only its complexity). Although from the scientific and technical point of view the achieved classification was satisfying, its complexity constitutes an obstacle for a readability and comprehension of various possibilities.

To overcome this problem, the Annex 50 group proposed a simplified categorisation of possible heat pumps implementations in multi-family buildings described in following paragraphs. The working group of Annex 50 is aware of the fact that choosing a simplification over completeness results in some of the aspects not being described and presented sufficiently broad and exhaustive. The oversimplification may even be seen as disturbing and artificial, but this approach has a clear goal to “translate complexity”. Discussions with the housing industries confirm the need for such simplified classification. To see the potential possibilities in an easy and understandable way can be crucial for taking decisions by building’s owners or buildings administrators, who very often do not possess sufficient knowledge and experience to comprehend the complexity.

It is to be mentioned that the way to propose the simplified categorisation was a difficult challenge. The final outcome is a result of longstanding discussions and compromises acknowledging the technical and scientifical shortcomings of this approach.

4. “Solution matrix”

During the process of gathering knowledge and practice, the work group faced a rich variety of cases and characteristics to consider. Depending on the focus of the system design, for instance, a specific MFB type, the conclusions would vary. Structuring the information in a matrix format provided a response to this issue. The work was carried out with the vision of a description of all solutions in a standardized way. This allowed to explore each scenario, from centralized to completely decentralized HP installation, through the lens of new to non-renovated MFB, building size, heating and/or domestic hot water (DHW) production need, HP only or hybrid system and to reflect on specific issue for each one. It is an attempt to cover all potentially encountered cases. The intention is to help identify the best possible solution for each case and inform on concepts that may be unusual in some countries.
4.1. General classification

A key point to classify heat pump systems, is to define the level at which the integration is realized. This ranges from all centralized to completely decentralized installations with different types of intermediate solutions. This first level of classification consists of five so-called “solutions families”. These generic groups are aligned by their level of system centralization in the following schematic drawings (Figure 3).

Each “solution family” comprises of several “family members”. The members are variations within one logical group (Figure 4).

The following listed solutions have been identified. They are described in order from the most centralized to the most decentralized concept.

- **Solution 1.1 „one heat pump for all“**
  One central heat pump system for the whole building, both for space heating and DHW

- **Solution 1.2 „one for heating, one for DHW“**
  One heat pump system for each mode. One for space heating, separate one for DHW

- **Solution 1.3 „HP for heating, another device for DHW“**
One heat pump system for the space heating, separate heat generator (fossil, biomass, electric, …) for DHW.

• **Solution 1.4 „HP for DHW, other device for heating“**
  
  One HP system for DHW, separate heat generator (fossil, biomass, electric, …) for space heating.

• **Solution 1.5 „one hybrid heat pump for all“**
  
  One hybrid heat pump system for space heating and DHW for the whole building

• **Solution 2.1 „one mode – central, second - decentral“**
  
  One central heat pump system for one mode (for example space heating). Decentral heat pumps for the second mode (for example DHW).

• **Solution 2.2 „heating – central, DHW – decentral EL“**
  
  One central heat pump system for space heating. Decentral direct electrical heaters for DHW.

• **Solution 3.1 „one HP for a number of apartments“**
  
  One heat pump system for space heating and DHW for several apartments (usually grouped by levels or staircases).

• **Solution 3.2 „apartments grouped by mode“**
  
  One heat pump system provides one mode (space heating or DHW) for several apartments (usually grouped by levels or staircases).

• **Solution 3.3 „apartments grouped by heat generator“**
  
  The apartments are grouped by heat generators (usually grouped by levels or staircases).

• **Solution 4.1 „individual solution for each apartment“**
  
  Each apartment has individual concept of space heating and DHW.

• **Solution 4.2 „one apartment - one mode“**
  
  Decentral heat pump for one mode for one apartment.

• **Solution 5.1 „heat pump for individual room“**
  
  One heat pump for space heating (or cooling) for one room of the apartment.

### 4.2. Solutions description

All solutions listed in the above paragraph have been described in detail within 8 categories listed below. The standardized categories allow for a better comparison of solutions.

- **Main characteristic of the concept**
  
  Maximally concise description of the solution

- **Size of building, number of apartments**
  
  This category indicates for what size of the building the solution is favourable. For the sake of clarity, three categories of the buildings have been defined. Depending on the number of apartments: “small” buildings consist of 4 to 10 apartments, “average” - 11 to 20 apartments, and “large” – of more than 20 apartments.

- **Energy standard, insulation level**
  
  In this category three building types have been distinct. New buildings with a high energetical standard; retrofitted with an average energetical standard and old, un-retrofitted buildings with a poor energetical standard. It was decided not to declare strict values expressing the energy demand.

- **Heat Sources**
  
  The general categorization of the solutions in the “solution matrix” does not consider the heat source of the building. This description category is an attempt to indicate which heat sources are preferable for each solution.

- **Heat distribution and temperatures levels**
  
  This category describes the type and way of heat distribution for space heating and DHW. Additionally, the temperature levels for each mode are indicated.

- **DHW and storage characteristic**
  
  This category describes the type and way of provision of the DHW for the building. Also, the necessity of the storage tanks is indicated.

- **Complexity of installation**
  
  The estimated effort for the installation of the system is described in this section.

- **Specific issues of the concept**
  
  Any additional information about the solution finds its place under this category.
4.2.1. General remarks to the concept’s description

Significant simplification of the presented categorization allows for a quick and understandable overview of heat pump solutions for multi-family buildings. The description of each category is deliberately short and simplified, to be comprehensible for broad audience. This approach consequences with technical superficiality. Presented descriptions do not aim at being fully exhaustive. They rather form a basis for further discussions. Each description is a compromise between different views of the involved Annex partners. In some cases, a specific national perspective results in a different view on the topic. Some descriptions within solutions from the same “family” repeat.

4.2.2. Example of the solution’s description

Comprehensive description of all solutions is available either on the website of the Annex 50 (https://heatpumpingtechnologies.org/annex50/) or in the final report of the project [3]. Below example presents the solution 1.1 called „one heat pump for all“

![Schematic hydronic system of the solution and the placement in the “solution matrix”](image)

Description according to the eighth categories:

- **Main characteristic of the concept**
  One central heat pump system for the whole building, both for space heating and DHW.

- **Size of building, number of apartments**
  This solution is a typical solution in SFH (single family house). It may also be common to apply in smaller MFB with a small number of apartments. In case of large buildings, more than 1 heat pump may be necessary to meet the required heating capacity (cascade solution).

- **Energy standard, insulation level**
  Most suitable for buildings with higher energy standards (new buildings). This concept may be used also for buildings with an average energy standard. For poor insulated houses it is not excluded, however more challenging to implement.

- **Heat Sources**
  All heat sources possible. For large buildings with high energy demand the heating capacity can be a restricting factor for the outside air as a heat source. When outside air is used as HP-source, the HPs should preferably be installed on the roof or in dedicated containers near the technical room. For larger systems, the sound emissions may be a problem for air-source heat pumps.

- **Heat distribution and temperatures levels**
  The heat distribution occurs through the whole building, which increases the heat losses. The heat pump must be able to provide two temperature levels for space heating and DHW or the heat production needs to always meet the high temperature requirements for DHW.

- **DHW and storage characteristic**
  In the central solution for DHW the heat losses account for a significant part of the energy consumption. Storage tanks for DHW are needed. Separate consideration about legionella needed (for example ultra-filtration).

- **Complexity of installation**
  In case of retrofitting, the old heating distribution system may be maintained. In some cases, partial or complete exchange of radiators in each apartment may be required. In case of new buildings, long piping through the whole building is necessary.

- **Specific issues of the concept**
The old heat generator can be replaced (during retrofitting) without changing the distribution system.

In addition to the eight categories, the main advantages and disadvantages have been identified. Similarly here, to concisely indicate strong and week sides of the concept was a balancing act between shortness and comprehensiveness. In case of the example solution 1.1. the positive aspects are: optimal for smaller MFB’s, one controller, existing distribution maintained and simple replacement of a gas boiler. The negative aspect are the high thermal distribution losses.

5. Holistic approach to present the results of Annex 50

The approach of the Annex 50 was to find the way to create a holistic (integrated) method of presenting its results. The categorisation of the solutions and the description of each of them is only a part of the “solutions matrix”. Other parts are the case study database and the individual examples of case studies of heat pumps in multi-family buildings. Each part of the matrix can be used or presented as a stand-alone component. Figure 6 shows the schematic connection between each component of the matrix.

The elaborated case studies are also linked to the certain examples of solutions from the classification described in the previous section. Through providing concrete examples, the theory has been brought to the practice.

6. Discussion

The results of the Annex 50 have been achieved with the best knowledge and belief of the project partners. Nevertheless, presented outcomes may certainly be flawed with some shortcomings.

The description of the proposed “solution matrix” should rather be seen as a framework prepared for further elaboration, than as an accomplished task. Each description is a compromise between various views of the involved Annex partners. In some cases, a specific national perspective results in a different view on the topic. It is recommended to open the discussion about the characteristic of each concept to the broader audience.

With the simplified approach chosen to classify and to describe the solutions, the planned tool “solution finder”, suggesting particular solutions for certain types of buildings etc., cannot be seen and used as a “pre-planning” tool. It is and will be, even with further improvements, solely a hint-assistant on the way to find the right solution and to recognise existing possibilities.

The case studies database should be regarded as a well-established tool with a large expanding potential. The collected cases show explicitly the applicability of heat pumps in multi-family buildings. Despite the significant effort, with the information at the disposal it was not possible to ensure that all case descriptions are of the same level of detail and completeness. The data base should be further developed with more case studies in order to reach its full potential.
7. Conclusions

The importance of implementation of heat pumps in residential buildings, and in multi-family buildings in particular, has grown significantly in the last years and has even further intensified in the days of the crucial and unprecedented debate on independency from fossil energy sources. It’s undeniable that heat pumps technology will play a key role to achieve both the climate neutrality and the fossil fuels independency.

The variety of multi-family buildings and their characteristics make it possible to apply various technical solutions based on heat pumps. Nevertheless, the large heterogeneity of the multi-family buildings leads to individual solutions which are difficult to apply on a large scale. More standardisation of the products and the solutions is therefore needed and crucial.

The proposed categorisation and a simplified schematic visualisation of heat pumps solutions in multi-family buildings provides a user-friendly entry point for the building’s owners and/or decision-makers. Rephrasing, it can be the first step towards implementation of heat pumps by disenchanting the complexity of the possible solutions.

The work of Annex 50 will be continued in the newly initiated Annex 62 “Heat pumps for multi-family buildings in cities” (started in January 2023 with the planned duration of 3 years). The tools described in the paper will be consequently improved and developed. Furthermore, new aspects of the application of heat pumps in multi-family buildings will be addressed.

Acknowledgements

This paper and the results behind it would not have been possible without the exceptional support of all partners working within the frame of the Annex 50. I am grateful to all of those with whom I have had the pleasure to work during this project. Namely Odile Cauret (EDF – Research & Development, France), Nicole Calame (CSD INGÉNIEURS SA, Switzerland), Jeannette Wapler (Fraunhofer ISE, Germany), Charles Geelen (Infinitus Energy Solutions, Netherlands), Marco Simonetti (Politecnico di Torino, Italy), Andreas Zottl (AIT Austrian Institute of Technology GmbH, Austria) and Svend Vinther Pedersen (Danish Technological Institute, Denmark).

I would like to express my deep gratitude to all partners for each hour of fruitful discussions, for their patient guidance, enthusiastic encouragement, and useful critiques during the finalization of the final report.

This work was supported by the German Ministry of Economics and Technology (BMWi), under the Grant 03SBE0001B upon decision of the German Bundestag and supervised by the Project Manager Jülich (PTJ).

Heat pump application in cluster of buildings and positive energy districts

Carsten Wemhoener*

IET Institute of Energy Technology, OST Eastern Switzerland University of Applied Sciences, Campus Rapperswil, Oberseestrasse 10, 8640 Rapperswil, Switzerland

Abstract

A new Annex numbered 61 in the Technology Collaboration Programme (TCP) on Heat Pumping Technologies HPT of the International Energy Agency IEA started in September 2022 and deals with heat pump (HP) application in clusters of buildings as well as positive energy neighborhoods and districts (PED). The focus is on smaller clusters of buildings and new built, but there are also contributions to the district level and retrofit situations, where concepts are developed for larger clusters and to move the cluster or district closer to positive energy or a net zero emission balance, respectively. Based on the state-of-the-art of HP in PED the Annex systematically investigates HP concepts in more detail regarding design and control by simulation. The core activities are techno-economic concept analyses accompanied by monitoring of real case studies both for new built and renovation. The Annex delivers recommendations for HP application in cluster of building and districts to increase market shares of HP also in larger buildings and non-residential applications. The paper gives an outline of the Annex and first interim results of the Annex work.

1. Introduction

Climate protection is presently the largest challenge for the humankind. The global carbon budget for keeping the 1.5 °C target established in the Paris Agreement of 2015 [1] is reached within a time frame of less than 10 years at current CO₂-equivalent emissions [2]. Thus, efforts in all fields to reduce greenhouse gas emissions are urgently required and many cities have already declared a climate emergency in the recent years.

In many countries worldwide, the built environment plays a key role for carbon emission reduction, since in particular the existing building stock has a poor energetic quality. On the other hand, buildings can thereby also contribute to a fast emission reductions. In the EU, for instance, 36% of the carbon emissions are due to buildings, so reaching ambitious climate targets will be strongly facilitated by transforming the building sector. For new buildings, standards have developed to high performance requirements. Furthermore, buildings shall contribute to cover their own demand, leading to the nearly zero energy concepts (nZEB), which has been established in the EU with the recast of the Energy Performance of Buildings Directive (EPBD) [3] and is the current requirement from January 1, 2021 in the EU member states. In addition, the USA and Canada as well as Japan and China have targets to reach Net Zero Energy Buildings (NZEB) in the time frame of 2020 to 2030. Ambitious targets, though, are harder to achieve in existing buildings. However, the latest version of the EPBD of 2018 also requires the member states to develop retrofit strategies to notably enhance the energy performance of the building stock. For new dwellings, also examples to even transcend the nZEB balance and reach a positive energy balance exist with the ability to export parts of on-site energy production to connected grids. This concept can be extended to clusters of buildings and districts deriving a positive energy district.

* Corresponding author. Tel.: +41 (0)58 257 4325; fax: +41 (0)58 257 44 00.
E-mail address: carsten.wemhoener@ost.ch
However, former work, among others in the HPT Annex 49 on "Design and integration of HP in nZEB" confirmed, that in particular for larger residential and office buildings, reaching a positive energy balance on the individual building level can still be challenging. In this sense, extension to clusters of buildings with different load structures also have potential to enhance the heat pump (HP) performance and enable to reach ambitious energy targets.

On the other hand, in the Net Zero Roadmap of the International Energy Agency [2], HP are seen as dominating heating systems with a share of 50% globally by 2045.

HP are already establishing as standard heating system in the new built market in many countries, so the integration of heat pumps in the energy system on the large scale is a future task. Application of (larger) HP for the use in cluster of buildings and neighborhoods, though, are not yet as common. Comprehensive recommendations for the best integration of the HP from a purely decentralized use on individual building level to an entirely centralized integration on district level are missing, and performance potentials of HP application in districts depending on load boundary conditions are not obvious. Moreover, further benefits of HP in cluster of buildings regarding storage options and unlocking of energy flexibility as well as economic implications are further investigated to entirely assess potentials and facilitate ambitious energy performance and emission reduction targets.

2. Outline of the Annex

On this background, the new Annex 61 in the Technology Collaboration Programme (TCP) on Heat Pumping Technologies (HPT) of the IEA entitled "Heat Pumps in Positive Energy Districts" studies the application of HP for clusters of buildings and positive energy neighborhoods (PEN) or districts (PED), respectively. A focus is on smaller clusters of buildings and neighborhoods, mainly with residential and office use. While a majority of project contributions concentrates on new built clusters, quite some projects also focus on strategies to increase the energy performance of existing neighborhoods to approach a zero energy/emission balance, which is also in the scope of the Annex. Thereby, renovation strategies include both the improvement of the building envelope and the integration of HP, and optimized concepts of the combination of both approaches to improve the energy performance are to be evaluated.

Besides the unique performance features of HP and the ability to provide the different building services of space (SH)/domestic hot water (DHW) heating and space cooling (SC)/dehumidification (DH) even at the same time, HP are also a key technology to link the on-site electricity production and heating/cooling demands in districts, respectively. Thus, supposed benefits of the HP integration in districts are manifold.

- the high energy performance of HP enables to reach ambitious energy/emission targets
- the simultaneous operation of HP for different building services enables a waste heat recovery for other building services, e.g. by simultaneous space cooling and DHW heating within the district
- the link of electric and thermal energy allows for load balancing within the district of electric and/or thermal loads as well as on-site electricity production for enhanced self-consumption
- the load balancing can also provide energy flexibility for connected grids, so that the district can provide services for other parts of the city

In order to assess the HP potentials the Annex work follows a 4-step methodology divided into Tasks. Based on the state-of-the-art analysis of HP use in already existing clusters of buildings or PED, a concept analysis for HP in PED is carried out. For promising concepts, a detailed techno-economic analysis is accomplished and backed-up by monitoring of HP operation in PED, which are evaluated in parallel to the concept analysis. Details on the individual Tasks is given in the following

2.1. Task 1: State of the art analysis (September 2022 – June 2023)

Starting from already existing HP systems in cluster of buildings, the state of the art is characterized and boundary conditions for the follow-on tasks are gathered. As Key Performance Indicators (KPI) CO2-eq.-emissions and further technical and economic KPI are considered. As result of Task 1 an assessment of technically realistic options for PED as well as an economic estimation of reachable ambition levels and the economic handicap could be evaluated. Therefore, standardized load profiles are generated and used for archetype district, e.g. entire residential use, mixed residential and office use etc. These archetype districts are to be characterized by the building quality reflected in the loads, the available renewable sources and the on-site energy production options.
2.2. Task 2: Generic concepts development (January 2023 – June 2024)

Task 1 is followed by Task 2 for the analysis of generic system concepts. On the second Annex meeting a first categorization of the generic system concepts has been discussed and the following top level categories have been derived. Starting from decentralized concepts on individual building level as reference, a stepwise path to an entirely central concept with the different steps have been defined, comprising as second category a purely electric connections, as third category a collective heat source, as fourth category a semi-centralized integration and a fifth category the fully central integration. Semi central integration is understood in terms of mixed centralized and decentralized HP, e.g. a central SH HP combined with a decentralized second HP, possibly also as "booster" HP for DHW. The categories are to be further detailed into subsystems in order to derive an overview of different possible configurations. For each of the subsystem, a short technical characterization is to be elaborated. As result, an as far as possible complete overview of generic integration options of the HP in districts with pros and cons and favorable applications as well as recommendations are foreseen.

2.3. Task 3: Techno-economic analysis of concepts (January 2024 – December 2025)

Based on the favorable system concepts derived in Task 2 a more detailed techno-economic analysis is carried out, in particular regarding the design and control as well as integration with storage and other generators to optimize the HP operation regarding performance, renewable energy integration, system cost and energy flexibility. The detailed investigations are carried out by simulations where also modelling aspects of larger heat pumps are a research topic. Task 3 also serves to evaluate optimization potentials of real systems in monitoring in Task 4, which in turn yield operation and performance data to validate the models.

2.4. Task 4: Monitoring and system optimization of the real performance of HP in districts (January 2023 – December 2025)

As mentioned above Task 4 is dedicated to the evaluation of the real performance of HP in district applications and to the identification of typical optimization potentials in the real operation for the different heat pump integration options in monitoring. Moreover, a comparison and verification to simulated values is enabled by the real operational data.

2.5. Task 5: Dissemination of interim results (September 2022 – December 2025)

All task are accompanied by dissemination activities like workshops, articles, website information and presentations, which are summarized in an overarching Task 5.

3. Overview of selected contributions and interim results

The IEA HPT Annex 6 is still in the starting phase since it officially started in September 2022. However, two meeting have been held, where first definitions and results have been discussed. Thus, in the following, a more detailed description of Annex contributions along the single Annex Tasks linked to first interim results are summarized to give better impression of intended and ongoing Annex work.

3.1. State of the art results in Task 1

First results on the state of the art are given in terms of PED definitions and an evaluation of realized PEDs concepts in Germany and Switzerland.

3.1.1. International and national definitions of PED

Even though the concept of PED is developed since 2015, there is no uniform definition up to now. In Seifried et al. [4] a detailed evaluation of applied definitions is provided by the analysis of five EU programs and nine prominent PED project and common items and differences are analyzed. In Figure 1 left, the PED framework developed by Joint Programming Initiative of Urban Europe (JPI UE) which seeks to create a uniform vision for PED and states PED as "energy-efficient and energy-flexible urban areas or groups of connected buildings which produce net zero GHG emissions and actively manage an annual local or regional surplus production of renewable energy. They require integration of different systems and infrastructures and interaction between buildings, the users and the regional energy, mobility and ICT systems, while securing the energy supply and a good life for all in line with social, economic and environmental sustainability.” While this definition has a focus on the operational phase, a Swiss definition of a "2000 W Areal" is based on the SIA 2040 efficiency path [5], which takes into account the whole life cycle incorporating also the embodied energy for the construction and demolition phase and the building induced mobility linked to the site as basic energy boundary. However, as can be seen in Figure 2 on the left, also other criteria like management and communication processes, surrounding and use are contained.

A characteristic, though, which is contained in several definitions, is besides the efficiency and the on-site energy generation the requirement for energy flexibility in order to manage the local or regional energy flows also in conjunction with connected local or regional grids.

Seifried et al. [4] conclude from their evaluation that there are still a lot of differences, among other on the PED boundary, the calculation method of the energy balance and the scope for non-energy matters. An important fact is defining the fundamental purpose and application, which can lead to a universal framework.

3.1.2. Interim results on the evaluation of existing PED in Germany and Switzerland

At the Steinbeis Innovation Center (SIZ) EnergiePlus, a first review of existing PED in Germany with a particular focus on heat pump operation has been compiled and is summarized in the following.
The overall number of PED found adds up to 42 documented projects, of which 2/3 are in realization or already realized, while the remaining 1/3 is still in the planning phase or will not be realized. Thereby, projects are not evenly spread in Germany, but most of the projects are located in just two federal states “Baden-Württemberg” and “Hessen”. Based on available data, only 16 of the total of 42 have been evaluated. Regarding the energy system, all PED are equipped with PV-systems, while installed solar thermal systems are below 20%. HP are with 60% the most applied heating system followed by combined heat and power (CHP) with 40%. Further energy generators are small wind turbines as well as district heating.

With respect to the HP, eight of them are centrally integrated, while two are decentral. The CHP is mainly linked to thermal grids within the PED, and only two transcend the PED physical boundary. The size of the PED are quite different in the range of 16 – 480 flats. However, most of the PED have above 50 and below 200 flats, also including the districts in planning.

In Switzerland, PED are currently dominated by the 2000 W districts, counting 44 projects, which, however, are also differentiated to projects in realization (25%), in planning and in transition (together 75%). Projects in transition are related to transform existing districts to the requirements of a 2000 W district.

The term 2000 W district is based on a budget approach developed at the Swiss Federal Institute of Technology ETH stating that a continuous global power consumption of 2000 W/P/year (corresponding to 17500 kWh/P/year) for all energy services including transport and industry sector is sustainable. It developed as long-term vision for the Swiss energy consumption. However, due to the newer results on climate change the objectives of the 2000 W vision have been significantly tighten in order to comply with the net zero targets by 2050 [7]. Furthermore, the 2000 W district certification is currently linked to the efficiency label MINERGIE [8] and to the sustainability label SNBS [9], which may also change the name of the certification.

Only 4 projects are listed as so-called “plus energy district”, which is a different initiative to document high performance districts with a positive energy balance. For this certification, only operational energy is taken into account for the balance. The 2000 W projects are more evenly spread in 13 of the 26 federal states, but only five federal states have projects in use. Heat pumps are the dominating heat generator besides district heating, with shares in the range of 90%, often combined with PV, which also reaches fractions above 90%. More than half of the projects use heating grids, and about 30% use the ground as heat source. Also almost all projects plan to import certified green electricity. Regarding the use of the districts, the majority has a mixed use with a range of 200 to 1500 workplaces. These districts include also offices, restaurants, hotels etc. 9 districts are only for residential use without any workplace and commercial or retail areas. The number of buildings reaches from one to 53, whereby the total area reaches from 4500 m² to 900'000 m². The number of flats reach up to 1500; while the smallest contains just 81. Regarding the supply systems, nearly all districts incorporate heat pumps and PV production partly combined with other heat generators. Imported green electricity is often found, as well, and one district uses a river hydro power plant to generate electricity in the district. The heat production is mostly local, i.e. there is still potential for the extension of heating grids. Some districts use biogas to dampen peak load. One district also produces its own biogas.

3.2. Generic system concepts in Task 2

Based on the outline in chap. 2.2 the different categories are depicted in direction of increasing integration of the heat pump into the district in Figure 2.

![Fig. 2: HP integration categories defined in Task 2 in the direction of increasing HP integration](image)

Currently, the subsystems are gathered and a template is elaborated for the compilation of system characteristics.
3.3. Techno-economic analysis of promising cluster concepts by simulation in Task 3

Task 3 has not yet started, but is dedicated to the in-depth techno-economic analysis for favourable concepts identified in Task 2.

3.4. Monitoring of HP application in clusters and districts in Task 4

Monitoring of HP is an important feedback of the real performance, on the one hand for the energy assessment, on the other hand for simulation validation. In turn, simulation in Task 3 are used to identify optimization potentials in order to improve the real operation.

In the following, an outline of four different clusters and districts, respectively are given, which also visualize the different categories of generic concepts for the heat pumps integration in Task 2, see chapter 2.2.

3.4.1. Cluster of eight terraced plus energy single family houses Herzo Base in Herzogenaurach, Germany

The cluster of eight terraced houses is located in Herzogenaurach, Germany in the new district Herzo Base and built in 2017. The buildings were designed as an “all electric buildings”, which means that the only source of energy is electricity. A PV-system (88 kWp) on the roofs delivers an annual surplus of energy. The idea of small neighbourhoods creating an energy community and share energy systems enables higher potential to increase the PV self-consumption. Furthermore, synergies between different electrical loads lead to a more even electrical profile and reduces electrical load peaks. The terraced houses share a central heat pump system of two modulating HP (MHPs) of each 17 kWth, with geothermal heat source as well as a battery system with a capacity of 40 kWhel. The supply of domestic hot water is decentralized in each terraced house by a domestic hot water-HP (Booster), which use the heating buffer storage units as heat source. All eight terraced houses are equipped with floor heating and decentralized ventilation devices. The objectives of the field monitoring is the evaluation of the plus energy balance and PV self-consumption. Another aspect is the field test and evaluation of advanced control strategies in order to increase PV self-consumption and reduce energy costs. Figure 3 shows the building cluster and its position in the district.

Fig. 3: Building cluster Herzo Base, Herzogenaurach, DE

3.4.2. Clusters of multi-family buildings in Konstanz and Wolfsburg, Germany

The planning and implementation of a completely renewable energy supply for a block of residential buildings in an urban structure presents a challenge. This was achieved in the two projects by providing heat using a ground-coupled HP. The multi-family houses in Konstanz and Wolfsburg were completed in 2016 and supply a net floor area of 1140 and 9500 m².

Fig. 4: Cluster of multi-family buildings in Konstanz (left) [source: WOBAK] and Wolfsburg (right), DE
Figure 4 shows the building cluster in Konstanz (two buildings) and Wolfsburg (four buildings). The energy concepts of the residential buildings are based on heat supply via HP.

The generated heat is temporarily stored in buffer tanks and delivered to the low-temperature heating systems. The DHW is heated via fresh water stations or storage tank charging systems. Decentralized exhaust air systems or central ventilation systems ensure a constant air exchange. Natural ventilation via the windows is possible in all properties. Photovoltaic systems are installed to cover the electrical energy needs of the system technology and the connected households. The system technology is optimized for so-called "PV self-consumption", which means direct use of the photovoltaic yields.

Electrical energy from the PV systems that cannot be directly consumed or stored is fed into the public electricity grid. The comparison of the multi-family buildings refers to their efficiency, ecology and economy, with the overall balance and thus the total consumption of electrical energy serving as the basis for evaluation.

The consumption of the buildings is made-up of the electricity consumption of HP and circulation pumps, general electricity (lift, staircase, garage, etc.) and the user electricity of the individual flats (appliances).

3.4.3. New built district Campagne, Innsbruck, Austria

A new low-energy residential district is being built in Innsbruck, Austria. The building owners (social housing companies) had to make decisions with respect to the energy quality of the buildings and the heating system with respect to the energy and environmental impact. The district will be composed of 16 buildings grouped in four blocks, see Figure 5. The main part of the buildings is residential and will consist of approximately 1100 new apartments for a total surface of 78027 m². Moreover, sport facilities, cafes, schools and kindergartens will be constructed. In the planning phase, a cooperative process was carried out, involving neighboring residents and local associations.

Fig. 5: Building cluster of Campagne, Innsbruck, AT (source: ibkinf.at; stadtteilzentrum-reichenau.at, Bogenfeld Architekten)

The buildings are built according to Passive House standard (space heating demand lower than 15 kWh/(m²·yr)). The space heating demand is supplied by a groundwater HP and the emission system is floor heating. The domestic hot water is provided by the district heating network, which accounts for a high proportion of heat by renewable sources, industrial waste and bioenergy. The shares of renewable sources and industrial waste heat of the district heating of Innsbruck are higher than other cities in Austria and it is foreseen that these shares are going to increase in the future. Photovoltaic panels are installed on the roof of the buildings to cover the electrical demand of auxiliaries. Moreover, sustainable mobility solutions are planned to enhance the electric mobility. System simulations have already been performed, while also monitoring of the buildings is intended.
3.4.4. Papieri district, Cham, Switzerland

The Papieri district in Cham, CH, is an old estate of the Paper industry, which is rebuilt to a comprehensive new neighborhood in six phases over the next years for 1000 inhabitants and 1000 additional workplaces in the final development. Figure 6 left shows a picture of the district, the first development phase is depicted in Figure 6 middle, and the energy concept of the borehole fields connected to the central HP heating and cooling is shown in Figure 6 on the right.

The neighborhood consists of industrial heritage buildings of the paper industry which are preserved and retrofitted for a new use and are amended by new buildings, which create a mix of about 30% of existing and 70% of new buildings. In the first phase depicted in Figure 6 middle, 105 freehold apartments and 160 rental apartments together with 4400 m² floor area of commercial and office use will be commissioned by the end of 2022.

The estate development is designed in a way that all building services of heating, cooling and domestic hot water are entirely supplied by renewable energy. About 40% of the electricity use in the district is generated on-site. The electricity is generated by a 6500 m² PV-system of an installed peak capacity of 1.27 MWp and an estimated annual electricity production of 1.1 GWh, which is installed on the roof of the new buildings. As second electricity generator, a hydro power plant with an installed capacity of 240 kW and a calculated annual production of 1.25 GWh is installed in the river Lorze, which run through the district. The remaining electricity is imported as certified green electricity from the utility in order to reach a zero emission balance.

The space heating and cooling as well as the DHW production is supplied entirely renewable by four central ammonia HP of a total capacity of 4 MW, which use borehole fields of totally 192 ground probes of 320 m depth as heat source. As second heat source, the river water of the Lorze is used either directly as heat source or as regeneration source for the borehole fields. The comfort cooling for the residential and office use is planned to be operated primarily by freecooling from the boreholes. Active cooling by the HP in chiller operation is only provided for peak load cooling, whereby all the recooling (waste) heat from the active chiller operation is to be recovered for other uses like DHW production or for the regeneration of the borehole fields.

Since neither the modelling and simulation nor the monitoring has started, yet, only the above-mentioned energy concept and design data are available of the neighborhood. The HP system will be modelled, simulated and monitored in order to optimize the first operation years and retrieve on-site information for the further development of the neighborhood in the later project phases. The evaluation includes the verification of the system performance of the centralized HP and the zero emission balance.

A special focus of the simulation and the monitoring is a more detailed analysis of the operation and the energy balance of the borehole fields for combined space heating, DHW and cooling operation. Moreover, the options for the interaction of the two heat sources of the borehole fields and the river water is investigated. Performance potentials are seen in the use of the source with most favorable temperature level, the regeneration of the borehole field for space heating and the simultaneous operation of the HP for heating and cooling in combination with high free-cooling shares. Thus, the objective for the system operation is the maximize the system performance of the HP by an optimized management of the borehole field as heat source and (free-) cooling heat sink and the integration of the ground and river water heat source.

3.4.5. Summary of monitoring projects and link to other tasks

The selected monitoring concepts combine both different sizes of the cluster for smaller groups of 2 and 3 buildings to larger neighbourhoods of up to 1000 flats in 16 buildings. Figure 7 depicts the outlined monitoring projects as contributions to the IEA HPT in the categories of the Task 2.
Moreover, the uses range from smaller residential to larger multi-family, combined also with commercial and office use in the district. Even though for this selection, the focus is on new built there is also monitoring projects for retrofit concepts, even a variety of concept in 7 nearly identical buildings, which enables a direct concept comparison as well as larger districts build-up of retrofit and new built. By the chosen monitoring projects, it also becomes clear, that the different integration options according to the categories in Task 2 followed by the in-depth analysis in Task 3 can be well covered.

4. Conclusions and outlook

Positive energy districts are an ambitious concept, which is currently promoted in order to enhance a high energy performance and on-site energy production as part of the transition of the urban energy systems. Extending the system boundary from the individual building to clusters of buildings and neighbourhoods offers the combination of different load structures, which can unlock opportunities to increase on-site self-consumption of the produced electricity in the cluster by load balancing and to enhance the performance by waste heat recovery from one building service for another. Heat pumps can play an important role in positive energy district concepts, since they facilitate to reach ambitious energy targets by their high energy performance and can link both electric and thermal loads as well as different thermal uses like heating and cooling. As further aspect, sector coupling within the district and with connected grids can provide energy flexibility within and over the boundaries of the district.

The upcoming Annex 61 in the Technology Collaboration Programme on Heat Pumping Technologies TCP of the IEA investigate heat pump concepts for building cluster and positive energy districts. Starting with decentralized solutions on the individual building level, higher integration of the HP in the districts up to entirely centralized solutions and integration with other energy generators/supply like district heating is evaluated technically and economically. Based on generic concepts a detailed techno-economic analysis shall deliver favorable applications of HP in positive energy districts and recommendations for the integration, design and control of the HP systems.

As insight to the national contributions, the paper presents four case studies with different degree of integration of the heat pump in the cluster or district. Already existing results of the case studies confirm that reaching a positive energy balance is a challenge, which requires high building performance to limit the loads, high performance generators for efficient energy supply and vast energy production with the cluster or district, in particular for larger buildings and non-residential use.

Higher integration of the heat pump can create opportunities of higher on-site energy consumption and waste heat recovery for different building services in the cluster, which may further increase the energy performance and flexibility, but may also increase the cost and losses due to necessary grid connections. Both technical and economic trade-offs with be analyzed in the Annex 61.

Results of the case studies underline that HP reach high performance values in the application in clusters and can facilitate to reach ambitious objectives of zero or plus energy neighbourhoods or districts due to its unique features of even simultaneous provision of different building services with high performance. Furthermore, HP offer energy flexibility for higher PV self-consumption and reduced grid interactions. The upcoming Annex will derive favorable HP concepts for districts by simulation and monitoring in different case studies.
Acknowledgements

The IEA HPT Annex 61 is a collaborative research work and results are based on contributions of all participating persons and institutions. The good collaboration and open exchange is highly appreciated. The support and funding of the Swiss Federal Office of Energy SFOE highly acknowledged.

Abstract

Market data for several thousand heat pumps are available in different databases in Europe. Information therein of different versions over time allow the analysis of the evolution of the state of the art of heat pumps. Contrary to typical investigations of single systems by research groups as kind of “bottom-up approaches” to develop new systems or to argue why a specific refrigerant might be applicable due to reached efficiency etc., we try to gain insights into the state-of-the-art of the European heat pump market with a “top-down approach”. The study begins with a comparison of such available databases and their specific differences. The gained product data are aggregated with additional information usually not part of such databases like the age of equipment, dimensions, etc. Thereby a very comprehensive new database arises. Based on this database we show the course over time of important parameters, such as used refrigerants and efficiency, but also sound emissions and refrigerant charge. Where possible the analysis comprises sensitivity analysis of different parameters linked to the used refrigerants and impacts of the applied refrigerant’s thermodynamics.

1. Introduction

Due to the F-gas regulations and the resulting phase down of high GWP (global warming potential) refrigerants such as R407C and R410A, rising effort is spent in academic and industrial research and development towards the use of refrigerants with low GWP [1]. Especially, natural refrigerants like hydrocarbons and carbon dioxide are of interest. However, how fast can a change on the market towards low-GWP refrigerants happen? Beside the choice of refrigerant type, sound emissions of heat pumps become more and more relevant for installation of heat pumps, especially in dense cities. Is there a trend towards less noisy heat pumps visible in the market data? And lastly, an increase in thermal efficiency is a dominant driver for the industry? Is a stagnation of efficiency in sight? Or what is the efficiencies to compete with when new systems are developed? These questions can partly be answered by looking deeply into available market data for heat pumps in public and non-public databases.

The Eastern Switzerland University of Applied Sciences OST publishes every year performance figures of heat pump measurements in their accredited lab. In the last report [2], they show a significant proportion of outdoor installed heat pump units in the lab testing (increase from 17% in 2014 to 32% in 2020) and an increase in their thermal performance (COP increase from 3.5 in 2014 to 4.2 in 2020; operation condition: A2/W35). They state that outdoor installation of heat pumps might increase in future further on. Another finding from OST was that since 2018 the number of heat pumps with low-GWP refrigerants R32 and R290 increased up to 40% of the tested heat pump models in 2020. The authors state that a further increase is probable. Since 2005 OST has measured 249 air-to-water heat pumps and 217 brine-to-water heat pumps according to the
standard EN 14511, such that this database is a good representative of the heat pump market in Europe. However, local boundary conditions in Switzerland, such as a change in the Swiss quality label for heat pumps [3] affect heat pump design and thus performance in the lab tests accordingly.

In the paper [4] from Park et al., the authors present comparative data that might help policy makers to create more effective air conditioning (AC) efficiency market-transformation programs. The paper explores relationships between the room AC efficiency performance metrics of different regions around the world using performance data for split room AC models, including reversible heat pumps which shows the relevance related to the usage of cross-correlated product databases.

Evaluation reports for subsidization programs for the promotion of heat pumps and thus a decarbonization of heat production are another crucial resource to investigate market dynamics and changes in the state-of-the-art of domestic heat pump. Several countries publish such reports in recent years on a regular basis [5–7] which were main resources on a just recently published meta study from IRENA with a global approach on analyzing costs and markets of heat pumps [8].

All research articles and reports listed above show significant trends of performance categorized e.g. for types of heat pumps. Their results can help policy makers and industry to learn from past trends and to estimate future trends. Our work will continue this trend analysis with heat pump data from large European databases and own data collection and adds the time of market introduction into perspective as another relevant figure. It helps to gain knowledge about heat pumps and is a figure which wasn’t used before to the best knowledge of the authors.

2. Databases

For the following analysis of the European heat pump market several different databases have been used. These databases are listed in Table 1.

According to the website the Heat Pump Keymark is a voluntary certification mark that supports the quality and performance of heat pumps on the European market. It can apply to all heat pumps, combination heat pumps and hot water heaters. The certification is based on independent third-party testing and is compliant with efficiency requirements as set by Ecodesign Lot 1, 2 and 10. The European heat pump sector is pinning

See website [www.ehpa.org/heat-pump-keymark](http://www.ehpa.org/heat-pump-keymark), last accessed 30.11.2022
hopes into the idea to have in the future a standardized eligibility framework within the EEA based on the HP Keymark. The database is of good quality due to the strict work based on test reports. The GET product database is mainly for installers to find product lists for boilers and collectors to help them prepare the system design declaration required for grant submissions.

The BAFA database is a set of heat pump models listed as being eligible in terms of the legal and technical constraints in the framework of the German heat pump subsidization scheme. It comprises EN 14511 efficiencies, heating capacities and certain system and circuit specifications (in versions until 14th December 2020). In recent versions publicly available data were minimized and harmonised towards other product databases being compatible to implementing directives (mainly 206/2012 and 813/2013) of the ecodesign regulation rules which made the list less attractive for statistical purposes as within this study.

The SAP Appendix Q Database provides individual branded product performance information that can be accessed and used as an adjunct to the SAP calculation. A product’s performance information is determined by testing against a specification agreed by different stakeholders in England.

The HARP database provides information on the efficiency of heating appliances available in Ireland for use in domestic funding schemes. Product submissions include product test data, product identification documentation and HARP submission forms. The database has been in operation since 2006.

The Eurovent Certita Certification database is the largest and most professional database but more dedicated to commercial appliances and less used for heat pumps in residential houses. Its objectives are in the range of serving R&D departments of participating member companies as well as using the data to participate in bids for public orders.

The propane heat pump database from Fraunhofer ISE, used within this paper, contains market available heat pumps with the refrigerant R290 (propane) in order to show evolution and trends in the market of propane heat pumps. The database is based on the BAFA database but extended with data provided from the manufacturers. The database is non-public and lists more than 100 different types (vapor compression circuits) of propane heat pumps resulting several hundred individual models as variants from those different cycles.

Other national databases are available from different countries that are operating a heat pump funding scheme. Without being complete these are for example Canada, Belgium, Denmark, Spain, Austria, Switzerland, Belgium, Czech Republic as well as Poland.

Toppen databases are usually a subset of the large portfolios of heat pumps available in the European Economic Area (EEA). Usually, products are relatively new to serve the aim of solely offering highly efficient, modern and environmentally friendly products to the market.

3. Evaluation

Based on this preliminary work to evaluate the existing databases and to generate a new database an analysis of relevant parameters started.

3.1. Refrigerant charge

The refrigerant charge is strongly dependent on the heating capacity of the heat pump. An increase in capacity usually corresponds to an increase in component size (e.g. heat exchangers) and thus yields higher absolute but not necessarily to higher specific refrigerant charges. The ratio of charge and capacity is shown in Figure 1 and referred to as “specific charge”. The figure shows heat pump models from the BAFA database (No. 4 in Table 1). The year is based on the CE-marking dates (market introduction date) of the individual models. The data is separated into heat pumps with heating capacities below (a) and above (b) 12 kW. Comparing graph (a) and (b) regarding the increase in charge it is visible that the baseline is not strongly differing between smaller and larger systems. The inter decile range (between 10-90% of all models) for the smaller systems is in the range of 0.33-0.63 kg/kW and the inter decile range of the larger systems is in-between 0.1-0.52 kg/kW. This means that smaller systems have a faint larger specific charge amount than larger systems. But this strongly depends on the type of the used heat exchangers.

---

3 Personal communication to several CEO’s of heat pump manufacturer in November 2022.
Figure 1. Refrigerant charge in kg per heating capacity in kW for different refrigerant types for air-to-water heat pumps. Operation point is A7/W35. a) for a heating capacity below 12 kW; b) for a heating capacity above 12 kW. Source: Own data and BAFA database (No. 4 in Table 1).

Different reasons for a specific charge higher than ca 0.8 kg/kW can be listed. For the authors, the most probable one is the usage of larger components in order to get a high COP.

A specific charge below 0.1 kg/kW is reached in less than 5% of the data. For these models the authors assume a design of the refrigeration circuits, optimized for low charge operation. Even though there are manufactures on the market with these low refrigerant charge heat pumps, a trend towards low charge cannot be seen from the analysis in Figure 1. At the same time the authors see strong R&D activities of the heat pump manufacturers with the flammable refrigerant R290. A safe operation is thereby linked strongly to the amount of refrigerant used. A reduction of R290 supports the safe operation. As Figure 1 shows the air-to-water heat pump models only, an assertion for brine-to-water heat pumps is not possible. The authors see for these systems market available low charge heat pumps and ongoing R&D activities\(^5\), such that specific charge for brine-to-water heat pumps will further decrease.

\(^5\) See https://www.lc150.eu/more_info/
3.2. Acoustics

Several of the databases includes sound power levels (database No. 1, 3, and 6). We focus on database No. 3 which is the Austrian GET product database. The GET database includes nominal and maximum sound power levels. A lot of models and thus entries in the database show a zero difference which means nominal and maximum sound power level are declared identical. This represents about 40% of all models listed in the database. The considered amount of listed air-to-water heat pumps is 1453 models. This leads to the conclusion that the data is not sufficiently reliable to investigate the sound power trends according to the time of market introduction. This is one of the reasons why for the revision of LOT 1 of the Ecodesign directive it was suggested to define operating conditions stricter than in the past. The taken recommendations are strongly linked to the recommendations and conclusions of the Swedish project on the acoustics of heat pumps to identify more reliable testing conditions [20]. This project was running in parallel to the IEA Annex 51 about the Acoustic Signatures of Heat Pumps [21].

![Figure 2: Sound power level of air-to-water heat pumps; L_WA: sound power level. source: get database (No.3 in Table 1).](image)

3.3. Performance

Based on the BAFA database No. 4 from Table 1, an analysis of the eligible heat pumps in Germany is done with focus on performance of heat pumps for different types of refrigerants. Figure 3 shows the coefficient of performance for six different refrigerants for all low-GWP air-to-water heat pumps in the BAFA database. The figure differentiates between four operation points of the heat pump. COPs for the lowest ambient air temperature of -7°C (blue bars) differ from 2.7 to 3.1 as a refrigerant-specific mean value. The variation within a refrigerant category can be more than one COP point (see the error bars) at this operating point; e.g., R32 reaches values up to 4 for a specific heat pump model and down to 2.5 for another model. For ambient conditions of +10°C (yellow bar) the mean COPs are highest, reaching values up to 5.6. Model-specific COPs reach values up to 6 at this operating point.

The number of heat pump models in each refrigerant category (grey boxes) ranges from 4 for R454C to more than 200 for R32. Thus, a comparison of performance should be done with caution for the categories with low number of models. Nevertheless, for the three refrigerants R32, R290 and R454B there are a large number of models and manufactures in the BAFA database, such that Figure 3 can give a good impression on performance.
Based on the data, we can conclude, that primarily the choice of a specific heat pump model leads to a higher impact on the performance than the secondary choice of a specific low-GWP refrigerant. But in combination best case situations occur. And this situation can be found at the German market. There were high sales numbers until the evaluated subsidization scheme MAP where we concluded that for R290 systems the share of sold units is much larger as for other low-GWP refrigerants, see Annex of [5] for the evaluation and the Annual Report 2021 of IEA Annex 54 [22]. However, R454B shows significant lower COP values than R32 or R290. This is in accordance with the material properties of the refrigerants.

3.4. Proportion of refrigerant type

The date of the CE marking of a heat pump is one criterion to estimate the date of the heat pump release into the market, other resources are for example the SAP Q database No. 2 as well as the HARP database No. 5 in which the assignment of a new model within these funding schemes is monitored. However, it can on the other hand express a revised heat pump which got changes. Therefore, a CE marking date expresses a constant working or improvement process.

Figure 4 shows the type of refrigerant in heat pumps in relation to the date of the last CE marking. The data is based on the BAFA list 2020 and extended by the CE marking date. It can be seen that the proportion of high-GWP refrigerants (GWP > 1500) such as R404A, R407C and R410A is decreasing the last 5 years. However, there is still a proportion of 50% in 2020 and thereafter with high-GWP refrigerants.
In Figure 4 it can be seen that within the last five years heat pumps with R290 are constantly marked with the CE marking, but stay below 10% of all heat pump CE markings in the BAFA database. Caution must be taken with the interpretation of Figure 4 for the heat pump market. The figure does not show sales numbers of heat pumps. A link between refrigerant and sales number needs additional data (e.g. [8]) besides the databases in Table 1. Data from before 2009 can be looked up in [2].

3.5. Focus Propane

In order to understand the market of propane heat pumps better, the database No. 4 and 7 from Table 1 (BAFA list and propane heat pump database Fraunhofer ISE) is used to show possible trends. Therefore, Figure 5 shows the efficiency in terms of the seasonal space heating energy efficiency $\eta_S$ for air-to-water heat pumps with four different refrigerants. The mean efficiency (black line) increased between 2007 and 2021 by more than 10%\(^6\). However, scattering of data is by a factor of two larger than this mean increase. Remarkably, there are two strong impacts on the data of this graph.

1. On the right side close to 2020 there are cluster-like structures which is the result of identical CE marking documents which were all updated and provided publicly at the same time from individual manufacturers. This is of course not the market introduction but more a consequence due to the changes/revision anywhere within the legal framework of these conformity declared product.

2. The same effect shows updates and pseudo-market introduction dates for R407C systems within the year 2018 which definitely is not resulting from newly introduced equipment (since no new R407C system should have been developed after about 2012 or earlier) but more to this issue of changes of the legal framework which might leads to regular CE marking updates for individual models. This has also a large impact on Figure 4.

Nevertheless, the dataset for Figure 5 is huge and it is assumed that tendencies and relations between the data are real and can be analyzed.

---

\(^6\) This is the consequence out of different definitions being used for SCOP (with changes at about 2018/2019) together with an unclear situation if all used resources to digitize and use SCOP values were updated based on the current understanding of this figure. Furthermore, the listed SCOP in product and especially eligible heat pump lists should have change in the time window of end of 2021 beginning of 2022 when BAFA for example at the last one has switched from system-wide calculations of $\eta_S$ to product-based values and it is not clear if entries of SCOP done by manufacturers themselves is always provided based on the one or the other then valid definition and it is best declared together with the value.
Figure 5. Evolution of $\eta_S$ at the supply temperature level of 35 °C of BAFA database and additional individual R290 HP specifications for air-to-water heat pumps.

For R290 the evolution shows a clear picture. With the introduction of a new compressor designed for propane and for heat pump application starting from 2010 the first propane refrigerant circuits show similar performance than those of other heat pumps. With the ongoing development improvements of propane-specific compressors on the market in 2016, performances increased strongly, and the propane heat pumps show performance values significantly above average.

4. Summary and Outlook

Several thousand heat pump models are listed in European databases with information such as performance and capacity. An evaluation of these databases individually can help for a view on current market available heat pumps. However, to express trends in performance, usage of refrigerant, acoustics, etc, additional information have to be collected for these datasets. This extension has been done by the authors. Especially the date of market introduction is a meaningful parameter which the authors included. They depicted the date by the CE-marking of the heat pump model as well as listing dates from database No. 2 and 5. Trends based on this representation show reasonable data point progression, with limitations based on revision of the CE-marking. A comparison of the efficiency among each database is difficult due to the different operation points used in the databases.

The main conclusions of the evaluation of these databases are:

- Specific refrigerant charge (in kg refrigerant per kW heating capacity) for air-to-water heat pumps shows a large scattering from 0.1 kg/kW up to 0.8 kg/kW with additional outliers. A clear trend towards reduced amount of refrigerant cannot be seen in the data up to the year 2021. The flammable refrigerant R290 shows lower specific charge than the other refrigerants within the database.
- A trend toward more silent heat pumps can be found in the data. However, a large proportion of the data points shows inconsistencies in terms of nominal and maximum sound power level, which reduces the informative value of the evaluation. Further filtering would be helpful to separate the dataset from non-modified fan blades and serrated trailing-edge fan blades which are nowadays the de-facto standard for quite axial fans.
- The performance of heat pumps (COPs) shows a recognizable dependency on the type of refrigerant. Market available heat pumps listed in the BAFA database show best performance for R290, followed by R32 and R454B (evaluation only for more than 50 different models per refrigerant type). The individual heat pump model has a stronger impact on the performance than the type of refrigerant.
• A large bandwidth of COPs shows large quality or design differences among the models; Simultaneously these differences show potential for performance increase among the majority of heat pumps.
• For R290 new components (e.g. compressor platforms) yielded a significant change in performance in the past. The authors assume still some more performance increase based on improved components in the future for R290 refrigerant circuits before an expected asymptotic final technical maturity level will be reached.

Integration of heat sources for heat pump operation in the larger capacity range

Carsten Wemhoener*, Christoph Meier

IET Institute of Energy Technology, OST Eastern Switzerland University of Applied Sciences, Campus Rapperswil, Oberseestrasse 10, 8640 Rapperswil, Switzerland

Abstract

In Switzerland, heat pumps (HP) in buildings with higher capacities still have lower market shares. The paper focuses on overcoming limitations of heat sources for HP capacities higher than 50 kW, e.g. for air-source due to noise problems or for borehole heat exchangers (BHE) due to space or drilling restrictions. By combining heat sources, a monovalent HP operation is enabled and due to synergies between the sources, also cost and efficiency benefits can result. By building and system simulations, it was found that the BHE size can be significantly reduced, if only winter peak loads are covered. This will circumvent both the noise limitations of the air-source and the space/drilling limitations of the BHE, and can even make dual-source operation more cost-effective. Regeneration can also result in smaller BHE design. For solar regeneration, favorable ratios regarding collector costs have been determined; while for air heat exchangers, special attention must be paid to the fan power and control. As conclusion, a dual source application does not only offer a monovalent HP application, but can also reduce cost and increase performance.

1. Introduction

Scenarios in many countries assume that heat pumps will be the predominant heating system in the future. In the Net Zero by 2050 report of the IEA of 2021 [1] it is evaluated that heat pumps will cover 50% of the global heat demand by 2045. While heat pumps already have a high market share in newly built, smaller residential buildings in Switzerland, their use in larger residential buildings and non-residential buildings with higher heat loads above 50 kW, especially in existing buildings, is still limited. One of the limitations regarding a higher diffusion of heat pumps for use in the higher capacity range are suitable heat sources, especially for heat generator replacements and renovations of existing buildings, where heat source limitations can be a major obstacle. In densely built areas of city quarters, limitations of air source heat pumps are mainly due to noise emissions, if many heat pumps are used on a small area and in a residential quarter with noise protection requirements. In Switzerland, the sound level is limited to 55 dB(A) at daytime and 45 dB(A) during the night to be approved for the installation permit [2]. On the other hand, also a ground source can be limited due to space restriction of the borehole heat exchanger, drilling limitation regarding depth due to ground layer structure and limitation due to the accessibility of the drilling area for the drilling machinery. Furthermore, the drilling density can also be a limitation, since with many borehole next to each other, the ground temperature is increasingly exhausted. One way to overcome the limitations of individual heat sources can be accessed by combining different heat sources, especially if synergies among heat sources can be exploited.

Thus, in this paper, combinations of heat sources are investigated with the aim of overcoming limitation on the source side and enabling a monovalent use of heat pumps despite limitations of individual sources. In this way, the market shares can be extended for larger capacities and renovation projects.

E-mail address: carsten.wemhoener@ost.ch.
The hypothesis is that synergies between the heat sources can be used for a better system performance and/or economic advantages compared to the use of only one single source, e.g. by using the heat source with the better temperature level or by exploiting design advantages. The project objective is to derive recommendations for the use of multi-source systems for higher capacity range applications.

2. Methodology

A literature review and market research delivered the result that so far hardly any commercial system solutions for multiple heat sources are available on the market from the relevant manufacturers. There are different examples for splitting the total heating capacity to different heat pumps, but only with the same heat source, which does not avoid problems in case of source restriction. This may be due to the several reasons:
- the retrofitting of buildings is emerging step by step
- currently, a peak load coverage by fossil fuels is still accepted in the market, which can relax the limitation on the heat source by downsizing the HP capacity
- multi-source systems are associated with a higher complexity and cost and thereby considered more error-prone and risky for the investor, designer and installer
- there are little reference systems with multi-source application

In research, there are several projects, but mainly covering solar assisted heat pumps, where solar energy is applied as regeneration source for the ground, e.g. [3], or a source storage, e.g. as ice storage, or also applied as heat source and/or in direct operation, e.g. for DHW production in summertime. However, since solar yield in winter cannot be guaranteed, either a source storage is required or the primary heat source has to be designed for the entire design heat load of the building. Natale et al. [4] investigate a dual source configuration of a ground and air-source regarding two control strategies. However, only switching between sources and no parallel operation of the two sources is considered. It was found, that even with smaller borehole design a similar performance can be reached, which enables a retrofitting for undersized borehole heat exchangers. Reum et al. [5] investigate control strategies for the air-source and horizontal ground collector, which also includes a parallel operation below a balance point temperature. The HP modelling is based on a black box model derived by test rig measurement. However, no implications for the design of the sources are given. A systematic evaluation of potentials that can be explored by different heat source integration is missing, though. Therefore, this project started with a characterization of different heat sources and combination options. Based on this characterization of heat sources, four strategies are considered for the integration of dual or multiple heat sources:

(a) peak load coverage by an additional heat source
(b) regeneration of the primary heat source by additional source(s)
(c) year-round base load operation by additional source(s)
(d) Preheating of the primary heat source by additional source(s) to increase the capacity output

Due to the higher practical relevance of the first two strategies, this paper will focus on evaluation of these two strategies. Typical applications for the third variant are e.g. an exhaust air or wastewater heat recovery for the DHW operation. The fourth variant can be interesting in cold climate regions with clear sky winter conditions, where the cold outdoor air can be preheated by solar energy use.

The variants for the above first two strategies were investigated by dynamic building and system simulation. The building and system technology has been modelled in Matlab-Simulink using the Carnot-Blockset [6]. The objective of the simulations is the investigation of the system configuration with respect to integration, design and control. Thereby, the main focus of the investigation is to enable the monovalent use of HP as sole heat generator without a peak load coverage by fossil energy or direct electric back-up heaters, in order to enable efficient and carbon free operation. Direct electric back-up heating for the space heating application is forbidden in Switzerland anyway. Thus, in this paper, the term "monovalent" refers to the heat generator and not to the heat source. It is thus understood as use without auxiliary heating, but possibly with multiple heat sources. The scope is set to the higher capacity range > 50 kW installed capacity of the HP, since for this capacity range the limitations of heat source are increasing, in particular for densely built environments in cities and heat generator replacement in existing buildings.

The investigations are carried out by means of simulations of generic residential buildings in the construction standard "new building" and "existing building" with a heat load of 60 kW (base variant) to 240 kW (upper limit for heat load variation). As a boundary condition for the design of borehole heat exchangers/borehole fields, the design criterion according to SIA 384/6 [7] was always taken as a requirement for all calculated variants, where it is required that the mean fluid temperature must not fall below -1.5 °C after 50 years of operation, e.g. as -3 °C inlet and 0 °C outlet of the borehole heat exchanger.

Legend: SH – space heating, DHW – domestic hot water

Thereby, effects of size scaling (e.g. probe spacing) as well as in the load profile (higher hot water share in new buildings) could be investigated. The different strategies can be compared according to energetic and economic criteria under the same boundary conditions (e.g. limited borehole depth). For this paper the key performance indicators of the seasonal performance factor (SPF) of the HP and the annualized life cycle cost are evaluated.

Table 1 gives an overview of the building and system parameters used for the simulation studies. The loads were used according to the standard use according to SIA 2024 [8] for multi-family houses. The site Zurich Meteoschweiz average year according to SIA 2028 [9] was used as weather data. To test the robustness of the design, variations including a cold year were also performed, both for the same weather data set of the cold year over 50 years and as a periodic variation of four normal years followed by a cold year. The heat pump was evaluated as a performance map based on manufacturer data for an air-to-water and brine-to-water heat pump. The higher loads are calculated by multiplying the load profile of the basic size of 60 kW.

The ground source model corresponds to a common approach of design programmes to have a finite difference model of the ground probe and the near surrounding and a step response function called “g-function” according to Eskilson [10] for the farer surrounding of the ground. The model has been validated by a cross programme comparison with the common design tool in Switzerland EWS [11] and also compared to monitoring data of a system in Feldmeilen, CH [3], which delivered feasible results. However, the validation does not cover the operation mode of a peak load coverage strategy investigated here, which is a future task within a demonstration project of a boiler replacement in two multi-family buildings, see chap. Conclusions. The upcoming demonstration project offers the opportunity to gather monitoring data of the peak load operation of the ground source field and is therefore well suited for further model validation work.

3. Results

The focus of this paper is on the first two integration options of the strategies "peak load coverage" and "regeneration". In the context of this publication, only the sole strategies are considered, although combinations of the strategies are also conceivable, which is particularly obvious for very high capacities in the range of the upper limit for the simulations of 240 kW and more, when the borehole field reaches a size, where regeneration is called for. The combination of the strategies can further improve the respective advantages of the individual strategies presented in the following.

3.1. Strategy (a) – Peak load coverage

For the integration variant (a) peak load coverage with borehole heat exchangers, advantages are offered in combination with capacity limitations of the primary heat source, as they may exist with the heat source outside air due to noise emissions. In the case of a sole ground source by borehole heat exchangers, on the other hand, space limitations may exist for the installation of a sufficient number of probes. Peak capacities, though, are often needed only for a rather short period, since in Switzerland HP are designed monovalently to the design outdoor temperature. Figure 1 shows the relative probe length compared to a 100% borehole heat exchanger heat source for the performed parameter variations with respect to new and existing buildings, different probe arrangements as line and compact rectangular field layout, different capacities of 60 kW and 240 kW, normal and cold weather and different thermal conductivity of the grouting of 2 W/(mK) and 0.8 W/(mK).
Fig. 1. Parameter variations for the strategy "Peak load coverage" by ground probes

The basic setting is a compact field layout as rectangular. For the 60 kW building also a line configuration has been evaluated, which is closest to the 45° line and thereby has the least saving potentials compared to a 100% borehole heat exchanger. In fact, most results show robust behavior regarding the performed variation, which simplifies the design for different boundary conditions. The biggest difference is found indeed in the probe arrangement between linear and compact field design. The compact field shows a more digressive behavior since natural regeneration is more limited by the field effect, i.e. the shielding of the inner probes in the center from the surrounding undisturbed soil, and therefore, a lower discharging of the field by the operation for peak load coverage has an even higher impact.

As conclusion of the results depicted in Figure 1, with the combination of air as primary source and the ground for peak load operation, significantly less energy is extracted from the ground than with a ground source only, e.g. about 20% of the total energy when designed for 50% of the total heat load. This corresponds to a much shorter probe length of only 20% of the ground source-only case, which can overcome space restrictions that exist in particular in existing buildings. Furthermore, simulations show that a slightly higher capacity in the range of up to 70 W/m can be temporarily extracted, since long "natural" regeneration times exist for the borehole heat exchangers.

The simulation results further confirm that peak load coverage with borehole heat exchangers, in addition to alleviating capacity constraints, can provide performance and economic benefits such as lower overall investment costs and can unlock additional benefits of borehole heat exchangers as a heat sink for summer cooling.

Fig. 2. Performance of the concepts "Peak load coverage" by ground probes

Figure 2 shows the SPF as a function of the peak load share by the borehole heat exchanger for peak load coverage. Compared to an outdoor air source only (0%), the efficiency also increases with increasing peak load share by the ground source. The difference between the new and existing building is relatively small, since the lower space heating supply temperature is compensated by the higher DHW fraction.
This also explains the slightly better performance of the existing building for the 100% ground-source. Since the existing building is dominated by space heating, the supply temperature decreases, while the DHW stay constant for the entire year. For the air-source heat pump (0%) the performance in new built is better, since the higher DHW share can be provided very efficient due to the high outdoor air temperature during summer, which overcompensates the decreasing temperature in space heating in the existing building. For the ground source (100%), it is vice versa, i.e. the decreasing space heating temperature causes the better performance than the DHW temperatures.

The seasonal performance factor is averaged over the entire operating period of 50 years, since the system variants with higher ground fraction experience a cooling down of the ground and thereby lower source temperatures over the design period of 50 years.

Figure 3 shows an estimation of the cost structure for the case of the existing building depending on the peak load share by the borehole heat exchanger and in comparison to a bivalent solution with a fossil back-up boiler with natural gas as annualized life cycle cost (gas and electricity tariffs as of June 2022, see also Table 2). The used boundary conditions for the economic evaluation depicted in Figure 3 for the strategy “Peak load coverage” and Figure 4 and Figure 5 for the strategy “Regeneration” in section 3.2 are listed in Table 2.

Table 2. Boundary conditions for the economic evaluation in Fig. 3

The costs of the monovalent solution only with HP can result in lower specific costs than the peak coverage by natural gas, which, however, is strongly dependent on the market prices. For the HP solutions, there are economic advantages of the individual sources ground probes-only or air-source-only for the smaller capacity range of 60 kW. The individual sources, however, may not be possible to realize in case of restrictions. Moreover, the additional costs for a dual source HP solution are moderate at 50 €/kW and allow a monovalent HP operation without back-up heater. For larger capacities, the cost advantages of the individual sources decrease or even show higher costs, in particular for the ground source. This is due to the effect depicted in Figure 1. Due to the significantly smaller design of the ground source in relation to the 100% ground source, larger cost saving occur for higher capacities, which can cover the additional cost of the second heat source. This can reach the cost of the 100% air-source, since the air source has also increasing cost for higher capacities and may not be possible due to restrictions, anyway. Furthermore, in new buildings and compared to air-source only, there may be additional freecooling potential by the dual source HP. If this is taken into account as cost benefit in the economic calculation, the differences to the individual source disappear for the lower capacities, as well (not depicted in Figure 3).

3.2. Strategy (b) - regeneration

For variant (b) with regeneration, it is known that large borehole heat exchanger fields are only insufficiently regenerated by natural heat inflows from the ground, which makes technical regeneration necessary. Furthermore, with regeneration the probes can be arranged with smaller distance to each other without cooling down the ground too much and it may be possible to reduce the total probe length, which opens up options for more probes on less space and thus can overcome space limitations. In the project, the control of the HP using solar absorbers and PV/T collectors as well as outdoor air heat exchangers as synergy to heating/domestic hot water operation was systematically investigated for different building sizes. The parameters that were varied include probe field sizes, drilling depth, probe spacing and probe placement in the field.

While many studies have already been conducted on the regeneration of mostly larger borehole heat exchanger fields, the focus has often been laid on 100% regeneration or even seasonal storage through so-called "active" regeneration, i.e. a higher heat regeneration amount than the heat extraction, so that the ground temperatures can be successively raised [12]. In this project, however, the evaluation is carried out for the investigated regeneration sources with respect to necessary area and possible drilling depth as a trade-off between costs and regeneration demand or degree of regeneration in order to evaluate, how and what extend of space and drilling limitations can be overcome.

The results show that both limitations in the possible field size/probe depth and space as well as economic advantages can be achieved by a shorter overall probe length. For solar regeneration, for example, the focus of the economic analysis is on a cost-effective design as the optimal ratio between the collector area and the probe length. From the results, a representation as a contour plot was developed, from which the cost-optimized degree of regeneration can be found, depending on the regeneration source and the boundary conditions.

Fig. 4. Evaluation of the concept "Regeneration" with PV/T hybrid collector
Figure 4 shows the results of the parameter variations for the new building with a fixed probe spacing of 10 m and a design heat load of 240 kW and a regeneration by a photovoltaic thermal (PV/T) system.

By means of a reading example, the statements of the graphical representation are clarified. The plot correlates the specific annual costs vs. the degree of regeneration. Parameters of the contour plot are the probe depth (color-coded contours) and the available area per kW of extraction power as parameter curves. If, for example, a heat load of 240 kW is based on a probe field area of 3200 m$^2$ (13.4 m$^2$/kW as dashed line), a maximum of 32 probes can be drilled at a probe spacing of 10 m. If additionally a drilling depth restriction of 300 m is considered (line along the middle blue contour), this results in the purple area in the diagram of possible solutions.

Since the area is only reached at a regeneration degree of almost 20%, the design conditions for the ground probes field of -1.5 °C after 50 years can only be achieved with regeneration under these boundary conditions. The regeneration degree with the lowest annual costs is found at regeneration degrees of 60-80%, i.e. clearly below 100%, with annual costs of 270 €/kW (costs for drilling and regeneration, including also the benefits of the electricity generation by the PV/T collector).

Compared to a PV/T system a solar thermal regeneration could offer certain advantages in summer operation, because the DHW operation can be provided directly by the solar thermal system. By the PV/T system, a double benefit with electricity production can be achieved, but for commonly available unglazed PV/T less heat is supplied than with solar thermal collectors systems without PV coupling. Thus, possibly the hot water storage temperature level cannot be reached with PV/T only operation.

However, especially in the case of renovation, the roof area may be limited or may have unfavorable conditions due to orientation or shading. Therefore, regeneration by an air heat exchanger can also be a good option, especially in the case of space limitation in the renovation case. Figure 5 shows the same diagram for the regeneration by an air heat exchanger, i.e. for the same limitations of the borehole heat exchanger as in Figure 4. The economic evaluation for the air heat exchanger is quite similar to the regeneration with the PV/T collector. The field of possible designs also starts at almost 20% of regeneration and the lowest system costs are reached at a regeneration degree of 60-80%. Therefore, also for the regeneration source different combination are available which enables an adaptation to restriction in the concrete situation. While the above limitations of the solar regeneration sources can be avoided, care has to be taken for noise issues and the positioning of the air heat exchanger similar to the use as primary heat source. Further criteria and potentials for a high energy efficiency of the air heat exchanger are the fan power and improved control strategies.

Case study:

- Capacity demand: 240 kW
- BHE field area: 3200 m$^2$ (13.4 m$^2$/kW)
  - Max: 32 probes @ 10 m spacing
- Probe depth limitations: ca. 300 m
  - not possible without regeneration
  - minimum cost at 60-80% regeneration
  - specific annual cost of 280 €/kW

![Image](Fig. 5. Evaluation of the concept "regeneration" with air heat exchanger)

4. Discussion

The focus of the investigation was the larger diffusion of the use of HP as only heat generator without fossil back-up heating in the higher capacity range above 50 kW. One limitation for the higher capacity range can be limited heat sources, especially in the case of heat generator replacements in existing buildings. In order to enable a monovalent HP application also in the higher capacity range, combinations of heat sources and their integration and design have been investigated.
The hypothesis of the study was, that in particular for the higher capacity range, limitation of individual heat sources can be overcome and even benefits of higher performance and better economic values can be achieved due to the use of synergies between dual or multiple heat sources. In this paper, results of two investigated strategies entitled "peak load coverage" and "source regeneration" are reported.

It could be verified that with synergies between the heat sources, e.g. use of the better temperature conditions of the individual sources, i.e. the ground in winter time and the air in summer time, and adapted use of the ground, also performance advantages (compared to air source) and economic benefits (compared to ground-source) can be exploited.

For the conducted investigations on the strategy "peak load coverage", the combination of the heat sources "outdoor air" and "borehole heat exchangers", which are most frequently used in Switzerland, was considered. However, this does not limit the strategy of peak load coverage to these heat sources. The results can also be transferred to other heat source, where the "outdoor air" stands for a heat source that is limited in capacity, e.g. by noise protection requirements, and the ground stands for a heat source that can be stored, but which can also be subject to restrictions, e.g. by required space, drilling depth or other legal limitations. The combination allows a smaller dimensioning of both heat sources, so that both limitations can be overcome. Other possible combinations include groundwater or surface water with a limited pumping volume, or waste heat with a limited capacity in combination with air or geothermal probes. Depending on which source is considered as primary individual source, the performance may increase as shown in Figure 2 for the case of peak load coverage by ground source where air is considered as primary heat source.

In the strategy of "regeneration", the second source primarily serves to manage the storable primary heat source. In addition, though, the regeneration source can also take over e.g. the summer operation as only source, and thereby use seasonal advantages, in the case of solar thermal regeneration for instance the good summerly solar irradiation availability. In the case of air, heat exchangers the higher summer outdoor temperatures can be used, and thus further promote the regeneration of the primary heat source by a reduced use in summer.

The economic evaluation confirms that dual or multi-source system do not necessary have higher costs, since synergies between the sources may also decrease the cost. For the "peak load coverage" by ground probes, where a high peak capacity, but less energy is delivered by the ground probes, the decrease of the borehole heat exchanger size enables a cost decrease for the ground probes.

On the other hand, by regeneration of the ground, a cost optimized design can refund the investment in the second heat source for the regeneration and decrease the overall system costs. There is also a certain variability of regeneration sources, which can be designed according to respective on-site limitations especially in case of existing buildings. For the example outlined in this paper, the regeneration by PV/T collectors and by air heat exchanger lead to comparable overall system costs.

Moreover, the integration of a second source may also additionally enable further operation modes, such as a freecooling operation in case of additional use of geothermal probes as second source. However, the use of this freecooling option also depends on the installed emission system in the building. In the case of freecooling, larger surfaces for the heat transfer are required, which are classically installed in new buildings. Radiators in existing buildings are normally not suited for a freecooling operation, unless not supported by ventilators for enhanced convective heat transfer.

A drawback of dual or multi-source systems, though, is an increased system complexity. Results of this study should thus be elaborated to derive recommendations for an as far as possible simple and robust integration. However, further steps are required in order to derive more standardized guidelines for a dual or multi-source application.

Two other strategies of a "second source as base load" and a "source preheating" by a second source have not been discussed in this publication.

A "second source as base load" can typically be applied, if the one source has a more or less constant capacity and contributes to the overall coverage with this constant capacity throughout the whole year. As example, a wastewater heat recovery as second source is usually sufficient to constantly cover the DHW load throughout the year. In addition, waste heat from exhaust air can deliver a more or less constant heat source, which can help to overcome limitations of the primary source.

The strategy "source preheating" is particular promising in situations, where the temperature limitations during peak load hours is an obstacle. A situation can be cold days, which, however, have a high solar irradiation potential at clear skies, e.g. in northern or mountainous regions, where winter outdoor temperature can fall down to very low temperatures, even below the operating limit of the heat pumps, but are combined with high solar irradiation, which can be used to preheat the outdoor air source.
5. Conclusions and perspectives

Within the scope of the project, system solutions with the HP as only heat generator and dual source are investigated. However, in addition, the investigated strategies can also be useful for a combination with other heat generators or heat carriers. In combination with district heating, for instance, more buildings can be connected to the grid, if a decentralized coverage of the peak load with borehole heat exchangers is integrated. The load profile for the energy drawn from the grid shifts to a higher base load fraction due to the increase of the hot water share supplied by the district heating. Alternately, the district heat extraction can be better adapted to the application, e.g. existing grids can supply more buildings without increasing the pipe diameter/generator capacity, or more heat is available for high temperature applications, e.g. in existing buildings. These advantages can occur both for higher temperature grids, e.g. from waste incineration, or for low-temperature grids in terms of 5th generation district heating on waste heat level, such as waste heat from a waste water treatment plant.

The promising results both on the performance as on the economic evaluation can raise the question on cost and performance optimized combination of heat sources. Synergies for the individual heat sources in the combination can lead to more attractive multi-source systems than individual sources even in situations without the limitations of the sources. However, also the cost assumptions would need to be assured by practical applications. Furthermore, early adoptions and manufacturers or system developers as prime movers would be needed to enhance market extensions and knowledge to spread dual source systems. This could go hand in hand with an optimization and standardization of the systems for a certain capacity range.

A limitation of the results of the study is that they have been obtained by simulations only, so far. In order to approve their validity in practical application of a real system, monitoring of a system with respective limitations on the source side would be a fruitful verification which can promote the spread of the information on dual source HP applications by a best practice system and deliver further information and verification of systems models as well as on integration, design and control.

5.1. Demonstration project of dual source heat pumps for boiler replacement

In fact, in the course of the project, already a real case with the investigated limitations has been found. The project deals with the heat generator replacement of an old oil boiler, which supplies two existing multi-family buildings built in 1972 with 28 flats each and a heated area of totally 4180 m². The buildings have hardly been retrofitted and are mainly in their original state.

The total heating capacity of 200 kW is supplied by a common oil boiler and distribution line between the two buildings. The average annual heat consumption over the last 20 years was evaluated to 600 MWh/a.

The original concept aimed at the boiler replacement by a single-source ground-coupled HP, which significantly improves both the energy performance and the CO₂-emission reduction.

Due to the steep surrounding area, though, the space for the drilling of the boreholes is limited to the parking lot between the two buildings. The concept was detailed with ground probes in a depth of 295 m and an additional air heat exchanger for the regeneration of the ground probes. An air heat exchanger was chosen as regeneration source, since the retrofitting of the roofs of the two building is planned for the next years after the replacement of the heat generator. Therefore, the space on the roof was not available for solar regeneration.

However, during the drilling of the first three boreholes, artesian water has been found at 130 m, so the authorities defined an additional limit of drilling depth of maximum 120 m. With this new limitation, the concept with boreholes only is no longer sufficient to provide the whole source capacity for a heat pump operation and a dual source system of the ground and an extended air heat exchanger is now under consideration.

Since these boundary conditions correspond to the investigated limitations, the buildings are an ideal case study to gather further experience with a dual source combination of the ground heat exchanger and outdoor air heat source. A demonstration project has thus started in January 2023 and the monitoring data of the system can be used to verify simulation results, evaluate the real performance and cost of the dual source system and derive planning and design recommendation by a real monitored buildings.
Acknowledgements

Results outlined in this paper have been investigated in the project "HP-source – integration options for heat sources". The project supervision, support and funding of the Swiss Federal Office of Energy SFOE under the contract SI/502144-01 is highly appreciated and acknowledged.

Abstract

Six potential heating and cooling systems were simulated in a large (44-storey) proposed institutional/residential development on a Canadian university campus: a base case including natural gas boilers and a water-cooled chiller; an ambient loop (AL) coupled with conventional equipment (natural gas boilers and cooling tower); an AL-coupled wastewater heat pump (WWHP) system; a hybrid WWHP-conventional AL system; an AL-coupled ground-source heat pump (GSHP) system; and a hybrid GSHP-conventional AL system. The hybrid WWHP-conventional system and the two GSHP systems outperformed the base and conventional AL systems on all fronts, providing energy savings and greenhouse gas (GHG) emissions reductions while also costing less to operate on an annual basis than the base or conventional AL systems under both 2019 and 2030 energy pricing. Of the six systems investigated, the hybrid GSHP-conventional system had the lowest energy use, produced the least GHGs, and cost the least to operate under 2019 and 2030 price schemas. While the results of the simulation mediate towards the adoption of a GSHP-based system for this institutional/residential development, annual cost savings and GHG emissions reductions must be balanced against upfront costs, available energy resources, and logistical concerns such as the construction of a borehole field.

1. Introduction

Residential and commercial buildings in the US account for approximately 13\% of all greenhouse gas emissions [1]. Since most of the buildings that will exist in 2030 have already been constructed, the majority of opportunities to reduce GHG emissions in buildings in the coming decades will come from improving the efficiency of existing building systems and from the electrification of fossil fuel-based space and water heating equipment. Ambient loop (AL) systems, also known as ambient loop heat pump (ALHP) systems, are a relatively clean and efficient substitute for conventional space heating and cooling systems, allowing for flexibility in the choice of coupled auxiliary heating and cooling equipment. Using a planned cold-climate institutional/residential development as a test case, this paper will investigate the performance of ambient loop systems paired with conventional equipment (natural gas boilers and cooling tower), wastewater heat pumps (WWHPs), and ground-source heat pumps (GSHPs). Annual energy usage, greenhouse gas (GHG) emissions, and energy costs will be compared, and recommendations will be made for system selection.

In an ambient loop system, refrigerant is circulated throughout a building at 8-25°C, with water-to-water or, more frequently, water-to-air heat pumps serving to ‘upgrade’ the energy in the ambient loop at-zone and provide heating or cooling to individual areas of the building [2] [3]. The simultaneous discharge of heat to and extraction of heat from the loop in different zones serves to maintain/moderate loop temperature; for this reason, ambient loop systems are well suited to buildings with simultaneous heating and cooling loads.

\textsuperscript{*} Corresponding author. Tel.: +1-647-915-2017
\textit{E-mail address:} mbrands@ryerson.ca
Ambient loops are also ideally suited to make use of low-temperature waste heat (e.g., from wastewater, minewater, or industrial discharge), and do not suffer from transmission losses to the same extent as conventional hot/chilled water systems [3].

Soil and urban wastewater, both of which maintain relatively constant year-round temperatures in the 10-25°C range, present promising heat sources/sinks for ALHP systems [4] [5] [6]. In a wastewater heat pump (WWHP) ambient loop system, ambient loop temperature is maintained via heat exchange with urban wastewater. Although institutional-scale WWHP systems have been implemented in a number of buildings worldwide – for example, the Rechts der Isar Medical Centre in Munich, Germany and Okanagan College in Kelowna, Canada – heating and cooling with wastewater remains relatively uncommon in North America, and there exists a substantial underutilized energy resource [7] [8]. A 2009 Canadian study suggested that an area with a population of 100,000 could produce 300,000 GJ of recoverable heat per year, enough to heat 3,000-5,000 single-family homes, while a 2013 Swiss study estimated that cooling Zurich’s wastewater by 1°C would correspond to a continuous delivery of 10 MW [6] [9]. An ALHP system which uses the earth as a heat source/sink is referred to as a ground-source heat pump (GSHP) or geo-exchange ambient loop system. GSHP systems share many advantages – including relatively high system coefficients of performance (COPs), and a high energy efficiency and decarbonization potential – with WWHP technology, but are better established in North America [10]. In this paper, WWHP modeling is conducted using Microsoft Excel and coupled thermodynamic plugins, while GSHP modelling is conducted in HyGCHP, a TRNSYS-based software module for analyzing hybrid geothermal systems. Subsequent sections of the report detail the characteristics of the analyzed building development, as well as the building energy model, ALHP system simulation methodology, and comparative results for the six systems under analysis.

2. Development characteristics and energy model

The proposed development will be located in downtown Toronto, Canada, on the campus of Toronto Metropolitan University (formerly Ryerson University). The development will consist of a 15-storey podium (including 14 teaching storeys and one mechanical floor) and an adjacent 44-storey residential tower. The podium is slated to contain: retail areas; a café; a science gallery; a dining hall; conference space; lecture theatres; active learning classrooms; study rooms; and computer, physics, chemistry, and biology labs. The tower will contain student residences. Key parameters of the development are given in Table 1.

<table>

<th>Table 1. Characteristics of proposed building development</th>
</tr>
</thead>
<tbody>
<tr>
<td>Development type</td>
</tr>
<tr>
<td>Floor area</td>
</tr>
<tr>
<td>Volume</td>
</tr>
</tbody>
</table>

Building energy modelling was performed in eQuest by a consulting firm employed by the University, with the podium-tower development being modelled as 204 separate zones. Table 2 gives peak demand and annual loads for heating and cooling, as per the eQuest model. The development is slightly heating-dominated both with respect to energy peaks and with respect to overall load.

<table>

</tr>
</tbody>
</table>

The development experiences almost year-round heating/cooling loads, with 0 annual no-load hours. Heating loads occur 8,715 hours a year (99.49% of the time) and cooling loads 8,758 hours a year (99.98% of the time), with the development having simultaneous heating and cooling demands for 8,713 hours each year.
(99.46% of the time). The presence of simultaneous heating and cooling loads over most of the year renders the development well-suited to an ambient loop system.

The proposed development is to be located in a densely-developed downtown area. This presents an opportunity with respect to WWHP implementation, as the site is adjacent to substantial untapped wastewater resources, but a challenge with respect to GSHP implementation, as a large borehole field would be required to meet the development’s heating/cooling loads and available space is limited.

3. Modelled heating and cooling systems

Six systems were modelled supplying the development’s heating and cooling needs: a base case with natural gas boilers and a water-cooled chiller (no AL); an ambient loop coupled with conventional equipment (natural gas boilers and cooling tower); an AL-coupled WWHP system; a hybrid WWHP-conventional AL system; an AL-coupled GSHP system; and a hybrid GSHP-conventional AL system.

Modelling for the base case and the two WWHP systems was performed in Microsoft Excel using the XSteam and Psych plugins, while modelling for the two GSHP systems was performed in HyGCHP. Weather data used in air- and sewer-temperature correlations while modelling the conventional and WWHP systems was obtained from Environment Canada (Toronto weather station 6158355).

3.1. Base case (natural gas boilers and water-cooled chiller)

Under the base case, the development’s space heating demands are met by natural gas boilers, while its space cooling demands are met by a water-cooled chiller. A constant 75% boiler efficiency was assumed, an industry-standard value as per the work of Kwiatek et al. [11]. Water-cooled chiller performance data was obtained from a reputable manufacturer, and is shown in Table 3. Two 3,285 kW chillers were required to meet the development’s cooling needs.

3.2. Conventional ambient loop

The conventional system model consists of: (1) a boiler model, (2) a cooling tower model, and (3) a heat pump model, integrated with a variable-flowrate ambient loop. Ambient-loop flowrate was set to $4.8 \times 10^{-5} \text{m}^3/\text{s}/\text{kW}$ (2.7 GPM/ton) of net heating/cooling demand and ambient-loop power draw to 0.349 kW/(kg/s) (22 W/GPM), both industry-standard values, the latter drawn from ASHRAE 90.1 [12]. As in the base case, boiler efficiency was kept constant at 75%.

An open-loop cooling tower model was created in Microsoft Excel. XSteam, a MATLAB/Excel plugin, and Psych, a psychrometric plugin, were used to determine the thermodynamic properties of steam/water and moist air, respectively, under Toronto climatic conditions. In-zone water-to-air heat pumps were used to provide heating and cooling to individual building zones. Heat pump COPs for heating and cooling were drawn from TRNSYS. Table 4 shows the coefficients of performance used.

An open-circuit cooling tower was modelled as per the schematic in Figure 1 below. Temperature ($T$, in °C) and specific enthalpy (h, in kJ/kg-K) are modelled at each state point, along with the relative humidity ($RH$, unitless) and humidity ratio ($\omega$, unitless) of the incoming and outgoing air. The specific enthalpy of air is denoted $h_a$ (in kJ/kg-K), while the specific enthalpy of saturated liquid water and saturated water vapour are denoted $h_f$ and $h_g$, respectively (also in kJ/kg-K). For air entering (State 3) and leaving (State 4) the cooling tower, both dry-bulb ($T_{DB}$) and wet-bulb ($T_{WB}$) temperatures are given.

Warm water entering the tower from the ambient loop (State 1) and cooled water returning to the ambient loop (State 2) share a single flowrate, $\dot{m}_w$ (in kg/s), with incoming makeup water ($\dot{m}_5$, in kg/s) compensating for evaporation such that mass balance is preserved. The tower is assumed to run only when there is a net demand for cooling. Further details for how makeup water rate and cooling tower air mass flowrate ($\dot{m}_a$, in kg/s) are determined on an hour-by-hour basis are given below.

![Fig. 1. Schematic of AL-coupled cooling tower (schematic adapted from [13])](image)

Ambient loop flowrate ($\dot{m}_w$) was set to vary with net heating/cooling demand, with makeup water rate and airflow rate determined on an hourly basis as a function of ambient loop flowrate and the properties of supply (State 1) and return (State 2) water in the ambient loop.

For hours in which there is a net demand for cooling, state points were fixed as follows:

- **State 1**: The thermodynamic properties of the supply water from the ambient loop are determined by the amount of heat rejected by the building’s water-to-air heat pumps. That is, $T_1 = (\dot{Q}_{cool})/\dot{m}_w C_{p1} + T_2$ where $\dot{Q}_{cool}$ is the heat rejected by all zones (in kW) and $\dot{m}_w$ and $C_{p1}$ are the ambient loop mass flowrate (in kg/s) and specific heat capacity of the water in the ambient loop (in kJ/kg-K).

- **State 2**: Water at State 2 is at the ambient loop temperature, which, when there is net demand for cooling, is defined as being 5°C above the outdoor wet-bulb temperature. That is $T_2 = T_{AL} = T_{3WB} + 5°C$. (When there is a net heating demand instead of a net cooling demand, ambient loop temperature is held constant at 11°C.)

- **State 3**: State 3 is outdoor ambient air. Dry-bulb and wet-bulb temperatures from Environment Canada (Toronto weather station 6158355) were used to establish the state.

- **State 4**: State 4 is moist leaving air. The following assumptions were made to determine the properties of leaving air at State 4:
a. Temperature at State 4 was taken as the average of outdoor ambient temperature and supply temperature from the ambient loop. That is, 
\[ T_4 = \frac{T_1 + T_{3DB}}{2} \]

b. Relative humidity at State 4 was assumed to be 20% higher than outdoor relative humidity, up to a maximum of 100%. That is, 
\[ RH_4 = RH_3 + 0.2 \]

- **State 5:** Makeup water, which compensates for evaporation, is also treated as being at the same temperature as the ambient loop temperature.

With these relationships in place, the mass flowrate of air through the cooling tower was found through Equation 1:

\[
\dot{m}_a = \frac{m_1(h_{f1} - h_{f2})}{h_{a4} - h_{a3} + \omega_4 h_{g4} - \omega_3 h_{g3} - (\omega_4 - \omega_3) h_{f5}} \tag{1}
\]

Note that when the system is in heating mode \( h_{f1} = h_{f2} \) and therefore the mass flowrate of air is 0 and the cooling tower is off/bypassed.

Equation 2 below gives the mass flowrate of makeup water in kg/s:

\[
\dot{m}_5 = \dot{m}_a (\omega_4 - \omega_3) \tag{2}
\]

As with airflow through the cooling tower, the makeup water rate is 0 when cooling is not required. The boiler and cooling tower models were integrated to create a conventional system ambient loop model capable of meeting the complete heating and cooling demands of the proposed development. Once loads were extracted from the eQuest model, heat extracted from and rejected to the ambient loop were defined as follows:

\[
\dot{Q}_{cool} = \dot{Q}_{in} \left(1 + \frac{1}{COP_c}\right) \tag{3}
\]

Where \( \dot{Q}_{cool} \) is heat rejected to the ambient loop (in kW), \( \dot{Q}_{in} \) is cooling load (kW), and \( COP_c \) is cooling coefficient of performance (unitless).

\[
\dot{Q}_{heat} = \dot{Q}_{out} \left(1 - \frac{1}{COP_H}\right) \tag{4}
\]

Where \( \dot{Q}_{heat} \) is heat extracted from the ambient loop (in kW), \( \dot{Q}_{out} \) is heating load (kW), and \( COP_H \) is heating coefficient of performance (unitless).

We then define the **net heat rejected (NHR)** as cooling minus heating for a given hour:

\[
NHR = \dot{Q}_{cool} - \dot{Q}_{heat} \tag{5}
\]

\( NHR \) determines how much cooling must be provided by the cooling towers or (if negative) how much heating must be supplied by the boilers. Boiler energy use and cooling tower air mass flowrate and makeup water rate were set to ensure that \( NHR \) was always met. Cooling tower power draw was determined as a function of flowrate through the tower, using the minimum efficiency value set by ASHRAE 90.1, \( 3.23 \times 10^{-3} \) (m³/s)/kW (38.2 GPM/hp) [12].

3.3. WWHP-coupled ambient loop (including hybridization)

For the WWHP system, it is proposed that a wetwell – a structure which receives sewage for handling – be constructed to tap into one of the sewers adjacent to the university campus. Wastewater will be screened for debris, passed through a bank of shell-and-tube wastewater-to-water heat exchangers housed in an energy transfer station (ETS), and – once its energy has been extracted – returned to the sewer. The shell side of the heat exchanger will be wastewater, while the tube side will be clean (ambient loop) water. This system configuration will ensure that only clean water circulates on the university side of the heat exchanger. The fluid pressure will also be higher on the tube side of the heat exchanger to ensure that in the event of a rupture clean water enters the wastewater side, and not vice versa, though it should be noted that such an emergency is unlikely.

Although the WWHP system is capable of meeting the development’s complete heating and cooling needs, a boiler plant and/or cooling tower(s) for may be retained for redundancy depending on local legislation and the preferences of the building operators. Regulations regarding redundancy may differ depending on the exact configuration of the WWHP system.

3.3.1. Sewer temperature correlation and wastewater energy estimation

Sewer temperature and flow data were received from Toronto Water for several sites in the Greater Toronto Area. In order to estimate available wastewater energy in a manner consistent with the Toronto outdoor air temperatures provided by Environment Canada (and because temperature data was available only for the August-October 2018 period), it was necessary to determine a correlation accounting for the relationship between sewer temperature and: (1) outdoor dry-bulb temperature, and (2) time of day.

Sewer temperature fluctuates seasonally with outdoor air temperature, with average sewer temperatures being higher in summer and lower in winter. Additionally, sewer temperature varies predictably within a 1-2°C window throughout the day; temperatures are lowest around 7AM-8AM and rise steadily towards a high point in the late morning/early afternoon (11AM-2PM). Temperatures then drop steadily until they reach another low point around 5PM-6PM, before climbing towards their highest point around midnight. While there is considerable day-to-day variation in the exact shape of the sewer temperature curve, this general pattern of two peaks and two valleys holds true throughout the year.

The flows from Sewer MH101, Site 005 were used to generate a correlation between wastewater temperature, seasonal outdoor dry-bulb temperature, and time of day according to the following method:

- A fifth-degree polynomial trendline was generated to represent variation in wastewater temperature as a function of time of day (“Correlation A”).
- Mean daily ambient temperature and mean daily wastewater temperature were correlated using a line of best fit (“Correlation B”).
- To capture the effect of seasonal variation, the $x^0$ value of the fifth-degree polynomial (y-intercept) was replaced with the estimated mean daily wastewater temperature as determined from Correlation B.
- An offset of +0.6°C was applied to reduce error.

RMSE between estimated sewer temperature and recorded sewer temperature under this method (“Correlation C”) was 0.73. The maximum modelled wastewater temperature was 25.6°C, while minimum modelled wastewater temperature was 19.6°C, values consistent with most urban sewersheds [4] [5] [6]. The coefficients of the line of best fit used are shown in Table 5 below.

<table>

</tr>
</tbody>
</table>

Where:

$$x_0 = \overline{T_{sewer}} + 0.6 = f(T_{DB}) = [0.1041 \times T_{DB} + 22.634] + 0.6$$ (6)
The estimated temperature profile was paired with a full year of actual flow data from a different monitoring site (103-119) to generate a complete temperature/flowrate profile. Maximum available sewer energy (i.e., energy available if the entire sewer flow is utilized) was calculated according to Equation 7 below:

\[ \dot{Q}_{\text{sewer}} = \dot{m} \times c_p \times \Delta T \]  

(7)

Where \( \dot{m} \) is the mass flowrate of the sewer, \( c_p \) is the specific heat capacity of water (wastewater), and \( \Delta T \) is the inlet-outlet temperature difference across the wastewater side of the heat exchanger, here taken to be 3°C due to municipal safety limits on wastewater temperature.

A 5°C difference between water and wastewater streams was assumed – that is, ambient loop temperature was taken to be 5°C higher than the sewer temperature in the cooling season and 5°C lower than the sewer temperature in the heating season. The lowest available sewer energy at any point during the year was found to be 5,416 kW (occurring in late March), sufficient – once heat pump efficiencies are taken into account – to meet the complete heating and cooling demands of the proposed development.

### 3.3.2. Hybrid WWHP-conventional ambient loop

As has been mentioned above, it is estimated that the energy content of available wastewater resources near the proposed development – estimated based on the flowrate of a comparably-sized sewer and sewer temperature-outdoor air temperature correlations based on other Toronto sewers – is capable of meeting the heating and cooling demands of the development. However, for the sake of comparison, a hybrid WWHP-conventional ambient loop scenario is also presented.

Under the hybrid scenario, it is assumed that wastewater resources are not sufficient to meet the demands of the development, so conventional equipment – namely, natural gas boilers and a water-cooled chiller – is reintroduced to make up the deficit, with wastewater remaining the first source of supply to the ambient loop. It was assumed under this scenario that there would be enough year-round flow to ensure constant supply for a single shell-and-tube heat exchanger; heat exchanger specifications were provided by the manufacturer. At full capacity, this shell-and-tube heat exchanger operates with a wastewater flowrate of 0.057 m³/s and clean water flowrate of 0.028 m³/s.

### 3.4. GSHP-coupled ambient loop (including hybridization)

In the two GSHP-coupled ambient loop scenarios (full geo-exchange and hybrid GSHP-conventional system), the ambient loop is paired with a ground heat exchanger. Modelling for the two GSHP-coupled scenarios was performed in HyGCHP, a module based on TRNSYS (Transient System Simulation Tool) used for analyzing hybrid geothermal energy systems. The parameters used in both simulated scenarios are given in Table 6 below.

3.4.1. Hybrid GSHP-conventional ambient loop

The final scenario simulated was a hybrid GSHP-conventional ambient loop. As in the hybrid WWHP-conventional ambient loop scenario, rejection of heat to and extraction of heat from the thermal reservoir (in this case, the ground rather than wastewater) remains the first order of supply, with conventional equipment – in this case, a single cooling tower – making up the remainder of the development’s demand. In the hybrid GSHP-conventional scenario, the borehole field is sized to meet heating demand.

4. Energy, cost, and GHG comparison

Natural gas and electricity prices used in estimating energy costs for the six heating/cooling systems are shown in Table 7. 2019 and 2030 prices are derived from Toronto Metropolitan University’s Carbon Reduction Roadmap (2021) [14]. It should be noted that natural gas costs are extremely volatile; 2022 natural gas costs are substantially higher than those of 2019, reflecting current sociopolitical conditions. With respect to electricity pricing, the University is a Class A consumer under the Ontario regulatory structure, meaning that it pays a global adjustment (GA) factor based on the percentage of the province’s electrical demand for which it is responsible during the top 5 draw hours every year; costs given in the Roadmap are therefore not simple marginal energy costs, but rather reflect estimated global adjustment.

Table 7. Factors used in calculating energy costs [14]

Canada’s 2021 National Inventory Report for greenhouse gas sources and sinks provided the factors used to calculate greenhouse gas emissions associated with: (1) electricity consumption from the Ontario grid, and (2) the burning of natural gas; these factors reflect 2019 conditions [15]. For electricity consumption, the average emissions factor (“AEF”), which represents the simplest measure of the grid’s GHG intensity, was used. GHG emissions factors are shown in Table 8 below.

<td>$503,889</td>
</tr>
</tbody>
</table>

The AL-coupled WWHP system provided a meaningful reduction in annual energy use as compared to the base case (57% reduction) and the conventional ambient loop (40% reduction), as well as significant greenhouse gas (GHG) emissions reductions (92% as compared to base case, 86% as compared to conventional ambient loop); however, under 2019 energy pricing, it was more costly to operate than either the base case (37% higher cost) or conventional AL (26% higher cost) systems. By 2030, the AL-coupled WWHP would...
provide slight costs savings as compared to the base (9% lower cost) and conventional AL (0.3% lower cost) systems.

By contrast, the hybrid WWHP-conventional was cheaper to operate than the base and conventional AL systems under both 2019 and 2030 energy costs. When compared to the base case, it provided 8% cost savings under 2019 pricing and 31% savings under 2030 pricing; when compared to the conventional AL system, it provided 15% cost savings under 2019 pricing and 24% savings under 2030 pricing. However, GHG emissions were significantly (243%) higher than for the pure WWHP system, and energy use slightly (5%) higher.

Of the six systems studied, the two GSHP systems – and particularly the hybrid GSHP-conventional system – performed best on all metrics (energy use, GHG emissions, 2019 energy costs, and 2030 energy costs). The hybrid GSHP system had an annual energy use of 3,218 MWh, only 56% of the energy used by the WWHP system and less than a quarter of the energy used by the development under the base case. Due to the offsetting of natural gas emissions, GHGs were significantly lower than in the base case for all four renewable-based systems (the hybrid and non-hybrid WWHP and GSHP systems). The hybrid GSHP system produced only 96 tonnes of GHGs annually, about 5% of the GHGs produced by the conventional system and 56% of the GHGs produced by the WWHP system.

The natural gas boilers were the largest energy consumer for the base case and conventional AL systems. For the WWHP AL system, heat pump electrical consumption represented the largest share of energy consumed, slightly edging out electrical consumption by the AL pumps. In the hybrid WWHP AL system, the boilers were again the largest energy consumers, representing the relative inefficiency of natural gas boilers. For the two GSHP systems, electrical draw by the heat pumps represented the majority of energy used.

5. Conclusion

The results of this investigation mediate towards the selection of a GSHP-based system for the proposed campus development, as the two GSHP-based systems had the lowest energy usage and GHG emissions of the systems studied, as well as the lowest costs under both 2019 and 2030 energy prices. However, it should be noted that this analysis had numerous limitations. Upfront costs and capital expenditures were not considered, nor were return-on-investment or the larger economic viability of the systems under study. The implementation of WWHP systems requires the cooperation of municipal authorities, who control access to city wastewater, while GSHP systems require large borehole fields which are often difficult to build in urban areas and whose construction can slow the development process.

In addition to the practical and economic concerns involved in the implementation of WWHP and GSHP systems, the current analysis was limited by the software used. HyGCHP is a software intended for simplified analysis of geo-exchange and hybrid geo-exchange systems; a more detailed analysis would use TRNSYS or equivalent software to analyze both the WWHP and GSHP configurations.

While a more complete analysis remains for future work, it is certain that, as carbon pricing in Canada continues to rise, the economic feasibility of heat pump systems such as those studied in this paper will increase and their implementation will become more widespread. By providing preliminary evidence for the viability of GSHP- and WWHP-based systems in a proposed campus development, the present study suggests two plausible alternatives to conventional heating and cooling; this is particularly significant in light of the underutilization of WWHP systems in Canada. Although it is not possible to draw broad generalizations from the results of this paper, the economic and environmental benefits of GSHPs and WWHPs for the institutional/residential development under study suggest that these types of heating and cooling systems may be worth investigating in other large institutional or residential buildings in Canada, particularly when climatic conditions and wastewater availability resemble the present scenario.

Development of a Simulation Tool for Ground Source Heat Pump Systems Using Horizontal Ground Heat Exchangers

Takao Katsura, Motohiro Maeda, Yutaka Shoji, Katsunori Nagano

Abstract

Ground source heat pump (GSHP) systems have been gaining attention in recent years as a one of renewable energy utilization system, but its widespread use in Japan has been delayed due to high installation costs. The introduction of horizontal ground heat exchangers (GHEs) has a possibility to reduce the initial cost, therefore, appropriate system design is required to install the horizontal GHEs. The authors developed a simulation tool for GSHP systems using horizontal GHEs. The developed simulation tool can calculate the ground temperature surrounding the GHE, which is affected by not only the heat extraction/injection via GHEs but also the temperature change at ground surface. In addition, this tool calculates the ground temperature surrounding the GHE by superposing the temperature response, and the temperature response of the spiral coil type GHE is calculated by applying artificial neural network (ANN). In this paper, outlines of calculation method are firstly introduced. Next, the required length of GHE was estimated as a case study using the developed simulation tool.

1. Introduction

In recent years, ground source heat pump (GSHP) systems that utilize underground thermal energy, a renewable energy heat source, have been spreading in many countries as a highly efficient heat source system. However, the total installed capacity in Japan is only 0.2 GW and much smaller than North America, China and European countries [1]. The main reason is the installation costs of ground heat exchangers (GHEs). The vertical type GHE generally used in existing GSHP systems in Japan has a high initial cost of 10,000 ~ 20,000 JPY/meter for installation. On the other hand, horizontal GHEs, which utilize shallow ground several meters deep from the ground surface, requires a large site for installation, but the installation cost is much lower than that of vertical GHE. Therefore, when a large site for GHE burial is available, the adoption of horizontal GHE is expected to expand the introduction of GSHP systems due to the significant reduction in initial costs.

Horizontal GHEs can be classified into (a) Straight pipe type, (b) Spiral coil type, and (c) Comb type, as shown in Photo 1. The spiral coil GHE to be considered in this study is known to have a larger heat exchange rate per heat exchange installation area than the conventional straight pipe type because of the areal heat exchange from the top and bottom of the coil [2]. Therefore, this type of GHE system can reduce the size of the GHE burial site and the initial cost of the GSHP system. On the other hand, appropriate system design is essential for the introduction of this system. Currently, numerical calculation models for the spiral coil GHEs were developed, but it is not suitable as a design tool because of its large computational load. Although Li et al. have derived a theoretical solution to calculate the underground temperature surrounding the spiral coil GHE with a relatively small computational load [3], the computational load becomes large when the average temperature of the pipe surface is calculated.

To address this challenge, the authors have focused on artificial neural networks (ANNs), which have recently attracted attention for their application to regression and classification problems. As an example of the application of ANNs to the calculation of GHE ambient temperature field, Pasquier et al. developed an ANN model to quickly and accurately determine the short-term G-function using a model based on the thermal
resistance and heat capacity [4]. The authors have also developed a regression model that reproduces the numerical results of a moving infinite cylinder problem using ANN, and have shown a fast and accurate method for calculating GHE ambient temperature in groundwater flow fields [5]. Therefore, in this study, we construct a temperature response regression model that reproduces the theoretical analysis results presented by Li et al. [3] based on the high functional representation capability of ANN and its fast computation speed, and develop a fast and accurate simulation model.

Finally, using the developed simulation tool for performance prediction, we will conduct case studies to determine the required scale of GHE.

2. An artificial neural network model for fast computation of temperature response of spiral coil GHE

2.1. Parameter study with theoretical solution

In order to achieve a fast calculation of the average temperature response of the spiral coil GHE, a regression model is constructed by having ANN learn the results of calculating the average temperature response with the theoretical solution. The parameters that determine the shape of the spiral coil are the loop interval \( D \), the ring radius \( r \), and the number of rings \( N \). The input parameters to the ANN are four variables, including these three variables and the dimensionless time (Fourier number) \( F_o = at/r_p^2 \). In addition, a dimensionless average temperature \( \theta = \theta_{\text{rs,mean}} \lambda r_p/q_r \) was given as output for training.

In the parameter study using the theoretical solution [3], several patterns of coil geometries were prepared and the dimensionless average temperature response of the spiral coil GHE surface over 10 years was calculated at one-hour intervals. As shown in Figure 1, total of 27 patterns were studied, three patterns for each variable. The results of the calculated dimensionless temperature response are shown in Figure 2.

![Photo 1. Types of horizontal GHEs](image)

![Fig. 1. Parameters that determine the shape of the spiral coil](image)
2.2. Outlines of machine learning

Figure 3 shows a diagram of the ANN. The model is a feed-forward neural network in which all units are coupled, and a ReLU function is set as the activation function in each hidden layer. In machine learning, there are hyperparameters, such as the number of hidden layers and units in ANN, that must be determined in advance during training. In this study, Bayesian optimization was used as the optimization method for hyperparameters. The hyperparameters and their search ranges are shown in Table 1. The maximum evaluation time for Bayesian optimization was 72 hours, and the maximum number of evaluations was 50. To verify the ANN performance, the dataset was randomly divided into a training dataset, a validation dataset, and a test dataset at a certain ratio of 7:1.5:1.5, respectively. The mean squared error (MSE) value was used for the loss function in the ANN learning process.

Figure 4 shows the flowchart of ANN learning. The ANN is trained on the given hyperparameter settings applying the Bayesian optimization algorithm and using the training dataset. The learned ANN is then validated using the validation dataset.

---

**Table 1** Hyperparameters and their search ranges

<table>
<thead>
<tr>
<th>Parameter</th>
<th>Search range</th>
</tr>
</thead>

</tr>
</tbody>
</table>
This is iterated within the maximum evaluation time and number of times, and the MSE for the test data is calculated for the result that finally minimizes the MSE of the verification result. The performance of the ANN is then determined.

2.3. Result of machine learning

The ANN was trained in the search range of hyperparameters in the previous section. The hyperparameters that resulted in the smallest MSE as a result of Bayesian optimization are shown in Table 2. Figure 5 shows the process of determining hyperparameters by Bayesian optimization. Note that $n_{\text{Hidden}}$, $n_{\text{Unit}}$, LR, epoch, and Weight Decay for each trial are shown in Figure 5 as data labels. From Figure 5, it can be seen that the parameters are updated so that the MSE becomes smaller as the number of training trials progresses.

Within the maximum evaluation time and number of iterations, the number of iterations was 50, and the minimum MSE was obtained at the 29th iteration. Bayesian optimization results show that the MSE for the validation data set is $1.46 \times 10^{-9}$, which is sufficiently small for a regression model. Figure 6 shows a comparison of the temperature response between the obtained ANN regression model and the theoretical solution under the condition of a ring radius of 0.4 m as an example. The MSE was $2.26 \times 10^{-9}$ on average. This indicates that the constructed ANN model shows good regression performance and that the generalization performance of the learned ANN is adequate. Furthermore, a comparison of the time required for 10 years of calculations with $N=100$ rings shows that the ANN model takes about 2 seconds to calculate the temperature response, while the theoretical analysis takes about 20 hours, indicating that the ANN regression model significantly reduces the calculation time. This temperature response was applied to the temperature response calculation of the calculation flow shown in Figure 7, and a simulation tool was created.
Fig. 6. Temperature response between the obtained ANN regression model and the theoretical solution

Fig. 7. A calculation flowchart of simulation tool for GSHP system with spiral coil GHE
3. Case studies to determine the required scale of GHE

3.1. Calculation conditions

Using the simulation tool for the GSHP system with spiral coil GHEs described above, the GHE size required to cover the annual thermal load for a residential house is investigated. Akita and Tokyo were selected as target cities for semi-cold and moderate climate regions, respectively.

Figure 8 shows the assumed residential house. This model is assumed to have a total floor area of 116m² and high insulation performance. The heat loss coefficient per floor area and temperature difference is set as 1.0 W/(m² · K) in Akita and 1.4 W/(m² · K) in Tokyo, considering that it should be less than half that of the energy conservation standard in Japan. Air conditioning was set to operate continuously 24 hours a day, with the heating temperature set at 20°C and the cooling temperature at 26°C. The hourly heating and cooling load were calculated by using AE-CAD/AE-Simheat [6], which is a commercially available thermal load calculation. Figure 9 shows the hourly cooling and heating loads in annual.

The soil and GHE conditions were set as shown in Table 3. The soil effective thermal conductivity was set at 1.0 W/(m · K) and the circulation flow rate was kept constant at 20 L/min. The minimum GHE size (L in Figure 1) required to keep the fluid temperature of GHE outlet within the range of -5~35°C throughout the year was defined as the GHE required size in each city.

![Fig. 8. The subjected residential house](image)

3.2. Result and discussions

The minimum GHE sizes were 51 m in Akita and 60 m in Tokyo, respectively. Also, the variation of heat carrier fluid temperature of GHE outlet are shown in Figure 10 when the minimum GHE sizes were given. It was confirmed that the heat carrier fluid temperature reached the lower limit in Akita and the heat carrier fluid temperature reached the upper limit in Tokyo as a result. Based on this result, if spiral coil GHEs with a length L of 10 m are installed at intervals of 2 m, a site area of approx. 80 m$^2$ (= 2 m intervals $\times$ 4 $\times$ 10 m) would be required in Akita and about 100 m$^2$ (= 2 m intervals $\times$ 5 $\times$ 10 m) in Tokyo. While it is difficult to secure a site area in Tokyo due to the high population density, it is possible to secure a site area in Akita.

4. Summary

In this study, an ANN regression model of the ambient temperature response of the ground heat exchanger was developed using the theoretical solution in order to develop a simulation tool for horizontal spiral coil type ground heat exchangers. Case studies were conducted in each city to determine the required heat exchanger length, and the following findings were obtained.

1) A regression model of the temperature response function was created by training ANN on the results of the theoretical analysis. As a result, a highly accurate regression model with an MSE of $1.46 \times 10^{-9}$ was created for the validation data set. Furthermore, the ANN model required only about 2 seconds of computation time over a 10-year period with 100 number of rings, a significant reduction in the computation load.

2) The required GHEX length in each city was examined. In Akita, the required GHEX length was 51 m for the spiral coil method and 46 m for the horizontal unit method. In Tokyo, the GHEX length for the spiral coil method was 60 m and that for the horizontal unit method was 58 m. In both cities, the GHEX length for the horizontal unit method was shorter than that for the spiral coil method.

Abstract

The current study proposed a novel thermal response test methodology to minimize the testing time, and save labor time and testing cost; it utilizes an oscillatory heat flux called OscRTT. The oscillating heating flux has the shape of a sinusoidal wave with a frequency of $1.74 \times 10^{-3}$ Hz, an average value of 14 kW, and an amplitude of ±6 kW. A new TRT machine is customized to control the heating injection pattern frequency and amplitude. Five OTRTs are conducted at sites with various geological and hydrological conditions with an apparent thermal conductivity range of 1.2 ~ 3.1 W/m.K. The sites are located in Sapporo city, Niseko city in Hokkaido prefecture, Miyoshi city in Hiroshima prefecture, Kai city in Yamanashi prefecture, and Tokyo city in Japan. All sites’ borehole depths and diameters are 300 m and 250 mm. The fluid temperature and soil undisturbed temperature profiles are measured using optical fiber cables inserted inside the U-tube legs. While, A new analysis method is presented to filter, smooth, and fit the recorded data to find the response temperature amplitude at inlet and outlet to the borehole. The borehole and subsurface thermal response are analyzed to find the amplitude ratio, phase shift angle between inlet and outlet temperature responses, and effective thermal conductivity. The accuracy and validity of the proposed method are examined by comparing the output with the results from the conventional TRTs. Five OscTRTs are carried out for 24 hours, while the normal TRTs are conducted for 60 hours. The results show that the OscRTT shortened the time needed for TRT by 60% with high accuracy. Also, a linear relationship between the amplitude ratio and effective thermal conductivity is derived.

1. Introduction

Ground source heat pump systems (GSHPs) for subsurface heat utilization have recently developed due to their energy saving, high efficiency, and no pollutant emission\cite{1}. The local soil's thermal parameters must be first known when designing GSHPs. The thermal conductivity of the ground ($\lambda$) and thermal resistance ($R_b$) of the ground heat exchanger (GHE) are the two most important design parameters for borehole thermal energy storage (BTES) systems\cite{2}. An in-situ thermal response test (TRT) may determine these two parameters, which gives reliable design data. The common TRT includes boreholes, fluid circulation, temperature control devices, and data acquisition instruments. Temperature sensors are installed at the inlet and outlet of the GHE to measure the average temperature of the circulating fluid. Many portable test devices are small in size and easy to operate\cite{3}. The first step of the test is to determine the undisturbed ground temperature. This is usually made by temperature logging in the borehole or by evaluating the fluid temperature of the circulating fluid before the heating/cooling is switched on. The fluid inlet and outlet temperatures are measured by Pt 100 sensors, while a magnetic flow meter measures the fluid flow rate. The flowing fluid is heated using an electrical heater with 5-10 kW. A data logger records all the data for 48 to 72 hours with a time interval of 30 seconds or 60 seconds\cite{4}. Using the basic theory of heat transfer, the relationship between the average temperature of circulating fluid and the temperature of the borehole wall can be expressed as shown in Eq. (1):
\[ q = \frac{T(\tau) - T_b(\tau)}{R_b} \] (1)

Where \( q \) is the heating injected heat per meter, W/m; \( \bar{T} \) is the average fluid temperature, K; \( T_b \) is the temperature of the borehole, K; \( \tau \) is the test time, sec.; \( R_b \) is the borehole thermal resistance (m.K)/W; it includes the convection thermal resistance from the fluid to the inner tube surface (\( R_{\text{conv}} \)), the conduction thermal resistance of the pipe material (\( R_p \)), and the conduction thermal resistance through the grouting material[5]. This equation is conditioned to the minimum test time to affirm the steady state of heat transfer inside the borehole and neglect the unsteady heat transfer period. Therefore, the test time \( \tau > 10\tau_b \) [6] where \( \tau_b \) is calculated according to Eq. (2)

\[ \tau_b = \frac{r_b^2}{a_s} \] (2)

Where \( r_b \) is the borehole radius, m, and \( a_s \) is the grouting material thermal diffusivity, m²/s. Due to the complexity of solving the theoretical basis for the heat transfer analysis outside the borehole, the Boltzmann transformation is used to obtain the mathematical expression of the approximate infinite line source (ILS) model. The average fluid temperature is expressed as indicated in Eq. (3)

\[ \bar{T}(\tau) = \frac{q}{4\pi a_s} \ln(\tau) + q \left[ R_b + \frac{1}{4\pi a_s} \left( \ln \frac{4\pi a_s^2}{\tau_b} - \gamma \right) \right] + T_g \] (3)

where \( T_g \) is the undisturbed soil temperature, K, \( a_s \) is the thermal diffusivity of soil, m²/s; \( \gamma \) is the Euler’s Constant (0.5772 [•]).

Ingerson et al., in 1984, developed the infinite cylindrical source model (ICS) to consider the radial heat transfer through the borehole. While many improved models were developed to describe the heat transfer process more accurately, like the finite line source (FLS) by Zeng et al. in 2002[7], the infinite moving line source model (MILS) [8]and moving finite line source model (MFLS)[9].

Based on the ILS model, the linear regression method takes advantage of the linear relationship between the average inlet and outlet temperature of GHE and the logarithm of test time. Soil thermal conductivity can be obtained according to the fitting curve’s slope. The borehole’s thermal resistance can be obtained according to the identified thermal conductivity, as calculated from Eq. (4) and Eq.(5).

\[ \lambda_s = \frac{q}{4\pi k} \] (4)

\[ R_b = \frac{1}{4\pi a_s} \left[ \bar{T} - T_g \right] - \ln \left( \frac{4\pi a_s^2}{\tau_b} \right) + \gamma \] (5)

Based on the literature, all the TRT tests considered a constant heat injection through the borehole heat exchangers, and the test lasted for four days of continuous operation. To the author’s best knowledge, very few researchers conducted a TRT test with a variable heat injection. Oberdorfer [10] proposed oscillatory injection rates for a short period (OTRT) instead of a constant step; he expected that the new methods could:

- Controle and limit the investigation area by adjusting the oscillatory signal frequency.
- Extract additional information about the borehole and subsurface properties.

The heat injection rate is supposed to be a sinusoidal function with the amplitude \( P_1 \) and the angular frequency \( \omega_0 \). And a constant heat rate \( P_0 \), which is larger than the oscillation amplitude, is added to the sinusoidal signal, as shown in Eq. (6)

\[ P(t) = P_0 + P_1 \sin(\omega_0 t), \quad |P_0| > |P_1| \] (6)

After carefully scanning the literature, we found that the TRT using oscillatory heating is not comprehensively investigated and is not yet matured. Therefore the current study will focus on advancing this method to predict the subsurface thermophysical properties precisely within a short test time and present the mature version of this new method.
2. Field test set-up

2.1. Borehole construction

The experimental investigation is conducted in five cities to experience various geological and thermal conditions in Hokkaido, Hiroshima, Yamanashi, and Tokyo prefectures in Japan, as shown in Fig (1a). At each site, conventional TRT, which applied a constant heating rate for 60 hours, and OTRT with an oscillatory heating rate for 24 hours are conducted. Each test is followed by a recovery period to affirm the full recovery of the subsurface’s thermal condition before the next test. During the drilling, soil samples at various depths are collected and identified accordingly at each site. Fig. (1b) depicts the geological layers associated with depth. The site in Niseko city has volcanic ash at the shallow depth and shale and tuff at the deep layer. Furthermore, the Miyoshi site shows a different profile containing only two layers; conglomerate in the shallow depth, and rhyolite rock occupies the rest of the depth. At last, Kai city is located on almost three layers; gravel, tuff, and sandy clay. The average depth thermal conductivity is 1.4, 1.2, 3.1, 2.1, and 1.6 W/m.K in Sapporo, Niseko, Miyoshi, Kai, and Tokyo cities.

![Field study set-up](image)

Fig. 1 Field study set-up, (a) Experimental sites locations, (b) Geological column in each site

Five boreholes with a depth of 300 m are drilled in 5 cities in Japan. Fluid based recirculatory method using mud rotary drilling with a rapid rotation speed is used in all sites except the Hiroshima site as shown in Fig(2a). A drilling head with a tricone bit with a diameter of 9" 7/8 inches is used to drill a borehole. While, In Hiroshima, downhole drilling with rotation and vibration is used because the geological column consists of only Rhyolit and Conglomerate rocks. Then A U-tube shown in Fig.(2b) is inserted in the borehole. The U-tube is made by the HakaGerodur company located in Switzerland. The U-tube is made of one unit of extruded Polyethylene PE100-RC (resistance to cracking) and polyamide PA12. Buckling pressure resistance is up to 43 bar, Probe lengths 200 to 410 m in rolls, as shown in Fig. (2b). The cross-section and specifications of the tube is shown in Fig.(2c) and listed in Table (1).

A pair of optical fiber sensors are inserted into the U-tube’s legs to measure the vertical temperature. Then the OFS is connected to the DTS instrument (made by Ap sensing in German). The temperatures are recorded every 0.5 m every 1 minute, and these results are used to calculate the heat transfer rate’s vertical profile and the vertical profile of the effective thermal conductivity. The specification of the DTS

2.2. Oscillatory Thermal Response Test Machine

A new TRT machine is customized and is equipped with a variable speed, three-phase, 200 V centrifugal pump with a power of 1.5 kW and a flow rate of 60 L/m (item No. 9). Furthermore; the flow rate is controlled by changing the frequency via an inverter (item No. 11). The machine is also equipped with two single-phase electrical heaters connected in series with a total capacity of 20 kW (items No. 6 and 7). Two three-phase thyristors power regulators control the electric energy supplied to these two heaters (items No. 12, 13). Moreover, a programmable adjusts the heating injection rate using the user interface and software (item No. 14).
An Electromagnetic flow meter is used to measure the fluid flow rate. A liquid tank (60 Litre) is used for liquid backup (item No. 4). These pieces of equipment are fixed inside a mobile carriage with dimensions of 930*1250*1580. Figure 3 illustrates the control panel and a mini data logger (item No. 16). This data logger records the fluid supply and returns temperatures, the ambient air temperature (item No. 2), fluid flow rate, heating power, and accumulated energy consumption. The schematic diagram presented in Fig. (3) explains the circuit diagram of the TRT machine.

2.3. Operation of the TRT test

After finalizing the set-up of the TRT machine, the operation procedure of the conventional TRT is summarized in the following steps:

- The pump is started to circulate the liquid (Ethylene glycol 40% in Sapporo and Niseko, and water in other locations) through the U-tube for 30 minutes to evacuate the air inside the U-tube.
- The flow rate measurement is observed to check the fluctuation until all the air inside the loop is expelled into the atmosphere. Once the flow rate becomes stable, this means the loop is free of any air bubbles and is ready to start heating and collecting the data.
- A constant heat rate of 20 kW(66 W/m) is injected into the BHE for 60 hours during the NTRT. While, The oscillatory heating wave is programmed by the software and transferred to the CHINO controller by means of a USB connection in the following form:
  \[ Q = q_{avg} + A \cdot \sin\left(\frac{2\pi t}{T}\right) \]
  as shown in Fig. (6b). The \( q_{avg} \) is 14 kW, the Amplitude A is ±4 kW, and T is 1 hour.
- Supply and return fluid temperatures, flow rates, power injection, and fluid temperature distribution are instantly measured and recorded every 30 seconds.
- After the NTRT is continually operated for 60 hours and OcTRT is continued for 24 hours, the heating and pumping are stopped,

while the soil temperature profile measurements are continued during the recovery period for two weeks

2.4. Analysis method

As explained earlier, the OscTRT is a superposition of constant heating and oscillatory heating with a certain amplitude and frequency. Therefore, the new analysis method is proposed to decompose these two cycles and calculate the effective thermal conductivity from the constant heating part while calculating the amplitude ratio and phase shift from the oscillatory part.

The new analysis method includes two main steps; data processing and data analysis. The data processing steps are shown in Fig.(4). The steps are:

1. Inlet and outlet temperature measurements are filtered by using a Savitzky-Golay filter. And it is smoothed using a moving average of the elements using a fixed window length of 0.03 that is determined heuristically. The A Savitzky–Golay filter is a digital filter that can be applied to a set of digital data points to smooth the data.
2. Then the minimum and maximum peaks location and values of the filtered inlet and outlet temperatures data are determined and saved.
3. The average values of the maximum and minimum peaks are calculated.
4. The average values are subtracted from the filtered data to extract the oscillatory part.
5. The slope of the average values is calculated, then used to calculate the effective thermal conductivity using Eq.(4)

The steps of data processing are summarized in Fig.(3)
After the data is processed, the next step is data analysis to calculate the amplitude and phase shift angle of both inlet and outlet temperatures. The following procedure is proposed as depicted in Fig.(5):

1- Fitting the oscillatory part of the inlet and outlet temperature to the oscillatory function indicated in Eq.(7,8)

\[ T_{\text{in}}(t) = A_{\text{in},0} \cdot \sin(\omega_0 t + \varphi_{\text{in}}) \]  \tag{7}

\[ T_{\text{out}}(t) = A_{\text{out},0} \cdot \sin(\omega_0 t + \varphi_{\text{out}}) \]  \tag{8}

Where \( A_{\text{in},0} \) and \( A_{\text{out},0} \) are the amplitude of inlet and outlet temperatures (ºC), \( \omega_0 \) is the frequency (Hz), and \( \varphi_{\text{in}} \) and \( \varphi_{\text{out}} \) are the phase shift (sec).

2- Calculate the amplitude ratio between outlet and inlet temperature \( (A_{\text{out},0}/A_{\text{in},0}) \)

3- Calculate the phase shift lag between the outlet and inlet temperatures \( (\varphi_{\text{out}} - \varphi_{\text{in}}) \)

4- Find the relationship between the amplitude ratio \( (A_{\text{out},0}/A_{\text{in},0}) \) and the effective thermal conductivity \( (\lambda_{\text{eff}}) \). These steps are summarized in Fig.(8)
3. Results and discussions

The following subsections indicate the results of the initial soil temperature profiles, the results of both the conventional TRT and OTRT, the fluid temperature profiles, the heat rate distribution profile, the effective thermal conductivity distribution profile, and the relationship between the amplitude ratio and the effective thermal conductivities.

3.1. Undisturbed soil temperature

The OFS measures the undisturbed soil temperature distribution profile before starting the TRT. It shows the natural soil temperature profile without any external disturbance. A comparison between these profiles is depicted in Fig. (6). Moreover, the soil surface temperature is affected by the energy balance on the soil surface at the test time. Generally, each profile also lists the temperature gradient for every 100 m. The Niseko site shows the highest temperature gradient of 10.9 °C/100 m, where the temperature reaches the value of 42 °C at the bottom of the borehole. This result shows a significant potential in this site which can be used for a direct heating system or hot spring applications. Meanwhile, the gradient is the lowest at the Tokyo site, with a value of 1.9 °C/100 m, where the temperature at the bottom of the borehole is 21 °C. Furthermore, the slopes at Sapporo and Kai cities are similar, with values of 3.9 °C and 3.4 °C, respectively.

3.2. Conventional TRT

The inlet and outlet temperatures are recorded using PT100 sensors every two seconds. The flow rate and injected heat are recorded by the electromagnetic and power meters, respectively. The data are manipulated every 1 minute for 60 hours. The average fluid temperature is calculated, and the relation between the average fluid temperature and the logarithmic value of the time is depicted in Fig. (7). The figures indicate that the temperature increased with time, reaching a maximum value of 48 °C in Niseko city as shown in Fig. (7b). The heat transferred from the deep surrounding soil affects the fluid temperatures. The linear relationship through the period from 12~ 60 hours is developed. The slope of the linear relationship is used later to calculate the effective thermal conductivity in each city. The slope is varied from one city to another according to the geological and hydrological conditions in each site, the maximum slope in Niseko city reaches a value of 4.34 °C/hr and a minimum value of 1.79 °C/hr in Miyoshi city.
Fig. 7: The linear relationship between log time and $T_f$. (a) Sapporo, (b) Niseko, (b) Miyoshi, (c) Kai, (d) Tokyo cities
The calculated \( \lambda_{eff} \) are 1.62 W/m.K, 1.38 W/m.K, 2.98 W/m.K, 1.95 W/m.K, and 1.44 W/m.K in Sapporo, Niseko, Miyoshi, Kai, and Tokyo sites, respectively. Compared with the geological column, the error value is maximum in Kai city with a value of 50%, while the minimum value is achieved in Tokyo city. Therefore, these results show a possibility of groundwater flow impact on the measurement results in Kai city and need more investigation to assure this hypothesis.

Two pairs of optical fiber sensors were inserted in each leg of the U-tube to measure the fluid temperature distribution every 0.5 m and record the measurements every minute, as depicted in Fig. (8). The results are reduced by averaging the temperature every 1 hour and 5 meters. Figure 8 depicts the fluid temperature profile every 10 hours. In Niseko city, the temperature at the bottom of the borehole has recorded the highest value of 47 °C. Also, the slope of the profile is almost straight through the depth of 180 m to 300 m, because of the impact of the heat dissipated from the deep geothermal layer in this site. In comparison, Miyoshi shows the lowest temperature at the bottom edge of the borehole, with a temperature of 32 °C.

Using the information of the flow rate and the temperature profile distribution in both DL and UL tubes, the vertical profile of the total heat transfer rate and effective thermal conductivity can be calculated, as shown in Fig. (9). Also, these results are represent the average values of 12 hr~ 60 hr. As a simplification, the depth is divided into 6 layers, but for more insight investigation, these results have to consider the precise calculation of the number of layers. Also, it is clear to define the layer with a potential of groundwater impact and further prediction of groundwater flow speed.
3.3. Oscillatory TRT

The inlet and outlet temperatures are recorded simultaneously with the flow rate measurement every two seconds. The measurements are filtered and smoothed, as shown in Fig.(A1a) in Appendix A. Then, the maximum and minimum peak location and values are determined, as shown in Fig.(A1b). Moreover, the average values of each inlet and outlet temperature, as well as the heating rate, are calculated as depicted in Fig. (A1c). The oscillating part of the signal is isolated by subtracting the average values from the original smoothed data, as indicated by Fig. (A1d). Finally, the slope of the linear relationship between the average value and logarithmic scale of the time is calculated and used to calculate then the effective thermal conductivity, as shown in Fig. (A1e). Figure A1 depicts the steps of the data processing steps for the test conducted in Kai city, while the same steps are applied for all tests in other sites.

These steps are followed by the data analysis steps, as explained in the previous sections. Figure (B1) in Appendix B depicts these steps for the data recorded in Kai city. The oscillatory part, which is extracted and shown in Fig.(A1d), is fitted with the values calculated from Eq.(7). The fminsearch function in Matlab is used to minimize the root mean square errors between the fitted and experimental data by changing the multi-variables (Amplitude A, phase shift ϕ, and cycle time ω₀ in Eq.(7). fminsearch uses the Nelder-Mead simplex algorithm; The algorithm first creates a simplex around the initial guess x₀ by adding 5% of each component of x₀(i) to x₀.

Figures B1a, and b, depict the fitting functions for inlet and outlet temperatures. Figure (8a, and b) depict λ_{eff} calculated from the NTRT and OscTRT in periods of 12~15 hr, 12~30 hr, and 12~60 hr in NTRT, respectively, while the periods are 12~15 hr, 12~20 hr, and 12~24 hr in OscTRT. The NTRT results show instability and differences between the three periods, with a maximum value of 0.54 W/m.K in Miyoshi. While the results of the OscTRT show more stability and robustness with a maximum difference of 0.04 W/m.K in Sapporo city. The NTRT is vulnerable and is affected strongly by the daily variation of the heat energy on the soil surface, while the OscTRT response shows more robustness. As the OscTRT follows the periodic heating pattern with maximum and minimum values of 20 kW and 8 kW with an average value of 14 kW, it absorbs the daily impact on the surface. Also, the same robustness can be noted in the amplitude ratio values in different periods of the OscTRT as shown in Fig. (8c).

These results concluded that the period of 14 hours of an OscTRT is enough to calculate the λ_{eff} with an accuracy of 98 % in three sites (Sapporo, Niseko, and Miyoshi), 87% in one site (Kai city) and 74% in one site (Tokyo city). Hence the OscTRT has a promising potential to save more than 77 % of the time needed for NTRT.
3.4. Comparison between the NTRT and OscTRT

The comparison between the effective conductivity, which is calculated from the OscTRT and the NTRT, is indicated in Fig.(8d). The root means square error (RMSE) between the two results is 0.25 W/m.K with a square error maximum value of 0.27 w/m.K in Tokyo city. Be noted that the OscTRT is conducted for 24 hours compared to NTRT with more than 60 hours. The error values are -0.04,-0.04,+0.01,+0.22 and -0.52 W/m.K for Sapporo, Niseko, Kai, Miyoshi, and Tokyo cities. The error value includes the measurements error and operating errors. In addition, the error is maximum in Kai and Tokyo city, where we expected that the groundwater affects the underground’s thermal response. Therefore, it is noteworthy that the relationship between the amplitude ratio of inlet and outlet temperatures and the effective conductivities which are calculated from the NTRT could be a rational alternative to predict the conductivity with the help of numerical simulations and artificial intelligence applications, as shown in Fig. (9). Although The three sites have distinct geological, hydrological, and thermal conditions, a linear relationship can be derived from Fig.(9).

On the other hand, we believe this method needs a comprehensive investigation to explore and clarify the impact of these parameters on the response and amplitude ratio. These goals are the main objectives of future studies using inclusive computational fluid dynamics simulations.
4. Conclusions

A new thermal response test method is proposed to shorten test time and save test and labor costs, using an oscillating heating signal in the form of a sine wave with a specific amplitude and frequency. In this study there are many conclusions can be derived as follows:

1- A new OTRT is proposed to decrease the TRT time from 60 hours to 14 hours and save test and labor costs by 77 %.
2- The effective conductivity, which the new OTRT calculates, has an RMSE of 0.25 W/m.K compared with the NTRT.
3- The new TRT machine has been built and tested successfully.
4- A new analysis method is developed.
5- A new key parameter (Amp. Ratio between Inlet and Outlet temperatures) is proposed for future investigation
6- A linear relationship is defined between the effective conductivity and amplitude ratio, which shows a good potential to generalize this method in future work.
7- Various geological, hydrological, and thermal conditions are tested.

Although the OscTRT shows promising potential using the experimental measurements in different hydrological, geological, and thermal conditions, this method needs a comprehensive investigation to explore and clarify the impact of these parameters on the response and amplitude ratio. These goals are the main objectives of future studies using inclusive computational fluid dynamics simulations and artificial intelligence.

Abstract

Ejector-driven systems have been shown to be promising for heating applications. Most of the research works have been devoted to cooling purposes, while little attention has been focused on heating applications. An experimental steam ejector heat pump system (EHP) was designed and constructed to assess its applicability to water heating applications. The effect of the primary nozzle exit position (NXP) on the performance of the steam ejector system was investigated for a primary nozzle throat diameter of 1.5 mm and 2.0 mm. The ejector system was run for high-temperature evaporator (HTE) temperatures of 120, 130, and 140 °C and low-temperature evaporator (LTE) temperatures of 10, 15 and 20 °C. The target of this investigation was to attain the highest condensing temperature to be able to use the proposed system for water heating purposes. The ejector heat pump coefficient of performance (EHP COP) was used to determine the system efficiency. Larger LTE temperatures were found to result in higher EHP COPs and condensing temperatures. A maximum EHP COP of 2.02 was attained for a HTE and LTE temperatures 120 °C and 20 °C, respectively, however only resulted in a condensing temperature of 22.88 °C. Higher HTE temperatures were found to result in higher condensing temperatures, but at the cost of EHP COP.

1. Introduction

In the United States an estimated 18% of residential energy consumption is used for domestic hot water (DHW) production [1], however a significant portion of the energy required to power these systems is lost in the delivery process, coming in the form of waste heat. Studies have found the more electrically driven a DHW heater is, the higher the primary energy loss will be in the generation and transmission process, and by increasing the share of DHW heaters powered by natural gas, the primary energy efficiency of the system can increase by as much as 65% [2]. These findings indicate an opportunity to pursue the idea of utilizing thermally driven heat pumps for DHW production. Not only are they able to eliminate the primary energy losses in the transmission process of electrical energy, but also, they are able to integrate the waste heat by recycling it back into the system, therefore, they can deliver more useful energy than they consume. A 2015 study conducted by the Lawrence Livermore National Laboratory estimated waste heat accounted for 60% of the total US energy consumption, with 75% of that waste heat being at a temperature of 230 °C or less [3]. If this excess thermal energy can be recycled back into a heat pump system, the electricity demand of a heat pump can be decreased by as much as 80% [4].

Presently, the thermally driven heat pump sector is dominated by sorption technologies [5]. However, research in this sector is ongoing and still at a relatively low maturity level. More research is needed to develop a deeper and more fundamental understanding of the working mechanisms and system performances. One field that has shown promise and great market potential are thermally driven ejector heat pump (EHP) systems. Research on thermally driven ejector systems have been conducted in the past for refrigeration purposes, these are known as ejector refrigeration systems (ERSs). Ejector driven systems are seen as an attractive option as
they require little maintenance due to their lack of moving parts and do not require high ozone potential refrigerant to operate, thus helping to reduce our carbon footprint. Despite this, research on ERS systems has found that these systems yield lower COPs compared to the vapor compression refrigeration systems which continue to dominate the market [6]. Recently there has been a resurgence in ERS research due to a growing environmental concern, yet EHP systems remain relatively untouched. This lack of interest could be attributed to the historical difficulty in understanding the theoretical efficiency of the ejector cycle [7].

A typical ejector system consists of a HTE, LTE, ejector, pump, throttling valve, and a condenser, as seen in Figure 1a. The primary fluid (PF) is superheated in the HTE, which is then accelerated through a converging-diverging nozzle, reaching supersonic speeds at the nozzle exit position (NXP). This creates a low-pressure which leads to a suction effect of the secondary fluid (SF) within the LTE, thus, entraining water vapor into the suction chamber, which leads to a cooling effect. The two steams mix in the mixing chamber and then experience a normal shock at some point along the constant area section. This leads to a sharp increase in pressure and decrease in the velocity of the fluid flow. The fluid mixture then continues to decelerate as it travels along the diffuser and is eventually ejected into the condenser where the fluids then enter a reservoir and are returned to the LTE and HTE through a throttling valve and pump, respectively. The pressure and velocity profiles are shown in Figure 1b.

![Diagram](image)

Figure 1: (a) Schematic of typical ejector cycle and (b) pressure and velocity profiles of fluid flow along ejector.
Most ejector experimental studies found in literature focus on operating the ejector system under critical conditions, meaning both the primary and secondary fluids being choked at their inlets, due to the fact it will result in the highest COPs, as shown in Figure 2. Despite this, the theoretical results from Spitzenberger et al [8], suggest that for an EHP system a high $COP_{EJT}$ does not necessarily correlate to a high COP for the EHP, rather the ejector should be operated within the subcritical zone, in order to maximize the $P_b$, to achieve the highest condensing temperature possible. The goal of this investigation is focused on the ejector cycle to try and achieve the maximum condensing temperature possible, in order to develop the single-stage gas-fired ejector heat pump water heater first proposed in Spitzenberger et al [8], which aims to produce a domestic hot water (DHW) supply 14.5 °C to a target delivery temperature of 51.7 °C.

2. Experimental

In this section, the experimental setup in addition to the function of each component is discussed in detail. Error propagation in the COP of the EHP is determined based on the uncertainty of each variable.

2.1. Experimental setup description

A schematic and image of the experimental setup is shown in Figure 3. The power inputs into the HTE and LTE were supplied by two electrical resistance immersion heaters, connected to a variable voltage transformer capable of supplying 240 V to the system. These allowed the heat added to the HTE and LTE to be set to a specific value to be able to control the pressure and temperature of the working fluid within each vessel. The condenser was a shell-in-tube heat exchanger, consisting of a stainless-steel shell and copper tubing, designed to have a cooling capacity of 7 kW. The cooling fluid was supplied by a constant temperature thermal bath (Maxi Cool Recirculating chiller-RC150-C0021) set to deliver water at a temperature of 14.5 °C to simulate domestic tap water [7].

The input voltages across the electrical heaters within the HTE and LTE were monitored using the Keithley 2701 digital multimeter which had an accuracy of 4% [9]. Type-T thermocouples with an accuracy of ± 0.5 °C were used to measure the temperature of the PF in the HTE, SF in the LTE, condenser, and the inlet and outlet temperatures of the cooling water across the condenser. Pressure transducers with an accuracy of 0.08% were installed in the HTE, LTE and condenser to monitor their internal pressures. In addition to this, pressure taps were added along the ejector’s axis to measure the static pressure profile along the ejector.
The heating capacities within the HTE, LTE, along with the cooling capacity in the condenser are calculated using:

$$\dot{Q}_{LTE} = I \times V$$
$$\dot{Q}_{LTE} = I \times V$$
$$\dot{Q}_{HTE} = \dot{m}_w c_p (T_{out} - T_{in})$$

where $I$ is the current, $V$ is the voltage, $\dot{m}_w$ is the cooling water mass flow rate, and $T_{out}$ and $T_{in}$ are the cooling water outlet and inlet temperatures, respectively.

Energy losses within the system were estimated by performing an energy balance across the entire system. Comparing the sum of the thermal load from the HTE and LTE to the condenser cooling capacity. The difference between the two was always found to be less than 4% indicating the system was well insulated. The pumping power was assumed to be negligible compared to the input power into the HTE, therefore the heating-cycle COP of the EHP is determined from [7]:

$$\text{COP}_{EHP} = \frac{\dot{Q}_c}{\dot{Q}_{HTE}}$$

Tests were run of HTE temperatures of 120 – 140 °C and LTE temperatures of 10 – 20 °C for primary nozzles with throat diameters of 1.5 and 2 mm. Additional trials were run at LTE temperatures of 25 and 30 °C for the 1.5 mm primary nozzle throat.
2.2. Uncertainty Analysis

To ensure the reliability of the experimental measurements, a few of the trials were repeated three times under the same operating conditions, and the COP values were calculated and compared. The deviation between the similar tests were found to be less than 3%, thus indicating the repeatability and reliability of the experimental setup and measurements. The relative error is estimated by

\[
(\delta_{\text{COP}_{\text{EHPP}}})^2 = \left( \frac{\partial \text{COP}_{\text{EHPP}}}{\partial \bar{Q}_c} \delta_{\bar{Q}_c} \right)^2 + \left( \frac{\partial \text{COP}_{\text{EHPP}}}{\partial \bar{Q}_{\text{HTE}}} \delta_{\bar{Q}_{\text{HTE}}} \right)^2
\]

where

\[
(\delta_{\bar{Q}_c})^2 = \left( \frac{\partial \bar{Q}_c}{\partial \Delta T_w} \delta_{\Delta T_w} \right)^2 + \left( \frac{\partial \bar{Q}_c}{\partial \bar{m}_w} \delta_{\bar{m}_w} \right)^2
\]

and it is found that it is about 6.5%.

3. Results and Discussion

The pressure profiles inside the ejector are presented at various LTE and HTE temperatures to attempt to understand they affect the flow behaviour within the ejector and ultimately the performance of the EHP COP. This section ends with a performance diagram that summarizes the COP and back pressure at various operating conditions.

3.1. Effect of HTE temperature

The temperature of the HTE can be changed by adjusting the input voltage to the heater. The pressure profile along the ejector at various HTE temperatures can be observed in Figure 4. It can be observed that when the HTE temperature was increased from 120 °C to 140 °C, the backpressure rose from 2.8 to 3.4 kPa, corresponding to temperatures of 22.88 °C and 26.12 °C, respectively. It should be noted that the first three pressure transducers from the left to right, read the pressures of the entrained flow from the LTE to be nearly the same. Starting at the P4, the variations in the pressure reading were observed, thus indicating the pressure during the mixing process is not constant. The pressure was then observed to increase then decrease at P5, which is in the constant area section. A pressure drop is then observed at P6 and P7, which is a result of an increase in the velocity of the fluid flow. The normal shock appeared to take place somewhere between P7 and P8, which lead to a sharp increase in the static pressure and decrease in the flow velocity. Beyond that, the pressure continued to increase, as the steam travelled along the divergent diffuser section.

The pressure variation depends on the HTE temperature, which controls the mixing pressure and pressure rise across the normal shock. From Figure 4, it can be observed that an increase in HTE temperature from 120 °C to 130 °C, resulted in a 0.29 kPa increase in the backpressure (P9). When the HTE temperature was further increased to 140 °C, the backpressure reached 3.36 kPa, with is 0.53 kPa higher than a HTE temperature of 120 °C. Based on these results it can be concluded that an increase in the HTE can help to attain larger backpressures and in turn larger condensing temperature, thus increasing the temperature life of the heat pump, however, this also results in lower EHP COPs, as shown in Figure 5. The EHP COP was found to decrease from 2.02 to 1.62, when the HTE temperature dropped from 140 °C to 120 °C, which is ~20% decrease in the EHP COP.
Figure 4: Pressure profile along the ejector at various HTE temperatures for nozzle throat diameter of 1.5 mm.

Figure 5: HTE temperature effect on the EHP COP using a nozzle throat diameter of 1.5 mm

3.2. Effect of LTE temperature

The pressure profile along the ejector at various LTE temperatures can be seen in Figure 6. It can be observed that the pressure rises when the LTE temperature increases. For each of the trials the pressures decreased slightly as the steam travelled along the first three pressure transducers, then at the fourth pressure transducer, the pressure was found to significantly depend on the LTE temperature. As shown in Figure 6, a LTE temperature of 20 °C resulted in the largest backpressure. At lower LTE temperatures, a lower amount of water vapor is entrained into the mixing chamber, and the vapor that is entrained has less momentum.

As shown in Figure 7, the temperature of the LTE has a significant effect on the EHP COP, which was found to increase as the LTE temperature increased. A 140% improvement in the EHP COP was observed when the LTE temperature was increased from 10 °C to 20 °C, 1.28 and 1.80, respectively. More importantly, not only did increasing the LTE temperature increase the EHP COP, it also resulted in increased backpressures or temperature life of the heat pump.
3.3. Effect of nozzle throat diameter

The EHP COP for the two different primary nozzles can be observed in Figure 8. It was found that the nozzle with the smaller throat diameter, 1.5 mm, performed better than that with the 2.0 mm throat diameter. A decrease in the throat diameter, resulted in a decrease in the mass flow rate of the PF travelling through the nozzle. This is also directly related to the heat input to the HTE, which in turn results in a significant increase in the EHP COP. At a nozzle exit position of 0.40, the EHP COP improved from 1.40 to 1.80, a 29% improvement, when the nozzle throat sized was decreased from 2.0 mm to 1.5 mm. A larger backpressure was able to be attained with the 2.0 mm nozzle. This trend shows that a smaller throat size is preferred for larger EHP COPs, while a larger throat diameter is better for larger backpressures. This result emphasizes the importance of optimizing the primary nozzle geometry to find the best compromise between EHP COP and backpressure.
Figure 8: EHP COP and back pressure using two different throat diameters at various NXP's

3.4. Ejector performance

A performance diagram depicting the EHP COP and backpressure at various operating conditions for the 1.5 mm nozzle can be seen in Figure 9. Larger LTE temperatures were found to correspond to larger EHP COPs and backpressures, while larger HTE temperatures resulted in lower EHP COPs and larger backpressures. It is found that to increase the backpressure or temperature lift of an EHP, the EHP COP will need to be sacrificed. The EHP map shown in Figure 9 can be used to select the idea working conditions that provide a compromise between the EHP COP and backpressure, that will best suit the requirements of the EHP system. It should be noted at the values will change with the nozzle size however, the general trend will remain the same.
4. Conclusion

In this work, on a steam-driven ejector heat pump for water heating purposes was built and tested to determine the effects of the operating conditions and design parameters of the EHP COP and backpressure under sub-critical conditions. Nine pressure transducers were installed along the axis of the ejector to observe the effects the operating conditions had on the static pressure profile of the steam as it travels through the ejector. The experimental results indicate larger LTE temperatures are better for larger EHP COPs and backpressures or a larger temperature lift for the EHP, while larger HTE temperatures also lead to higher backpressures, but the EHP COP is compromised. A larger throat diameter resulted in lower EHP COPs and larger backpressures. Therefore, it is important to carefully design a primary nozzle to get the desired trade-off between the EHP COP and backpressure. An ejector performance map is provided to help select the operating conditions for the desired set point for the EHP system. From this investigation it can be concluded that further work needs to be done to further develop a clear understanding of the behaviour of the fluid flow through an ejector, which can then be used to further improve the EHP system.

Abstract

This study searches for refrigerants with low global warming potential (GWP) and zero ozone depletion potential (ODP) for an ejector heat pump water heater (EHPWH). Several criteria are set, and R1336mzz(Z), R601a, R1233zd(E), R1224yd(Z), R1234ze(Z), and R600a are shortlisted. A theoretical model is built to study the performance of EHPWH and the corresponding ejector design at different operating conditions. For the same ejector design, a refrigerant with a high specific heat ratio produces a high entrainment ratio and heating COP. This is because the expansion wave angle in the ejector is small for refrigerants with a high specific heat ratio, allowing more mass flow rate to be entrained. A higher entrainment ratio does not necessarily correlate to a high COP because the saturation curve of the tested refrigerants is not the same. Results show that the heating COP of R601a is the highest, but it is extremely flammable. R1224yd(Z) and R1234ze(Z) are the most candidates for EHPWH when the trade-off between the COP and safety criteria is considered. The results presented in this work could help building an EHPWH using eco-friendly refrigerants.

Introduction

Buildings are responsible for 40% of global energy consumption and 33% of greenhouse gas emissions. Water heating accounts for about 20% of home's energy use. Using energy efficient water heater can reduce the monthly water heating bills. Ensuring new buildings are sustainable and energy-efficient is key to tackling climate change [1]. The Federal Sustainability Plan has been designed and set goals to reduce energy consumption and achieve net-zero emissions buildings by 2045, including a 50% reduction by 2032 [2]. Heat pump is the widely used technology to produce building cooling and heating energy. The proper working fluid selection for heat pump systems is a key parameter to address the Federal Sustainability Plan's ambitious goals by reducing carbon emissions, greenhouse gases, and energy consumption (i.e., achieving a high coefficient of performance (COP)). The suitable working fluids (refrigerants) should be non-toxicity, non-flammable, non-explosive, and eco-friendly with low Global Warming Potential (GWP) and zero Ozone Depletion Potential (ODP) [3], and have desired thermophysical properties, such as high latent heat of vaporization and high thermal conductivity [4].

The working fluids for cooling and heating systems can be classified into Hydrocarbons (HCs), Chlorofluorocarbons (CFCs), Hydrochlorofluorocarbons (HCFCs), Hydrofluorocarbons (HFCs), Hydrofluoroolefins (HFOs), Hydrofluoroethers (HFEs), Fluorocarbons (FCs), and natural refrigerants. CFCs

and HCFCs have high ozone depletion potential (ODP) and were phased out under Montreal Protocol. HFCs with high global warming potential (GWP >150) are being phased out. HCs are A3 flammable refrigerants, and only a few HCs, such as Isobutane (R600a), are approved by US Environmental Protection Agency (EPA) [5]. HFOs are developed as alternative refrigerants with low GWPs to replace HFCs and HCFCs [6]. HFEs are non-flammable fluids with low toxicity, chemically inert, and high-temperature stability. Recently, HFOs and HFEs have been investigated as alternative refrigerants for ejector refrigeration systems [4].

The ejector is a thermal-driven compressor that sucks vapor (secondary fluid) from a vessel at low pressure and lifts to a high pressure using a motive fluid (primary fluid) with higher pressure and temperature. The ejector heat pump for cooling and heating applications consists of an ejector, generator, evaporator, condenser, expansion valve, and pump, as shown in Fig. 1. It has many advantages over the electrically driven heat pump, such as simple construction, no moving parts, high reliability, and low cost, making it attractive for residential systems [7]. The ejector heat pump could be driven by different types of heat sources, such as low-grade waste heat (>70 ℃) and renewable energy [8]. Also, it has good potential to boost primary energy efficiency by avoiding the losses in electric generation and transmissions.

![Fig. 1. Schematic drawing of ejector heat pump.](image)

The coefficient of performance (COP) of the ejector heat pump is a function of the entrainment ratio and the ratio between the latent heat of vaporization of secondary fluid and primary fluid. The entrainment ratio is the ratio between the mass flow rate of secondary fluid and primary fluid. It depends on the ejector design, operating conditions, and thermophysical properties of the working fluid. Aphornratana et al. [9] conducted experimental tests for an R11 ejector using two different mixing chambers to study the effect of secondary flow choking on the ejector performance. The cooling COP of the cycle varied from 0.1 to 0.25. It was found that higher performance is obtained only when the secondary flow is choked. Ma et al. [10] investigated water and used a spindle to control the water vapor in the primary nozzle according to the heat input. The experimental measurements revealed that a short primary nozzle produces maximum cooling energy, while the longer primary nozzle has a higher COP. Dong et al. [11] reported that the steam ejector cooling cycle could produce a COP of 0.66 when the HTET operates between 55 ℃ and 70 ℃. Experimental measurements indicated that the COP decreases when the condenser pressure increases. Shovon et al. [12] tested the performance of a solar refrigeration system’s ejector cooling cycle using several working fluids under various operating conditions. The theoretical results highlighted the significant effect of the ejector area ratio on the cycle’s COP. Specifically, the COP could be doubled using R718 (water), which increased the ejector area ratio from 6.4 to 12.8, which is defined as the ratio between the constant ejector area and the nozzle throat area. However, the highest COP was calculated using R717 (ammonia), while the maximum cooling effect was produced using water as a working fluid. Geng et al. [13] performed experimental measurements and theoretical analysis to study the performance of the nitrogen ejector cooling cycle. Two primary nozzles with throat diameters of 0.155 mm and 0.185 mm were investigated. Test results showed that the back pressure rises when higher inlet temperatures for the evaporator and generator are used.

Previous studies revealed that the performance ejector cycle depends on the operating conditions and
design parameters. Also, the ejector should be designed for a specific working fluid to achieve higher performance. It is found that little attention has been paid to the ejector cycle for heating applications. Hence, there is a lack of identifying a proper eco-friendly working fluid and corresponding ejector design. Therefore, this study screens different working fluids for ejector heat pump for water heating (EHPWH) that uses a working fluid with low GWP and zero ODP, while the cycle operates under positive pressure with a high heating COP. Criteria for working fluid pairs are established, and candidates for EHPWH are shortlisted. A thermodynamic model for EHPWH is built to evaluate its heating COP using the shortlisted working fluids at various operating parameters. The corresponding geometrical specifications of the ejector are presented.

2. Criteria for selecting the working fluid pairs

The criteria for working fluids screening are established based on having low GWP and zero ODP. Table 1 lists the selected working fluids for GHPWH. In the EHPWH, the evaporator operates at the ambient temperature of 19.4 °C as specified for rating air-source heat pump water heaters by the US Department of Energy [33]. It assumed that the evaporator pinch point is 5.0 °C. Therefore, the evaporation temperature is set at 14.4 °C. Based on this temperature, the saturation pressure is estimated to identify which working fluid makes the system operates under a vacuum.

The Mach number at the exit of the primary nozzle affects the back pressure. This Mach number is a function of the working fluid's molecular weight and specific heat ratio. R1234ze(Z), R1234ze(E), and R1234yf have the same molecular weight. So, R1234ze(Z) is selected for investigation because its critical temperature is the highest, allowing the generator of heat pump to work at high temperature and subcritical conditions, and hence achieve higher condenser temperature f for the same ejector design. R290 and R1270 have relatively low critical temperatures (less than 100 °C), making them unsuitable for heat pump water heater that could produce hot water at 50 °C. R717 is usually a suitable refrigerant for chillers, not for heat pumps. Therefore, R601a, R1336mzz(Z), R1233zd(E), R1224yd(Z), R1234ze(Z), and R600a are investigated in this study.

3. Theoretical Model

A one-dimensional model is implemented in this study based on the following assumptions [14,15]:

---

Table 1. Selected refrigerants with low GWP and zero ODP for EHPWH.
1) The working fluids in the ejector are ideal gas with constant thermodynamic properties.
2) The process of the ejector is a steady state.
3) The flow inside the ejector is one-dimensional.
4) Inlet and outlet kinetic energies are neglected.
5) The irreversibility is respected using experimental coefficients, except that isentropic processes are considered.
6) The ejector walls are adiabatic.
7) Mixing primary (pf) and secondary (sf) streams starts at y–y (refer to Fig. 2).
8) Normal shockwave occurs after mixing primary and secondary streams (at section s-s).

![Diagram of the ejector](image)

Fig. 2. (a) A detailed schematic of the used ejector and (b) pressure and Mach number variation along the ejector (adapted from [14,16]).

The primary mass flow rate (coming from the generator) can be expressed as a function of temperature, pressure, and throat area.

\[
m_{pf} = \frac{P_g A_{ch}}{\sqrt{T_g}} \sqrt{\frac{2}{y+1}} \sqrt{\frac{y+1}{\eta_{pn}}} \tag{1}\]

where the primary nozzle isentropic efficiency \(\eta_{pn}\) is taken as 0.85.

\[
\frac{A_1}{A_t} \approx \frac{1}{M_{p1}^2} \left[ \frac{2}{y+1} \left( 1 + \frac{y - 1}{2} M_{p1}^2 \right) \right]^{\frac{y+1}{2(y-1)}} \tag{2}\]

\[
\frac{P_b}{P_{p1}} \approx \left( 1 + \frac{y - 1}{2} M_{p1}^2 \right)^{\frac{y}{2-\gamma}} \tag{3}\]

At y–y location, both streams (p and s) have the same pressure \(P_{py} = P_{sy}\). If it is assumed that the entrained flow is sonic at this location, the pressure ratio can be written as:

\[
\frac{P_e}{P_{sy}} \approx \left( \frac{y+1}{2} \right)^{\frac{y}{y-1}} \tag{4}\]
\[ \frac{P_{py}}{P_{p1}} \approx \left( \frac{1 + \frac{\gamma - 1}{2} M_{p1}^2}{1 + \frac{\gamma - 1}{2} M_{py}^2} \right)^{\frac{\gamma}{2-\gamma}} \]  

(5)

A coefficient \( \phi_p \) is added to the isentropic relation to account for viscous losses at the boundary between both streams. \( (\phi_p = 0.95) \). The area ratio of the expansion wave can be estimated from the following Equation:

\[ \frac{A_{py}}{A_1} = \frac{\phi_p M_{p1}}{M_{py}} \left[ 1 + \frac{\gamma - 1}{2} M_{p1}^2 \right]^{\frac{\gamma+1}{2(\gamma-1)}} \]  

(6)

The secondary (coming from the evaporator) mass flow rate is estimated by,

\[ \dot{m}_{sf} = \frac{P_e A_{sy}}{\sqrt{T_e}} \sqrt{\frac{\gamma}{R}} \left( \frac{2}{\gamma + 1} \right)^{\frac{\gamma+1}{2(\gamma-1)}} \sqrt{\eta_{sn}} \]  

(7)

Here, the isentropic efficiency of flow expansion \( (\eta_{sn}) \) is assumed to be 0.85. The total cross-section area at \( y-y \) is the same as that of the duct that extends to the aftershock region,

\[ A_3 = A_{py} + A_{sy} \quad \text{and} \quad AR = \frac{A_3}{A_t} \]  

(8)

where \( AR \) is the ejector area ratio.

Gas dynamic relations are used to specify the temperatures of streams based on upstream Mach number as,

\[ \frac{T_g}{T_{py}} = 1 + \frac{\gamma - 1}{2} M_{p1}^2 \]  

(9)

\[ \frac{T_e}{T_{sy}} = 1 + \frac{\gamma - 1}{2} M_{sy}^2 \]  

(10)

A section \( m-m \), both streams are assumed to be totally mixed. Thus, a mixing loss coefficient, \( \phi_m \), is introduced in the momentum equation between sections \( m-m \) and \( y-y \) as,

\[ \phi_m \left( \dot{m}_{p} u_{py} + \dot{m}_{s} u_{sy} \right) = \left( \dot{m}_{p} + \dot{m}_{s} \right) u_m \]  

(11)

Besides, the energy equation is written as,

\[ \dot{m}_{pf} \left( h_{py} + \frac{u_{py}^2}{2} \right) + \dot{m}_{sf} \left( h_{sy} + \frac{u_{sy}^2}{2} \right) = \left( \dot{m}_{pf} + \dot{m}_{sf} \right) \left( h_m + \frac{u_m^2}{2} \right) \]  

(12)

The velocities at different sections can be estimated using Mach number as,

\[ u_{py} = M_{py} \sqrt{Y_{pf}R T_{py}} \]  

(13)

\[ u_{sy} = M_{sy} \sqrt{Y_{sf}R_s T_{sy}} \]  

(14)

\[ u_m = M_{m} \sqrt{Y_{mR_mT_m}} \]  

(15)

After the two fluids completely mix, the flow is subjected to a normal shock at section \( s-s \), resulting in an increase in the flow pressure from \( P_m = P_{sy} = P_{py} \) to \( P_3 \). Then, the state ‘3’ is connecting with state ‘c’
(condenser pressure) through a diffusing process.
\[
P_3 \frac{P_m}{M_m^2} = 1 + \frac{2\gamma}{\gamma + 1} (M_m^2 - 1)
\] (16)
\[
M_3^2 = \frac{1 + \gamma - 1}{\gamma M_m^2 - \gamma - 1} \frac{M_m^2}{2}
\] (17)
\[
P_e \frac{P_3}{M_3} = \left(1 + \frac{\gamma - 1}{2} M_3^2\right)^{\frac{\gamma}{\gamma + 1}}
\] (18)

After finding the entrainment ratio, the COP of heat pump can be estimated as given:
\[
COP = 1 + \frac{m_{sf}}{m_{pf}} \times \frac{(h_v|_{T_e} - h_l|_{T_e})}{(h_v|_{T_g} - h_l|_{T_e})} = 1 + ER \times \frac{(h_v|_{T_e} - h_f|_{T_e})}{(h_v|_{T_g} - h_f|_{T_e})}
\] (19)

where \(ER\) is the ejector entrainment ratio, \(h_v\) is the specific enthalpy of saturated vapor, and \(h_f\) is the specific enthalpy of saturated liquid.

4. Model validation

The thermodynamic model is built in Engineering Equation Solver (EES) software. The results obtained from the present model are compared with previous experimental data from the literature. Table 2 presents a comparison between the present results and previous ones under the same operating conditions. It is found that the relative error is always less than 4%, indicating that the model is suitable for investigating the performance of ejector cycle.

Table 2. Comparison between present results and previous experimental data for ejector heat pump.

5. Results and Discussion

This section discusses the effect of the generator pressure and condenser temperature on the ejector area ratio (AR), the entrainment ratio (ER), and COP using the shortlisted working fluids. Discussion is presented about how the thermodynamic properties of the investigated refrigerants affect the ejector behavior and hence the COP of EHPWH.

5.1. Effect of working fluid

For a specific ejector design with an area ratio of 30, the entrainment ratio, mixing Mach number, and corresponding condenser temperature are presented in Fig. 3 for the investigated refrigerants. According to Equation (6), the expansion wave's angle increases when the working fluid's specific heat ratio decreases. This means that the surface area from which the secondary flow is entrained \(A_{sy}\) decreases when the specific heat ratio of the working fluid decreases. This leads to a decrease in the secondary flow mass flow rate and hence a reduction in the ejector entrainment ratio. So, it is found that the entrainment ratio is the highest using R600a because it has the highest specific heat ratio among the investigated refrigerants (see Table 1). The entrainment ratio of the ejector using R600a is about 3.27 at a heating COP of 3.42. However, R600a produces the lowest value of condenser temperature because the Mach number in the mixing section is found to be the lowest one. On the other hand, R1336mzz(Z) produces the highest condenser temperature of about 50 °C, which is more suitable for heating purposes. However, the entrainment ratio is the lowest and equals 0.4. Thus, for the same ejector, the trend of condenser temperature is always opposite to the trend of the entrainment ratio.
Fig. 3. ER and condenser pressure of ejector heat pump using different refrigerants at constant ejector area ratio at $P_g = 25$ bar.

Fig. 4 presents the entrainment ratio, Mach number in the mixing chamber, and ejector area ratio using the investigated working fluids to achieve a condenser temperature of 50 °C. All the investigated working fluids achieve almost similar COP of around 1.22 using different ejector area ratios. R601a achieves the highest entrainment ratio of about 0.51 and the highest heating COP of 1.28 using an ejector with an area ratio of 26.5. This behavior is because the generator temperature is the highest for R601a, which is about 168 °C. The ejector area ratio is the largest when the system uses R1336mzz(Z) due to its largest molecular weight of 164.1 kg/kmol. R600a could produce the required condenser temperature of 50 °C using the smallest ejector design of an area ratio of about 6.0 because R600a has the lowest molecular weight (see Table 1). The entrainment ratio and COP of R1233zd(E), R1224yd(Z), and R1234ze(z) are comparable, but R1224yd(Z) needs a bigger ejector to be able to achieve the desired condenser temperature.

Fig. 4. ER and ejector area ratio of ejector heat pump using different refrigerants at constant condenser pressure at $P_g = 25$ bar.

5.2. Effect of generator pressure

Fig. 5 presents the variation of ER at various generator pressures for the investigated working fluids. It is found that the ER increases as the generator pressure increases to achieve the same condenser temperature. It can be highlighted that the ER mainly depends on the generator temperature when the generator pressure is fixed. The ER of the ejector using R601a is always the highest and changes from 0.22 to 0.56 when the generator pressure changes from 1000 kPa to 3000 kPa, respectively. The highest ER of R601a is owing to the highest generator temperature. In turn, at any generator pressure, the generator temperature is the lowest when R600a is used, leading to the lowest value of ER.
The area ratio does not follow the same trend, as shown in Fig. 6. To achieve the same condenser pressure, the ejector area ratio should be high for working fluid with large molecular weight. Because R1233mzz(Z) has the highest value of the molecular weight, the ejector area ratio is the highest. For the heating COP, its trends do not follow the trends of ER, as presented in Fig. 7. R601a achieves the highest COP due to its highest ER. Interestingly, the heating COP of EHPWH using R1234ze(Z) rapidly increases and approaches the COP of R601a when the generator pressure increases. This behavior is due to the shape of the saturation curve (P-h diagram) of R1234ze(Z), where the latent heat of vaporization significantly decreases as the pressure increases, and hence the heat added in the generator decreases, leading to a remarkable increase in the heating COP. When the generator pressure changes from 1000 kPa to 3000 kPa, the heating COP produced using R601a and R1234ze(Z) increases by 15% and 26%, respectively. It is worth mentioning that the highest ER does not always correspond to the highest COP of EHPWH. The shape of the P-h diagram of refrigerant affects the amount of heat added in the generator and evaporator and hence the COP accordingly.

![Fig. 5. Effect of generator pressure on the ER at a condenser temperature of 50 ℃. (Solid lines indicate operation under vacuum and Dashed lines indicate operation above atmospheric).](image1)

![Fig. 6. Effect of generator pressure on the AR at a condenser temperature of 50 ℃. (Solid lines indicate operation under vacuum and Dashed lines indicate operation above atmospheric).](image2)
Fig. 7 Effect of generator pressure on the COP at a condenser temperature of 50 °C. (Solid lines indicate operation under vacuum and Dashed lines indicate operation above atmospheric).

5.3. Effect of condenser temperature

The variations of ER for the investigated refrigerants at various condenser temperatures are plotted in Fig. 8. It is found that the ER declines exponentially when the condenser temperature increases for the same ejector design of an area ratio of 30. Regardless of the condenser temperature, the ER is always the highest for R601a, followed by R1336mzz(Z). For R601a, the ER declines from 3.7 to 0.5 (more than 7 times reduction) when the condenser temperature changes 25 °C to 50 °C, respectively. This remarkable reduction is observed for all investigated refrigerants. This means that the ejector is very sensitive to condenser pressure, and it should be designed to a specific condenser temperature to be able to achieve higher ER. For Fig. 9, a refrigerant with a larger molecular weight needs a bigger ejector to be able to achieve the desired condenser temperature. Regardless of the variation in ER and AR, the heating COP of EHPWH barely changes when the type of the investigated refrigerant changes, as plotted in Fig. 10. R1234ze(Z) produces the highest COP when the condenser temperature is 25 °C. When the condenser temperature is 25 °C, the heating COP varies between 3.1 and 3.4 when different refrigerants are tested. When the condenser temperature is 40 °C, the heating COP is about 1.22 for the studied refrigerants. Therefore, when the safety class and working around atmospheric pressure or higher, it can be concluded that R1224yd(Z) and R1234ze(Z) are the most suitable candidates for EHPWH to produce hot water at about 50 °C.
6. Conclusion

The present study screens the available working fluids to identify the most suitable environmentally friendly refrigerants for EHPWH. A certain number of refrigerants with low GWP and zero ODP is shortlisted. A mathematical model is built to study the performance of EHPWH using the shortlisted refrigerants at different operating parameters. It is found that refrigerant with large molecular weight always needs a big ejector to achieve desired condenser temperature. It is highlighted that the heating COP is very sensitive to the condenser temperature. Thus, the ejector should be designed for specific operating conditions to be able to achieve high performance. Results indicate that the high ER does not always guarantee the high COP of EHPWH due to the change in the P-h diagram of the tested refrigerants. R601a and R1233zd(E) achieve the highest COP at any condenser temperature, while all the tested refrigerants produce similar heating COP at a condenser temperature of 50 °C. It can be concluded that R1224yd(Z) and R1234ze(Z) are suitable candidates for EHPWH when the trade-off between the COP, toxicity, flammability, and avoiding operating under low vacuum is considered.

Abstract

The purpose of this study was to propose and design the heat pump-driven liquid desiccant ventilation system with an ultrasonic atomization. The energy consumption was also compared with the conventional heat pump-driven liquid desiccant system. Because the proposed system could be operated at low solution flow rate than the reference system, the proposed system was suggested for energy benefits. The results indicated that the two systems showed similar heat pump cycle such as temperature of the evaporator and condenser. However, heat pump size could be reduced in the proposed system because of the low solution loads compared with the reference system. Finally, the proposed system could be operated with 30% reduced energy consumption during the summer season than the reference system.

Keywords: Liquid desiccant; heat pump; ultrasonic atomization; energy performance;

1. Introduction

The liquid desiccant (LD) has been suggested as an energy efficiency technology for air dehumidification because of its thermal characteristics [1, 2]. The LD technology has based on the mass transfer of the air and solution. The driving force is water vapor pressure difference in the LD system, while the conventional dehumidification method using condensation of the water vapor in the air. LD system has energy saving potential and high efficiency compared with the conventional condensation dehumidification because it does not use unnecessary energy to cool the air below the dew point temperature.

The LD technology was based on the heat and mass transfer between the air and solution by the difference of the water vapor pressure. To make the vapor pressure difference, the solution is cooled and heated before the absorber and regenerator intake. The various heat sources to provide the cooling and heating have been investigated. Badami and Portoraro suggested [3] a trigeneration plant which combined LD system and cooling tower for absorber, natural gas combined heat and power cogeneration system for regenerator. Especially, the heat pump was considered as an energy conservative heat source because it provides cooling and heating concurrently. Shin et al. [4] investigated the energy saving potential of the heat pump-driven LD system compared with conventional LD system which used cooling tower and boiler. The results indicated that the proposed LD system could reduce about 33% primary energy consumption per year. Niu et al. [5] performed the capacity matching between the LD and heat pump hybrid air-conditioning system via novel matching indices to system energy stability. Although many heat pump-driven LD systems have been proposed to reduce the energy consumption, some limitations have been observed: the solution cooling and heating loads are kept constant. Thus, the innovative design that can reduce the heat pump size is required to save the heat pump compressor power.

Meanwhile, LD system applied the solution atomization with ultrasound generator have been studied [6,7]. Yang et al. [6] investigated the mass transfer performance of the ultrasonic atomization LD dehumidification system experimentally. They also investigated the regeneration performance of the ultrasonic atomization LD regeneration system [7]. The results indicated that the proposed system could save about 35 – 60% according to the required regeneration rate. Lee and Jeong [8] evaluated the dehumidification and energy performance of the solution atomization-based LD dehumidifier. The solution atomization-based LD dehumidifier could save 17% solution consumption compared with the conventional LD dehumidifier.

In many researches, the solution atomization-based LD system could reduce the solution cooling and heating load because of the low liquid-to-gas ratio (L/G ratio). However, there are few cases where the solution atomization-based LD system and heat pump are combined and applied as a ventilation or air-conditioning system for buildings. Thus, the heat pump-driven LD system with an ultrasonic atomization was designed and evaluated. The heat pump sizing was performed to apply as a ventilation system via detailed simulation and energy saving potential was also investigated.

2. System Overview

2.1. Liquid desiccant unit

Figure 1 shows the liquid desiccant unit according to the solution atomization methods. Figure 1 (a) is the ultrasonic atomization-based LD unit. The solution was atomized as a fine droplet through the ultrasonic generator and nozzle to increase the heat and mass transfer area between the air and solution by increasing the surface area of the solution droplets. The air and solution contacted directly in the absorber and regenerator, and the dehumidification and regeneration occurred.

Figure 1 (b) is the packbed-based LD units. The solution and air contacted by packing materials such as cellulose type paper. The solution was atomized through the general nozzle onto the packing material. The air was passed through the packing material and dehumidified by contacting with the solution. The packing material was composed of a honeycomb structure to ensure the heat and mass transfer area in limited volume.

![Fig. 1. Schematic of the liquid desiccant unit](image)

2.2. Heat pump-driven liquid desiccant ventilation system

The heat pump-driven liquid desiccant ventilation system consisted of absorber, regenerator, heat pump, indirect evaporative cooler, two fans, and two pump as shown in Figure 2. The outdoor air was introduced to the absorber and dehumidified by the absorber. The air after the absorber passed the primary side of the indirect evaporative cooler and precooled. If the evaporative capacity is remained, the air was additionally cooled by a second evaporator.

Meanwhile, the liquid desiccant solution was circulated from absorber to regenerator. To make the water vapor pressure difference between the air and solution, the solution was cooled and heated before spraying the absorber and regenerator. The heat pump was used for solution cooling and heating concurrently.

The indoor latent load was treated by the heat pump-driven liquid desiccant ventilation system, while the parallel system was required to remove the indoor sensible load. The air-conditioning system based on heat pump cycle was selected as a parallel system.
3. Simulation Overview

3.1. Analysis of the liquid desiccant unit

The heat and mass transfer between the air and solution in the counter-flow absorber/regenerator is shown as a one-dimensional problem. Accordingly, the absorber/regenerator model based on the heat and mass conservation relations were expressed using Equations (1) – (5) [9,10]. All the following equations for each differential element are computed numerically using a forward-finite difference algorithm. In the following equations, 101 nodes are segmented along the length of the absorber and regenerator; the unit length (\(\Delta L\)) is \(L/100\). The mass transfer rate was calculated by the number of mass transfer unit (NTU), and the heat transfer rate was also calculated by the NTU and Lewis number (\(Le\)). The Lewis number was assumed to be a 0.92 by the heat and mass diffusivity of the air and solution [10].

\[
\frac{\omega_a^i - \omega_a^{i+1}}{\Delta L} = \frac{NTU}{L} \times (\omega_{a,in} - \omega_{eq,in})
\]

\[
\dot{m}_{a,in} \times (\omega_a^i - \omega_a^{i+1}) + \dot{m}_{s,in} \times x_s^{i,in} \times \left(\frac{1}{x_s^i} - \frac{1}{x_s^{i+1}}\right) = 0
\]  

\[
\dot{m}_{s}^{i+1} \times x_s^{i+1} = \dot{m}_{s}^i \times x_s^i
\]

\[
\frac{h_a^i - h_a^{i+1}}{\Delta L} = \frac{NTU \times Le}{L} \times \left(\frac{h_{a,eq}}{Le} + \left(\frac{h_{atm,eq}}{Le} - h_{atm,0^\circ C}\right) \times (\omega_{a,in} - \omega_{eq,in})\right)
\]

\[
\dot{m}_{a,in} \times (h_a^i - h_a^{i+1}) + \dot{m}_{s,in} \times x_s^{i,in} \times \left(\frac{h_s^{i+1} - h_s^i}{x_s} - \frac{h_s^i}{x_s}\right) = 0
\]

The number of transfer unit (NTU) was estimated by the open literature [11,12] through the mass transfer coefficient, heat and mass transfer area per system unit volume, system volume, and flow rate of the air (Equation (6)). The mass transfer coefficient \((k_m)\) was assumed to be 0.01 kg/m²s, the heat and mass transfer area per system unit volume can be calculated by Equations (7) and (8).

The heat and mass transfer area per system unit volume is difference with the solution atomization and contact methods between the air and solution. The solution was atomized into the absorber and the air and solution contacted directly without the packing materials in the ultrasonic atomized-based LD unit. Thus, the contact area between the air and solution is related to the surface area of the atomized solution with fine droplets, and calculated by solution flow rate and density, droplet size, cross-sectional area of the absorber and regenerator, and relative velocity between the air and solution (Equation (7)). While the solution wetted the packing materials and the air was passing through the packing materials in the packbed-based LD unit. In the packbed-based LD unit, the area was affected by the dimension of the packing material, and converted by channel sizes of the packing material, efficiency of the wetting area, and solution flow rate (Equation (8)).
\[ NTU = \frac{k_m \times S_p \times V}{m_a} \]  

(6)

\[ S_{v, UADS} = \frac{6 \times m_{v, in}}{p_{v, in} \times d_x \times Scross \times U_f a} \]  

(7)

\[ S_{v, packbed} = a \times (1 - 1.203 \left( \frac{u_3^{0.111}}{s \times g} \right) ) \]  

(8)

3.2. Heat pump sizing process

The heat pump was used for solution cooling and heating, thus the heat pump should be design with capacity to provide the sufficient cooling and heating for the LD unit. Because the solution heating load is bigger than the cooling load in the LD unit, the heat pump was designed with heating priority. The Figure 3 shows the sizing process of the heat pump. The first step is determining the temperature of the evaporator and condenser to satisfy the target solution temperature for absorber and regenerator. The second step is drawing the pressure-enthalpy diagram of the heat pump cycle through the determined temperature of the evaporator and condenser. The subcooled and superheated degrees were neglected at condenser and evaporator, respectively. The compressor outlet enthalpy of the refrigerant was assumed by the isentropic efficiency of the compressor, and it is assumed to be 0.75 [13]. The third step is estimating the mass flow rate of the refrigerant to satisfy the solution heating load. Finally, the extra solution cooling or extra evaporating load is determined by comparing the real solution cooling load and ideal evaporator capacity. As presented in Figure 3, if the real solution cooling load is greater than the ideal evaporator capacity, the extra solution cooling is needed. The extra solution cooling load was can be obtained by subtracting ideal evaporator capacity from real solution cooling load. Whereas the real solution cooling load is less than the ideal evaporator capacity, the extra evaporating is required to maintain a stable heat pump cycle. The extra evaporating load can be estimated by subtracting real solution cooling load from the ideal evaporator capacity, and it is used for indoor cooling. The R410A was selected as a refrigerant of the heat pump system.

3.3. Energy simulation

The energy was used for the heat pump-driven liquid desiccant system and indoor parallel system. The LD system consumed the energy in the compressor, fan, and pump. The air-conditioning system with heat pump cycle was selected as an indoor parallel system, and the indoor parallel system consumed the energy in the compressor.

The compressor power for LD system could be calculated by the refrigerant mass flow rate, and enthalpy at the in and out point of the compressor (Equation (9)). The remained indoor parallel system load could be estimated using Equation (10) through the extra evaporating load and indoor sensible load. The energy consumption of the parallel system could be calculated using the system COP by Equation (11). The fan is a variable speed, thus, it was estimated by Equations (12). The pump is a constant speed and the energy consumption was estimated by Equations (13) [14].

\[ P_{comp} = \dot{m}_{R410A} \times (h_{comp, out} - h_{comp, in}) \]  

(9)

\[ \dot{Q}_{parallel, remain} = \dot{Q}_{sen} - \dot{Q}_{extra, evap, load} \]  

(10)

\[ \dot{E}_{parallel} = \frac{\dot{Q}_{parallel, remain}}{COP_{indoor, system}} \]  

(11)

\[ P_{fan} = \frac{V_a \times \Delta P}{\eta_{fan}} \times (0.0013 + 0.147PLR + 0.9506PLR^2 - 0.0998PLR^3) \]  

(12)

\[ P_{pump} = \frac{d \times g \times \dot{V}_a \times h}{1000 \times \eta_{pump}} \]  

(13)
4. Results

4.1. Solution cooling and heating load

The solution cooling and heating load was estimated by the solution temperatures at each state of LD unit. Figure 4 shows the maximum solution cooling and heating load comparison of the ultrasonic atomized-based LD unit (i.e., the proposed system) and the packbed-based LD unit (i.e., the reference system).

The proposed system required low solution load than the reference system because the mass flow rate of the solution is different in each system. The proposed system operated 0.4 L/G ratio in the absorber and 0.6 L/G ratio in the regenerator, while the reference system operated 1.0 L/G ratio in the absorber and regenerator under the design condition. Thus, the proposed system needed 0.61 kW and 1.41 kW for solution cooling and heating, whereas the reference system required 1.54 kW and 2.16 kW for cooling and heating, respectively.
4.2. Heat pump design

The Figure 5 shows the heat pump cycle for solution cooling and heating. To satisfy the target solution temperature for absorber and regenerator (i.e., absorber target solution temperature = 20°C and regenerator target solution temperature = 50°C), the evaporator was designed the lower temperature (i.e., about 17°C) than the absorber target and the regenerator was designed the higher temperature (i.e., about 54°C) than the regenerator target. Because the two systems targeted the same temperature for absorber and regenerator, the evaporator and regenerator temperature were almost the same. On the other hand, each system has different in solution cooling and heating load for same target humidity ratio of the supply air because of the L/G ratio. Thus, the mass flow rate of the refrigerant is different. The heating load is greater than cooling load, the extra evaporator load occurred in all summer season. The detailed heat pump sizing results are indicated in Table 1.

![Fig. 5. Pressure-enthalpy diagram of the designed heat pump.](image)

</tbody>
</table>

4.3. Energy consumption

The energy consumption of each system during the summer season was shown in Figure 6. The compressor for LD unit power was consumed about 377.1 and 570.3 kWh in the proposed and reference system, respectively. The proposed system used 0.0087 kg/s refrigerant and the reference system used 0.0132 kg/s as indicated in Table 1, thus the compressor power could be reduced in the proposed system because of the low mass flow rate of the refrigerant. Also, because the extra evaporating load in the proposed system is bigger than the reference system, the remained indoor parallel system load is lower in the proposed system. Thus, the proposed system consumed about 330.2 kWh and the reference system consumed 412.3 kWh for indoor parallel system. The fan and pump energy could be reduced in the proposed system even considering PLR (part load ratio) because of the low pressure drop and low solution flow rate in LD unit than the reference system. Finally, the proposed system consumed 757.5 kWh and reference system consumed 1079.7 kWh during the summer season, and the proposed system could save about 30% energy consumption.
5. Conclusion

This study proposed a heat pump-driven LD ventilation system with a solution atomization technology. The detailed heat pump sizing was conducted to evaluate the energy benefits of the proposed system compared with the conventional LD ventilation system. The total energy consumption during the summer season was predicted.

The results show that the proposed and the reference system had similar heat pump cycle such as temperature of the evaporator and condenser because the target conditions of the LD unit are same. However, the proposed system could reduce the solution cooling and heating load than the reference system. Thus, the mass flow rate of the refrigerant of the heat pump combined with LD unit is difference and the proposed system required less refrigerant. Finally, the total energy consumption during the summer season could be saved about 30% in the heat pump-driven LD ventilation system with ultrasonic atomized compared with the conventional packbed-based LD ventilation system. In the future work, the system will be manufactured and evaluated experimentally.

Abstract

Heat pump suppliers only propose hydronic concepts for buildings up to 15 kWth, and very few suggest diagrams for large air-source heat pumps (> 50 kWth) in existing multifamily building. This paper analyses the energy and environmental performance of hybrid diagrams adapted to existing and large multifamily buildings via a validated numerical simulation model. The concepts correspond to different fuel-switch scenarios with the possibility of using existing boilers as a back-up. For each concept, sensitivity analysis assesses the impact of different levels of heat demand and heat pump capacity. As a result, over the different scenarios, the seasonal performance of the heat pump varies between 2.8 and 3.3, and the overall performance (heat pump and boiler) between 1.5 and 2.9. Considering the hourly CO₂eq content of the Swiss electricity mix, emissions of hybrid systems are 1.4 to 2.2 times higher than with a monovalent system. However, they remain 2.3 to 3.5 times lower than a gas boiler, which points out their adequacy as a transitional solution to proceed to a fuel-switch before retrofittin the building envelope.

Keywords: air-source heat pump; multifamily building; monovalent and hybrid systems; energy performance and CO₂ savings

Nomenclature

ASHP Air-Source Heat Pump
DHW Domestic hot water
HP Heat pump
MFB Multifamily building
SH Space heating
SPFHP Seasonal performance of the heat pump
SPFglobal Overall seasonal performance of the heat pump and boiler

In Switzerland, buildings account for nearly 50% of the final energy demand (100 TWh/yr) and 24% of the CO₂eq emissions (11.2 Mio. t/yr), representing one of the most important sectors for massive decarbonization [1,2]. About 70% of the building stock is still heated with individual fossil fuel boilers, and around 80% of them were constructed before the 21st century [3]. A specific issue concerns multifamily buildings (MFB), which in urban cantons represent 60-70% of the heated area. In parallel to retrofitting of the envelope, large existing MFBs could drastically reduce CO₂eq emissions by switching massively from fossil to renewable energy sources, in particular via heat pumps (HP).

In dense urban areas, air-source heat pumps (ASHP) often turn out to be the only available option for replacing fossil fuel boilers, since other renewable energy sources are often limited: too long distance to a lake or river, no groundwater or prohibition of its use (water protection), no district heating network due to crowded soil, lack of space for borehole fields, wood boilers prohibited in areas of excessive emissions, or limited solar energy due to roof size. In such a context, outside air often is the only renewable energy source for HP [4].

However, while ASHP systems represent the dominant renewable heating system for single-family houses and new buildings, they are rarely installed in large and existing MFBs. This is mainly explained by: i) lack of well-documented case studies proving the feasibility of such systems; ii) noise emissions, which can become a barrier; iii) HP weight and related structural constraints of the roof; iv) HP integration in the existing distribution system, designed originally for boilers; vii) high investment cost; viii) multiple households with diluted decision power and related problems of governance. Nowadays, those constraints make large ASHP (> 50 kWth) an exception rather than a standard solution, especially in non-retrofitted MFB [5–7].

One of the most significant technical challenges for installing ASHP in existing MFBs is the lack of standardized hydronic concepts adapted to existing MFBs (> 50 kWth), which usually concern power ratings up to about 15 kWth [8]. The reason is an obvious lack of market demand, which has yet to lead to the development of such diagrams. On the other hand, most of the literature on the design and operation of ASHP focuses on new or existing single-family houses (< 450 m2 of heated floor area), with capacities below 30 kWh [9–12], for which HPs are mostly standardized, storage capacity within the building usually isn’t a technical constraint, and optimal control strategies have already been developed.

1.1. Objective

In order to fill this gap, the objective of this paper concerns the development of monovalent and hybrid ASHP concepts (> 50 kWth), adapted to the specific context of existing MFB, without (or with delayed) renovation of the building envelope. The concepts correspond to different fuel-switch scenarios, with and without the possibility of using the existing modulating or non-modulating boiler. They are analyzed via numerical simulation and calibrated on in-situ measurements. For each concept, sensitivity analysis assesses the impact on energy and environmental performance of different levels of heat demand for space heating (SH) and domestic hot water (DHW), as well as HP capacity (under or oversizing).

The results of this study are part of the AirBiVal project [8] and also contribute to the IEA Annex 50 "Heat Pumps in Multi-Family Buildings for Space Heating and DHW" [13].

2. Hydronic concepts

Figure 1 shows the four hydronic concepts used in this study, which have been developed based on an extant literature review, discussions with experts in the field, and long-term in-situ monitoring of two pilot projects with large ASHP:

- **Monovalent heat pump operation**: corresponds to the case where it is possible (technically and financially) to install a HP to cover 100% of the demand. For this variant, it is essential to consider rooftop static, soundproofing, mechanical vibration, electricity capacity, and extra height construction limits. This concept is based on a monovalent pilot project installed in Geneva, for which a detailed monitoring campaign and related energy analysis were conducted [5].

- **Hybrid parallel operation with modulating boiler**: corresponds to the case where an existing or new modulating boiler is used in parallel operation with the HP. The boiler is positioned after the SH tank to protect the HP from high return temperatures. This is especially important when using existing oil boilers with low modulation. This concept is based on recommendations for HP systems with a thermal output of more than 15 kWth, elaborated on current knowledge from industry and research [14].

- **Hybrid parallel operation with a non-modulating boiler**: corresponds to the case where an existing non-modulating boiler is used in parallel operation with the HP. Ideally, the HP and non-modulating boiler should have their own SH tank, connected in series, to protect the HP from high return temperatures. However, in existing MFB space constraints usually lead to the installation of one tank only, in accordance with the proposed diagram. This concept is based on the hybrid pilot project installed in Geneva, for which an energy analysis and monitoring campaign were conducted [5].

- **Hybrid alternative operation with a non-modulating boiler**: corresponds to the case where an existing non-modulating boiler is used in alternative operation with the HP. It allows temporary
operation in hybrid mode, while waiting for a future retrofit of the building envelope. When the boiler is removed, the existing hydronic connections will not require any major modification. The concept is based on the diagrams developed within the RAVEL program [15].

**Figure 1. Hydronic concepts**

### 2.1. Diagrams control description

For each of the four concepts, following regulation and design aspects are considered:

- The HP switches between SH and DHW production to maintain the tanks at their respective setpoint temperatures. In the case of a simultaneous demand, priority is given to DHW.
- The HP is the only heat provider for DHW (no boiler backup), so as to force the HP to cover the DHW demand in summer, when outdoor temperatures are most favorable for performance, as well as to simplify the installations diagram.
- The HP reaches 60 °C for DHW to prevent legionella proliferation. An external, rather than internal, heat exchanger is used for DHW to provide enough heat transfer area between the HP loop and the DHW tank.
- For hybrid concepts, the gas boiler only provides heat for SH, in parallel or alternative operation with the HP. The boiler is switched on if the outside temperature is below the bivalence temperature ($T_{biv}$) and if the HP does not reach the SH setpoint temperatures.
- The operation below the bivalence temperature is as follows (Figure 2, left): a) in the case of a parallel configuration, the HP covers the heat load up to its capacity, and the boiler provides the complement; b) in the case of the alternative configuration, the boiler operates alone. The procedure for identification of the bivalence temperature is given in section 3.3.

Detailed information on functional analysis explaining the switching on/off of the equipment is given in [8].
3. System modeling

In order to evaluate the performance of the proposed concepts and compare them with each other, energy models are set up using TRNSYS [16], with a time step of 1 minute. First, the model is validated based on a monovalent pilot project to ensure that the model can fairly and accurately represent reality. Then, the model is normalized to reference conditions of use, which are also applied to the three-hybrid systems.

3.1. Validation of the monovalent system model

The model validation is based on the in-situ monitoring of a non-retrofitted MFB (4’047 m² of heated floor area), whose original fossil heat supply was replaced by a monovalent ASHP (312 kW_th @ 7°/45°C) for DHW and SH production. Monitored daily SH and DHW production, minimum/maximum outdoor temperature, as well as HP and backup boiler production (during HP failure in spring 2019) are presented in Figure 3, over two years of operation.

The model validation is carried out for one year (July 2019 to June 2020). The HP model uses the performance curves provided by the manufacturer. The tanks volume (SH: 1 m³ and DHW: 2 m³) and control parameters correspond to the ones of pilot project. The measured heat demand (SH and DHW), setpoint temperatures, and heating curves are provided to the simulation in hourly values. Detailed information on the controller settings used in the simulation is given in [8].

Figure 4 compares the simulated and monitored HP production as well as related electricity consumption on a daily basis. The simulated HP production faithfully reproduces the monitored values (with an annual error of 1%). On the other hand, the HP electricity consumption (without auxiliaries) is underestimated by around 20%, due to: i) the difficulty of considering all manual changes made to the real system; ii) the discrepancy between the HP performance of the manufacturer (used for the simulation) and of the monitoring (namely
partial load conditions, as well as defrost cycles outside the standard testing conditions). Despite this, the simulation/measurement correlations remain very satisfactory to serve as a basis for modeling the four proposed hydronic concepts.

Figure 3. Monitored monovalent ASHP system (July 2018–June 2020): Daily SH and DHW production, as well as minimum/maximum outdoor temperature (top); Daily HP and boiler production, over two years of operation (bottom).

Figure 4. Comparison of simulation results with the pilot project measurements (July 2019 to June 2020, daily values). The electricity consumption of the HP does not include the consumption of the auxiliaries.

3.2. Normalization to reference conditions of use

The model is then normalized to reference conditions of use, which consists in the following modifications:
- Reference climate year for Geneva, according to the SIA 2028 standard [17];
- SH demand derived from the energy signature of the monovalent pilot project (in hourly values), but adjusted to the SIA reference climate to reach an annual demand of 101 kWh/m².year. This value corresponds to the median value of the existing "post-war" building stock (1948-1980) [18];
- DHW demand (35 L/day.pers) given by an hourly schedule according to SIA 385/2 standard (SIA 2015) [19], but constant over the year.

The dynamic profile of the reference SH demand is presented in Figure 5, along with two alternatives (high and low demand) which will be used for sensitivity analysis (see section 6).

3.3. Systems sizing

The three hybrid systems models are derived from the monovalent model, which are adapted according to the hydronic concepts defined above in Figure 1. For each of the four systems, we use the above-defined reference condition of use. The components are sized according to the following procedure, for which the results are shown in Table 1.

* HP capacities for 7 °C at the evaporator inlet and 45 °C at the condenser outlet

HP capacity

For DHW, the HP capacity is sized according to the SIA 385/2 [19], assuming a typical demand of 45 L/day.person (as used by engineering companies when the DHW demand is unknown), storage and distribution losses of 30%, as well as 6 daily charging cycles with a duration of 1 hour each. The HP has to ensure the total DHW demand, it must therefore be able to produce at 60°C in the most critical conditions (outside temperature of -7°C for the Swiss plateau).

For SH, the method for sizing the HP capacity is different for monovalent and hybrid systems:

- **Monovalent system:** The HP supplies 100% of the building demand (DHW and SH). Its SH capacity is defined to be able to provide the maximum daily SH demand within 18 hours (the 6 remaining hours being reserved for 6 DHW cycles of 1 hour each), with a distribution temperature of 55°C and an outdoor temperature of -7°C.
- **Hybrid systems:** The HP capacity is sized according to a bivalence temperature, which is determined at the intersection between the energy signature of the building and the heating capacity of the HP manufacturer, with the objective of covering 80% of the SH and DHW demand with the HP (see Figure 2). This method results in a HP capacity of 40 – 60% of the maximum hourly heat demand (189 kW\text{a}), depending on the configuration (parallel or alternative operation).

Once the above sizing procedure has been applied separately for SH and DHW, the higher of the two HP capacity is selected, and adjusted to existing HP models on the market.
**Tank volume**

For DHW, the tank volume is sized according to the SIA 385/2, assuming the same conditions used for HP capacity sizing, explained above.

For SH, the tank is sized in relation with the HP capacity, to ensure that the HP runs for at least 20 minutes each time it is switched on. The aim is to prevent short cycling for ensuring the HP lifespan.

**Boiler capacity**

For the hybrid systems, we assume that an existing gas boiler is reused (installed before the implementation of the HP system), with a total capacity corresponding to the maximum hourly SH demand (189 kWth at -7°C outdoor), subdivided in two capacity levels (95 kWth each).

In the case of the parallel systems, the boiler completes the heat production of the HP below the bivalence point. It is assumed that only the first stage of the boiler is necessary. In the case of the alternative system, the boiler ensures the entire production below the bivalence point, whereby the two stages are therefore necessary.

4. **Performance indicators**

In order to evaluate and compare the performance of the different hydronic concepts, following energy and environmental performance indicators are used.

4.1. **Energy performance**

The annual energy performance of the system is evaluated by the seasonal performance factor (SPF$_{HP}$) according to Equation (1). It is defined as the ratio between annual heat production ($Q_{HP}$) and annual HP electricity consumption ($E_{HP}$).

$$SPF_{HP} = \frac{\sum Q_{HP}}{\sum E_{HP}}$$  \hspace{1cm} (1)

In the case of the hybrid system, the overall system performance is evaluated by Equation (2), where $Q_{boiler}$ is the annual heat production of the boiler and $E_{gas}$ is the related annual gas consumption. The efficiency of the boilers is assumed to be equal to 90% (relative to the higher heating value).

$$SPF_{global} = \frac{\sum (Q_{HP} + Q_{boiler})}{\sum (E_{HP} + E_{gas})}$$  \hspace{1cm} (2)

For all hybrid systems, HP capacity is sized to cover 80% of the annual heat production. In order to check if this objective is respected, the share of the HP production is calculated as follows:

$$HP\ share = \frac{Q_{HP}}{Q_{HP} + Q_{boiler}}$$  \hspace{1cm} (3)

4.2. **Environmental performance**

The emissions related to the HP electricity consumption are calculated using Equation (4), where $E_{HP,h}$ is the hourly electricity consumption of the HP (in kWh$_{elec}$) and $f_{elec,h}$ is the hourly CO$_{2eq}$ content of Swiss electricity, averaged over the years 2016 to 2019 (in gCO$_{2eq}$/kWh$_{elec}$). The latter is taken from Romano et al. [20], which considers domestic generation and imports from neighboring countries. The CO$_{2eq}$ electricity content has an overall average of 99 gCO$_{2eq}$/kWh$_{elec}$, but daily peak values in the winter reaching 300 gCO$_{2eq}$/kWh$_{elec}$.

$$C_{elec} = \sum h E_{HP,h} \cdot f_{elec,h}$$  \hspace{1cm} (4)

The gas boiler emissions ($C_{gas}$) are evaluated by a constant emission factor of 203 gCO$_{2eq}$/kWh$_{th}$ [1].

The total CO$_{2eq}$ emissions of the system (in gCO$_{2eq}$) are evaluated by Equation (5) and are finally related to the total heat demand (gCO$_{2eq}$/kWh$_{th}$) by Equation (6), where $Q_{SH}$ and $Q_{DHW}$ are the annual SH and DHW demand (in kWh$_{th}$), respectively:

$$C_{total} = \sum C_{elec} + C_{gas}$$

$$CO_{2eq}\ demand = \frac{\sum (Q_{SH} + Q_{DHW})}{C_{total}}$$
\[ C_{\text{global}} = C_{\text{elec}} + C_{\text{gas}} \] (5)

\[ C_{\text{th}} = \frac{C_{\text{global}}}{Q_{\text{SH}} + Q_{\text{DHW}}} \] (6)

5. Results for reference systems

The energy balances, performances, and CO\textsubscript{2eq} emissions of the 4 reference systems are shown in Figure 6. Given the boiler backup, in particular during the coldest days, the hybrid systems have a better SPF\textsubscript{HP} (between 3.13 and 3.20) than the monovalent system (2.85). As planned during sizing (with an objective of 80%), the HP share of the hybrids systems amounts to 79\%, except for the parallel non-modulating gas boiler (c), which drops to 71\%. In this case, since the boiler cannot modulate its capacity, it overproduces at each start-up, so the storage tank temperature exceeds its set point. As a result, despite a sufficient capacity, the HP is less solicited than it could be. As a result, the latter system consumes 35\% more gas than the other two hybrid systems.

The CO\textsubscript{2eq} emissions of the hybrid systems are 1.7 to 2 times higher than with the monovalent system. Two-thirds of their emissions are related to gas consumption, even though gas covers only 21\% to 29\% of the total heat demand. Thus, even with a high carbon content of the electricity mix in winter, the use of a HP remains more advantageous in terms of emissions, due to its high efficiency (> 2.8) compared to the boiler efficiency (90 \%). For comparison, a system with only a boiler emits nearly 3 times more CO\textsubscript{2eq} (119 tCO\textsubscript{2eq}/an) than the hybrid systems, and 5 times more than the monovalent system.

6. Sensitivity analysis

As a complement to the four reference cases, the impact of different levels of heat demand (SH and DHW) and HP capacity are assessed by following sensitivity analysis (see Table 2):

- Three levels of SH demand, representative of Geneva's post-war MFB stock (1948-1980) [18]: i) 78 kWh/m\textsuperscript{2}.year (1\textsuperscript{st} decile of MFB stock); ii) 101 kWh/m\textsuperscript{2}.year (median), corresponding to our reference case; and iii) 130 kWh/m\textsuperscript{2}.year (9\textsuperscript{th} decile).
- Three levels of DHW consumption: 25, 35 and 50 L/day.person, which correspond approximately to the minimum, median and 9\textsuperscript{th} decile of a benchmark of DHW demand of nearly one million m\textsuperscript{2} of heated floor area of MFB in Geneva [21].
- For the hybrid systems, three levels of HP capacity for SH: 30\%, 40-60\% and 80\% of the maximum hourly demand, with their respective bivalence temperature. Note that the intermediate case of 40-60\% (reference case) results from the above defined sizing procedure (with the objective to cover 80\% of the annual heat demand).

In each case, the HP capacity as well as the SH and DHW tanks are sized according to the method described in section 3.3. This concerns in particular separate HP sizing for SH and DHW, with selection of the higher of
the two values. In this regard, for hybrid systems, the “low capacity” for SH (30%) turns out to be unfit for the DHW constraint, so that these cases actually resume to the respective reference cases (see Table 2).

**HP capacity corresponding to an existing HP model, meeting the highest HP capacity required for the system.

7. Results of sensitivity analysis

The results of the sensitivity analysis are presented in Figure 7. In total, 26 variants are simulated (4 reference cases + 22 variants). For comparison, the CO₂eq emissions are also estimated for a "100% gas" system, where all boilers heat the same.

In the case of the monovalent system, the SPFₜₚₜ turns out very stable, at 2.85 ± 0.01. For the hybrid cases, it raises to values between 3.06 and 3.31 (due to boiler backup during the coldest days), except for the HP with "High capacity" (B6, C6, D6), for which it drops to around 2.90. For these cases, it turns out that the HP does in fact ensure almost 100% of the heat production, despite a significant reduction of the HP capacity as compared to the monovalent system (208 kWth instead of 274 kWth @7°C/45°C). Such result raises questions regarding the best method for sizing the HP, in particular for monovalent systems, to avoid oversizing and reduce investment costs.
For the hybrid systems (except for the “High capacity” cases, for the reason explained above), the \( \text{SPF}_{\text{global}} \), which considers the gas consumption and related heat production, drops to values between 1.52 and 2.40, with HP shares between 56% and 88%. Furthermore, the higher the overall performance (\( \text{SPF}_{\text{global}} \)) and HP share, the lower the HP performance (\( \text{SPF}_{\text{HP}} \)), due to lesser boiler backup during the colder days.

Emissions of the monovalent systems and hybrid cases with “High capacity” are around 49 gCO\(_{2}\text{eq}/\text{kWh}_{th}\). The hybrid systems reach values between 68 and 127 gCO\(_{2}\text{eq}/\text{kWh}_{th}\) (to be compared with the 247 gCO\(_{2}\text{eq}/\text{kWh}_{th}\) of the “100% gas” system).

At more specific levels:

- For all four system types, the variation of the DHW demand (“Low DHW” and “High DHW”) has no significant impact, as compared to the respective reference case.
- The same is true for cases with “High SH” demand. In parallel systems, the cases with “Low SH” demand (B3 and C3) lead to a minor increase of the HP share, with related decrease of \( \text{SPF}_{\text{HP}} \), increase of \( \text{SPF}_{\text{global}} \) and reduction in CO\(_{2}\text{eq} \) emissions. Latter is due to an “oversized” HP capacity in SH mode (due to sizing done for the DHW mode, see Table 2), which brings about a colder bivalence temperature (2°C) than for the reference case (4.5°C). As a result, the HP operates over a increased period of time, but in more severe conditions for its performance.
- As explained before, hybrid systems with “Low capacity” turn out to be unfit for the DHW constraint, so that these cases actually resume to the respective reference cases. Similarly, for the “High capacity” cases where the HP covers almost 100% of the heat production, de facto operating like the monovalent system.

![Figure 7. Results of the sensitivity analysis. Left axis: CO\(_{2}\text{eq}\) emissions per kWh\(_{th}\) of demand (bars) and HP share production (square points). Right axis: \( \text{SPF}_{\text{HP}} \) and \( \text{SPF}_{\text{global}} \) (triangles and circles points)](image)

8. Limitations and future work

With the hydronic concepts chosen in this study, the HP provides the entire DHW production, even for hybrid systems. At least for the parallel configurations, linking the boiler to the DHW production system would allow to reduce the HP capacity (see Table 2). While latter would most probably be interesting from an economic point of view, the environmental impact needs to be assessed.

Similarly, the proposed systems consist of a unique HP for SH and DHW, due to space availability and economic constraints. However, the installation of separate HPs for each mode (DHW and SH) could have the advantage of: i) adapting the HP capacity to the respective demands; ii) using refrigerants adapted to the temperature level of each operating mode; iii) simplifying the system hydronic and control.
Further work should also include: i) impact of sizing of storage tanks, in relation with actual constraints in existing MFB buildings; ii) sensitivity analysis regarding SH distribution temperature; iii) diverse climate conditions / locations; iv) sensitivity to / future evolution of the electricity mix and the related CO₂ content.

9. Conclusions

This paper aims to develop hybrid concepts with air-source heat pumps adapted to the specific context of existing multifamily buildings, without renovation of the building envelope. The concepts correspond to different fuel-switch scenarios, with and without the possibility of using pre-existing modulating or non-modulating boilers. They are analyzed via numerical simulations, validated on detailed in-situ monitoring. For each concept, a sensitivity analysis assesses the impact of different levels of heat demand and heat pump capacity (under or oversizing in hybrid mode), in terms of energy and environmental performance.

The sensitivity analysis shows that: for optimizing the energy mix and reducing CO₂ emissions, not only the heat pump performance should be considered, but also the overall system performance (heat pump and boiler). Over the different scenarios, the seasonal performance of the heat pump varies between 2.8 and 3.3, while the overall performance (heat pump and boiler) is between 1.5 and 2.9.

Despite reduced HP efficiency and high CO₂ content of the hourly electricity mix in winter, monovalent systems lead to lower emissions than hybrid systems. However, emissions of hybrid systems remain 2.3 to 3.5 times lower than with a fossil boiler, which points out their adequacy as a transitional solution to proceed to a fuel-switch before retrofitting the building envelope (hence avoiding sizing the heat pump to meet the entire demand before the renovation, when only a fraction of the heat pump capacity will be needed in the long term).

Among the hybrid systems, none of the analyzed systems stands out significantly in terms of performance. In addition to performance, the economic aspects also come into play when deciding which system to install. While these were not directly considered, several elements relating to the heat pump sizing were raised. In this regard, monovalent systems require the installation of a heat pump that is 2 to 3 times more powerful than hybrid systems, sized to ensure 80% of the production with the heat pump.

Abstract

Industrial heat pumps are gaining increasing interest as a way to decarbonize the industrial heat system. Waste heat is upgraded to useable temperature levels, leading to lower energy demand, lower energy costs and lower CO₂ emissions. Industry needs heat pumps which can operate at high temperatures (>200°C) and can achieve large temperature lifts. Conventional heat pumps do not have the capability to accomplish these requirements. The thermoacoustic heat pump (TAHP) is a auspicious innovative technology which uses acoustic power to lift heat from a low-temperature source to a high-temperature sink. High temperatures and large temperature lifts can be achieved by making use of Stirling cycle with a gas (helium) as working fluid. This paper presents the design, development, and test of a TAHP driven by a piston compressor which produced steam at 170°C with a high temperature lift. The heat pump has the potential to produce steam at a high temperature of at least 250°C.

1. Introduction

Industrial heat pumps are rising in popularity as a measure to decarbonize the industrial heat system. Heat pumps are highly efficient systems to upgrade low temperature industrial waste heat to useable temperature levels, resulting in lower energy demand, lower energy costs, and lower CO₂ emissions, especially if renewable electricity is used [1]. Heat pump development is aimed at achieving higher output temperatures to match the required high process temperatures in industry. Industry needs heat pumps which can operate up to temperatures of 200°C and can achieve large temperature lifts. Conventional heat pumps currently do not have the capability to accomplish these requirements [2]. The temperature that can be delivered by closed-cycle compression heat pumps under development for example is limited to 150°C due to the lack of appropriate refrigerants and compressors for high temperature applications [2].

Different types of heat pump technologies are conceivable for an industrial application [3]. Conventional compression heat pumps are limited in their operating range by the working medium they employ. In contrast, heat pump technology that is based on a gas cycle can be operated at a variety of temperatures, not limited by either condensation or evaporation temperatures/pressures. These include the reverse Brayton cycle heat pump, Stirling heat pump, and TAHP. The TAHP use a Stirling thermodynamic cycle which has the highest COP of all heat pump cycles. The difference between a conventional Stirling and thermoacoustic systems is that thermoacoustic systems have fewer moving parts. The electrically driven TAHP is an auspicious new technology which can operate over a large range of temperatures, up to high temperatures (> 200°C) and can achieve large temperature lifts (e.g. 100 K) using preferably pressurized Helium as working medium. This enables the development of flexible systems that can be applied for large variety of temperature conditions, based on the same design and same working fluid.

The study presented in this paper is the next step in the development of TAHPs for industrial applications. The first step was a laboratory heat pump setup designed and tested successfully for high temperature applications [4-5]. Secondly, a bench scale TAHP using an acoustic resonator has been developed and tested [6]. The current step in the development is to obtain a more compact and cost-effective heat pump by a TAHP re-design without an acoustic resonator. Another objective is to check the technical feasibility of using a commercial piston compressor as a driver for such a system. The possibility to use a commercially available piston compressors is of crucial importance to pave the path for the upscaling of TAHP to large capacities. Laboratory scale TAHPs use pistons driven by linear motors. However, linear motors are difficult to scale up and are very expensive. Piston compressors are already used in the gas industry and are commercially available at different scales up to MW’s which makes upscaling of TAHPs feasible. The last objective is to study the capability of the TAHP to produce steam at temperatures of 200 °C.

The remaining of this paper is organized as follows: section 2 discusses the working principle of the TAHP. Section 3 presents the design and construction of the TAHP. Section 4 discusses the instrumentation. Section 5 presents the experimental results. In section 6 conclusions are drawn.

2. Thermoacoustic heat pump

An illustration of a compact electrically driven TAHP is shown in Figure 1. TAHP uses acoustic power (W) to pump heat (Q_L) from a low temperature heat exchanger (LHX) and to deliver heat Q_H to a high temperature heat exchanger (HHX). The heat exchangers are linked to an external heat source and heat sink. The heat pump consists of a regenerator (REG) placed between the two heat exchangers which are placed inside a pressure vessel filled with helium gas at high pressure. The regenerator is a porous structure with very small channels where the heat pumping process takes place. An oscillating piston driven by an electrical motor supplies the acoustic power required for the heat pumping process. The acoustic wave generated by the piston forces the helium gas in the regenerator to execute a thermodynamic cycle similar to the Stirling cycle. The acoustic wave performs the compression, displacement, expansion, and the timing necessary for the Stirling cycle. The right phasing between the acoustic pressure and the gas velocity in the regenerator is realized by an acoustic circuit formed by the flow resistance of the regenerator, the acoustic inductance L formed by the annular space around the regenerator and heat exchangers, and an acoustic compliance C (volume of gas). It is worth noting that the functionality of the displacer piston in a conventional Stirling system is replaced by the combination of the inertance (fluidic inertia) and the compliance. This avoids the use of a second piston as mechanical piston displacer [7].

The operation of a TAHP will be explained by using an electric analog of the acoustic network, as shown in Figure 1. The acoustic pressure and velocity are analog to the electrical voltage and current, respectively. The fluidic resistance of the regenerator, the acoustic compliance, and the acoustic inductance are represented by an electric resistance R, electric capacitance C, and electric inductance L, respectively. The function of the network is to create the traveling-wave timing necessary for the Stirling cycle in the regenerator. The ideal phase difference between the acoustic pressure (P) and the acoustic flow (U) in the regenerator is zero (traveling acoustic wave).
An analysis of the simplified lumped-element electrical analog of the heat pump can be used to show how the acoustic flows, powers, and timing are determined by the different parameters and components in the circuit. The acoustic flow entering the regenerator at the hot side $U_H$ is damped by the temperature ratio across the regenerator $\tau = T_L/T_H$. An acoustic flow sink $[(1-\tau) U_H]$ is used to fulfill the condition of damping. $U_H$ is damped because acoustic power is used to pump heat. The parallel branches of the inertance and regenerator have the same voltage

$$\text{(1)}$$

The flows $U_H$ and $U_L$ are determined by the flow to the compliance

$$U_L + U_H = -i\omega C p_L$$

Combining expressions (1) and (2), $U_H$ is given by

$$U_H = \frac{\omega^2 L C}{R} \frac{p_H}{1 + \frac{i\omega L R}{R}}$$

Expression (1) shows that the flow in the inertance is $90^\circ$ out of phase from that in the regenerator. Expression (2) shows that the flows into the regenerator and inertance is controlled by the compliance $C$. Increasing the compliance volume will result in an increase of the flow through the regenerator. Expression (3) shows that if the impedance of the inertance $\omega L$ is much smaller than $R$, then $U_C$ and $p_C$ will be in phase corresponding to the traveling-wave phasing necessary for the Stirling cycle. Expression (3) shows also that the magnitude of acoustic flow is controlled by $R$, $L$, and $C$. In general $R$, $L$, and $C$ are designed to create an impedance in the regenerator which is 15-30 times the traveling wave impedance $\rho_m c/A$ to avoid large losses in the regenerator.

The acoustic power at the hot side of the regenerator in the case $L_o << R$ (pressure in phase with flow) is given by

$$W_H = \frac{1}{2} p_H U_H$$

Where $p_H$ is the magnitude of the acoustic pressure at the hot side. The acoustic power flowing out the cold end of the regenerator is given by

$$W_C = \frac{\tau_C}{\tau_H} W_H$$

An qualitative explanation of the working principle of the thermoacoustic effect is shown in Figure 3. As mentioned in the foregoing the thermoacoustic thermodynamic cycle is similar to Stirling cycle. Error! Reference source not found.a illustrates an acoustic wave traveling through the core of the heat pump. The wave enters at HHX and it is used to pump heat from a heat source to heat sink. As acoustic power is used to
pump heat the wave is damped. Error! Reference source not found.b illustrates the thermoacoustic cycle which consists of four steps. Step 1: Isothermal expansion (1→2), the gas expands isothermally in LHX and heat is absorbed by the gas. Step 2: Heating, the gas moves through the regenerator from LHX to HHX and it is heated at constant volume. Step 3: Isothermal compression (3→4), the gas is compressed isothermally in HHX and heat is rejected to HHX. Step 4: Cooling, the gas moves back through the regenerator from HHX to LHX and it is cooled at constant volume. Error! Reference source not found.c shows the pressure-volume diagram of the cycle which is elliptic due to the overlap between the different steps. The area of the ellipse corresponds to the acoustic power (W) used in the cycle.

![Thermoacoustic cycle diagram](image)

Figure 3 Illustration of the thermoacoustic cycle. (a) Acoustic wave travelling through the core. (b) Illustration of the four steps of the cycle. (c) Pressure-volume diagram.

The performance of the heat pump is characterized by the coefficient of performance (COP) which is the ratio of the heat delivered to the heat sink and the acoustic work used by the heat pump.

$$COP = \frac{Q_H}{W}$$  \hspace{1cm} (6)

The maximal theoretical limit for the COP of a heat pump is the Carnot coefficient of performance which is determined by the temperatures of the heat sink and the heat source and is given by

$$COPC = \frac{T_H}{T_H - T_L}$$  \hspace{1cm} (7)

In practice the COP is always lower than the COPC due to the different losses in the heat pump. It is worth noting that helium is used because of its high power density, thermodynamic performance and safe use. However, it becomes rare and hence expensive. Hydrogen is a better working medium than helium and it will be very abundant in near feature and thus much less expensive. For industrial applications hydrogen could be
the working medium for thermoacoustic systems.

3. Design and construction

As discussed in the foregoing, the aim of the study is to evaluate the feasibility of this compact system, of using a commercial piston compressor as a driver and the capability of the heat pump to produce steam at high temperature (~ 200°C). The starting point for the design is the piston compressor whose operation frequency and stroke will determine the operation conditions for the heat pump. A compressor is selected with a maximal speed of 1200 RPM, a stroke of 230 mm, and the piston diameter is 320 mm. Helium at a mean pressure of 50 bar is used as working fluid. This leads to the operation conditions for TAHP as given in Table 1. The drive ratio is the ratio of the acoustic pressure amplitude at the piston and the mean pressure of the gas.

The compressor is adapted by the supplier to comply with the expected load on the pin of the crosshead considering the thermoacoustic operation conditions [9]. An illustration of the TAHP as coupled to the compressor is shown in Figure 4. The piston compressor consists of a piston driven by an electric motor via a flywheel and a crankshaft. To limit the load on the pin of the cross-head when starting the compressor, a bypass with a starting valve is used in combination with a back volume. The back volume is a volume of gas at the crank-side of the piston which is used to balance the forces on the piston and hence to limit the load on the pin. When starting the compressor, the forces on the cross-head pin are too high and the valve must be open to limit the load on the pin. The bypass connects the back volume of the piston to the compliance to avoid large loading forces on the pin which might damage the driving system. Once the compressor is started, the valve is automatically closed and the measurements can proceed.

A cross-sectional view of the TAHP is shown in Figure 5. The driver system includes a balance piston connected to the crank which is used to minimize the vibrations due to the oscillating motion of the driving piston.
The main parts of the TAHP are the regenerator, heat exchangers, and the acoustic circuit. These parts are discussed shortly in the following. For the sealing, O-rings are used for the nozzles of the heat exchangers and for the connections of the different components of the heat pump. A pressure packing case is placed at the crank side of the piston to limit the helium leakage from the back volume to the housing of the crosshead, which is at atmospheric pressure. The packing is provided with cooling water to remove the heat generated by friction.

**Regenerator**

The regenerator consists of a stack of stainless steel screen with a diameter of 260 mm and length of 48 mm. The hydraulic radius of the regenerator is 43 μm and the volume porosity is 83 %. A picture of the regenerator is shown in Figure 6. This regenerator is designed for an operation frequency of 80 Hz and an operating pressure of 50 bar and is not optimal for the operational conditions summarized in Table 1. It is used as it is available in our laboratory and can be used directly for the test of the compressor as driver and for the production of steam at high temperature. The use of an optimal regenerator will result in higher thermal power and performance.

**Heat exchangers**

The heat exchangers LHX and HHX are finned, circular tube cross-flow heat exchangers as shown in Figure 7. These heat exchangers are made of copper fins and tubes and stainless steel headers. It consists of a single row of tubes with a diameter of 13.5 mm and the spacing between adjacent tubes (pitch) is 30 mm. The spacing between the fins is 0.88 mm and the fin thickness is 0.25 mm. Helium gas oscillates between the fins and a second fluid (water/steam/thermal oil) flows through the tubes. The maximum design temperature for the heat exchangers is 200°C.
Acoustic circuit

The feedback inertance, compliance, and regenerator flow resistance are designed to achieve the traveling-wave phasing in the regenerator and minimize viscous losses. The acoustic pressure and acoustic velocity have to be in phase at the regenerator midpoint (Stirling cycle). The feedback inertance \( L \) is formed by the annular space between the wall of the pressure vessel and the cylindrical holder of the regenerator and heat exchangers. The length of the annular space is 600 mm and the cross section is about 0.04 m\(^2\). The volume of the compliance is 14 litres.

4. Test bench and instrumentation

A thermal bench using thermal oil has different heating and cooling circuits which can be used to simulate heat source and heat sink for the heat pump. The LHX of the TAHP is coupled to a circuit of the thermal bench that supplies heat between 50-150°C by thermal oil. The HHX is coupled to a steam vessel where the steam produced by the TAHP can be condensed. The steam vessel contains a condenser which is cooled by the thermal bench. Pictures of the TAHP coupled to the thermal bench are shown in Figure 8.

Various sensors are placed through the system to measure the operating parameters of the heat pump as indicated in Figure 4 [6]. The oil and water flow into the heat exchangers are measured with flow meters. The temperatures of the oil and water/steam at the inlet and the outlet of the heat exchangers are measured with thermocouples. Several pressure sensors are placed throughout the system to measure the acoustic pressure at different locations in the system. The signals from the thermocouples are read by a PLC-data acquisition system and sent to a computer. The pressure signals (magnitude and phase) are first measured by lock-in amplifiers and then sent to a computer. The signals are recorded and displayed using Control Maestro. The acoustic power generated by the piston could not be measured.

5. Experimental results

The heat pump is designed to operate at 50 bar helium. However, the electrical motor which drives the compressor reaches its maximum torque at about 32 bars. Therefore, measurements are done with the TAHP at reduced pressure of 30 bars. Steam is produced at different temperatures and the measurement data for the steam production at 150 and 170°C are summarized in Table 2.
For the steam production at 170°C, the average temperature of the inlet and outlet temperatures of the oil at the LHX is 94°C and the temperature of the steam in the steam vessel is 170°C. The internal temperatures of the regenerator at the hot side and low temperature side are 194°C and 60°C, respectively. The external lift is 74 K while the internal lift is 134 K. The heat exchangers are performing poorly as the temperature difference across LHX between helium gas and oil is 33°C and across HHX between helium and steam is 26°C. The heat pump generates 4.7 kW of thermal power in the form of steam. This is lower than the design value due to the lower used mean pressure of 30 bar. The thermoacoustic computer code DeltaEC [10] predicts that operating at 50 bar, using an optimal regenerator and better heat exchangers with a temperature difference of 10 K, the heat pump would produce 16 kW of thermal power at 170°C with a COP of about 4 and for an external source temperature of 100°C.

As mentioned in the foregoing at the moment the acoustic power used by the TAHP can’t be measured. An internal energy balance was used to calculate the acoustic power used in the heat pump. This results in an indicative COP of about 3.

6. Conclusions

An electrically driven thermoacoustic heat pump is built and tested and it can be concluded that a piston compressor can be used as acoustic driver for a TAHP. This leads to a compact heat pump without acoustic resonator. Piston compressors are commercially available at different scales up to MW’s. This makes upscaling of thermoacoustic heat pumps feasible. The heat pump produces steam at different temperatures up to 170°C, supplying waste heat of 94°C. Higher temperatures can be achieved but not feasible with the current heat exchangers. The heat pump generates 4.7 kW of thermal power with a COP of about 4, excluding the losses in the compressor and internal heat losses. Large temperature differences are measured across the heat exchangers which indicates a poor heat transfer coefficient.

Simulation calculations using the thermoacoustic computer code DeltaEC [10] predicts that operating at 50 bar and using an optimal regenerator and better heat exchangers with a temperature difference of 10 K, the heat pump would produce 16 kW of thermal power at 170°C with a COP of about 4 for an external source temperature of 100°C.

In the near feature an optimal regenerator and optimized heat exchangers will be implemented to improve the performance of the heat pump and to generate steam at higher temperatures (>200°C). An acoustic power measurement system will be also incorporated enabling the measurement of acoustic power input and performance.

Optimisation of a Novel Dry Air-Ground Source (DAGS) Heat Pump System

Yebiyo, M., Badran B.E., Stignor C. H., Axell, M., Gustafsson O
RISE Research Institutes of Sweden, Drottning Kristinas väg 61, Stockholm

Abstract

Ground temperatures will often fluctuate in response to heat absorption or rejection. It is important to recognize that the ground is not an infinite energy source and that it is appropriate to prevent excessive heat extraction or rejection of the ground. Significant changes in ground temperature are likely to occur if exorbitant heat extraction rates from or rejection to the ground are tolerated for long periods. These variations in the ground temperature can have major adverse effects on the coefficient of performance (COP) of a ground source heat pump (GSHP) system and, thus, the system's overall performance. However, one method of regulating ground temperature imbalance is to reject heat when the ground and ambient temperatures favor this through a dry air cooler (DAC). In order to protect the system, rather than to improve performance, DACs are often fitted to GSHP systems to reject heat in extreme conditions. An empirical transient system simulation model (TRNSYS) was developed in this study and used to analyze the control algorithms to determine the optimal operation and control strategies for the GSHP system's performance. Specifically, the paper explores the impact of using a GSHP device with a DAC. This involves examining (i) the input of energy into the GSHP system, (ii) the annual ground temperature variation and (iii) the COP. The results show that considerable savings can be achieved with optimum operation and control strategies for a GSHP system.

Keywords: Ground Source Heat Pump, ground temperature variation, control optimisation, TRNSYS

1.0 Introduction.

GSHP systems can provide an efficient and economical alternative to gas, electric, or oil methods for heating and cooling buildings. The GSHP industry has matured from a technology standpoint yet continues to be dynamic with rapid growth rates. Péan et al. (2019) presented a concise review of the past, present, and future research highlighting some of the achievements and advantages of the GSHP system. Sarbu and Sebarchievici (2014) provided a detailed review of the GSHP systems, including their operation, energy, economic and environmental performances and recent advances.

In order to absorb or reject heat from the surrounding soil, GSHP systems have heat exchangers buried in the ground (ground loop). The rate at which heat is absorbed from the ground must not allow the temperature of the ground to fall too low during the winter, and during the summer, the heat absorbed in the winter must somehow be replenished. Otherwise, this will result in soil thermal imbalance (the mismatch between heat extraction and ground rejection) that can degrade the efficiency of the GSHP device.
Researchers are looking at hybrid GSHP systems to help solve the soil thermal imbalance problem. A hybrid GSHP system uses several different geothermal sources, outdoor air and geothermal sources, to balance the annual thermal load.

Three buildings (two cooling-dominated and one heating-dominated) using hybrid GSHP systems for a year were tracked and analysed by Hackel and Pertzborn (2011). In TRNSYS tool, models of hybrid GSHP systems were constructed; a closed-circuit cooling tower (CCCT, also referred to as a fluid cooler) was used as an additional device to meet a portion of the peak heating or cooling load. Their work has demonstrated that cost-effective and environmentally friendly hybrid GSHP systems are available.

Alavy et al. (2013) developed a rigorous mathematical and computational approach for sizing hybrid GSHP systems. They tested their methodology on ten cases, from residential to commercial and industrial buildings, and concluded that the method could result in significant reductions in initial costs of installation, payback period, and operation costs when compared to non-hybrid GSHP systems.

Lee et al. (2014) conducted an experimental study to compare the transient performance characteristics between a GSHP and a hybrid GSHP, accounting for the degradation of the ground thermal condition during long-term operation. They found that the hybrid GSHP lessened the deterioration of the ground thermal condition and increased the system performance during long-term operation. For the hybrid GSHP, supplementary heat rejecters or extractors were incorporated into the GSHP to control some portion of the heat rejection or extraction rate of the ground heat exchanger (GHE) to reduce the cooling or heating load imposed on the GHE.

Lee et al. (2015) proposed a hybrid GSHP system to solve the performance degradation of the GSHP systems under imbalanced load conditions. They designed a hybrid GSHP system composed of three flow loops: a refrigerant flow loop, a ground flow loop, and a supplemental flow loop. In their study, the transient performance characteristics of the hybrid GSHP were measured and analysed in the cooling mode at various flow loop configurations, including the hybrid GSHP systems with serial and parallel configurations. Their research showed that during the hybrid operation, the hybrid GSHP system with serial configuration showed a relatively higher coefficient of performance (COP) than the hybrid GSHP with parallel configuration due to the lower heat accumulation in the ground under the degraded ground thermal condition. In addition, they concluded that under the steady state condition, the COPs in the hybrid GSHP systems with serial and parallel configurations were 15% and 7% higher, respectively, than that in the standard GSHP system.

Beckers, Aguirre and Tester (2018) studied various hybrid and non-hybrid GSHP and air source heat pump (ASHP) configurations using TRNSYS, calibrated with data measured at the cellular tower shelter in Varna, New York, United States (Varna Site). To limit the impact of thermal imbalance, the hybrid GSHP with an air economiser (free cooling) directly blows cold ambient air into the shelter, and the hybrid GSHP with a dry fluid cooler uses cold ambient air to cool down the borehole heat exchanger heat transfer fluid. Their simulations indicated that hybrid GSHP systems allow the owner to save up to 30 per cent of lifetime electricity consumption compared to hybrid ASHP systems for cooling cellular tower shelters for the weather and operating conditions of the Varna Site. They found that a hybrid GSHP system with an air economiser works better if the aim is to minimise energy consumption and CO2 emissions. Omitting an air economiser, the next best alternative is a hybrid GSHP with a dry fluid cooler, followed by a GSHP-only scheme. They also found that increasing the total depth of the borehole heat exchanger would further minimise energy consumption while increasing the total cost of ownership marginally.

Liu et al. (2019) proposed a hybrid GSHP system with an auxiliary cooling tower to relieve soil thermal accumulation and performance degradation over a long-time operation in the cooling-dominated area in Shanghai. To study the proposed system’s performance and feasibility, the hybrid GSHP system simulation model was constructed in TRNSYS, and measurement data validated the reliability of the simulation. They concluded that the hybrid GSHP system remained stable in terms of the temperature variation of the soil, and the outlet temperature of the buried pipes were lower compared to standard GSHP systems over a ten-year operation.

Hou and Taherian (2019) designed and assembled a hybrid GSHP system in TRNSYS to examine the overall effectiveness of various pipe lengths. In their design, the hybrid GSHP was presented as a horizontal ground loop in parallel with a liquid dry cooler. They run simulations for a full calendar year to generate important analytical data such as annual energy consumption and heat...
rate. After analysing the results of various pipe lengths and diverter setpoint temperatures, the optimal values were recommended by them.

Hou et al. (2020) simulated and tested the effectiveness of a newly-developed temperature-controlled diverter for a hybrid GSHP system which combined a horizontal ground loop and a liquid dry cooler. Their main target was to examine the double-set temperature diverter’s overall effectiveness by switching the control strategies. Both short-term and long-term simulations were carried out in TRNSYS to analyse energy variation and soil thermal condition with respect to different diverter heating and cooling set temperatures. The short-term simulation results showed that the system’s overall performance was mainly influenced by the diverter’s heating set temperatures rather than cooling. Also, the usage ratio of the liquid dry cooler was decreasing while the diverter’s heating set temperature was increasing. Combining long-term COP values and soil thermal variation, they recommended that diverter heating set temperatures ranging from 8 °C to 10 °C could provide the system with a favourable COP value and less soil temperature impact in climate zones. They also found that the loss in soil temperature over ten years of operation was shown to be lessened by employing the liquid dry cooler enhanced with the dual setpoint diverter.

In order to protect the system, rather than to boost performance, DACs are often fitted to GSHP systems to reject heat in extreme conditions. Opportunities exist to use a DAC to improve the GSHP’s performance. These control systems are not, however, documented in any literature. This paper presents the development of a new TRNSYS model to investigate the effects of using DAC by selectively rejecting heat through DAC to reduce the degree of ground temperature saturation and thermal imbalance. The overview of the GSHP system and its operation, the setup of the simulation, the GSHP system and the various components used to create an empirical model of GSHP TRNSYS are further presented in this paper.

This paper explicitly explores the impact of using a DAC in combination with a GSHP device. This involves investigating (i) the rejection of heat, (ii) the input of energy to the GSHP system, fan and circulation pumps, (iii) COP and (iv) the variation in ground temperature. Additionally, the TRNSYS model was used to examine a number of control algorithms to identify optimal operation and control strategies for the GSHP system to improve system efficiency.

2.0 Description of the New System and Its Operation.

The proposed system uses the London South Bank University (LSBU) GSHP installation at one of the buildings called (K2) but operates differently from the initial setup. Four HP Reversible EKW130 units (WaterFurnace, Inc) are used by LSBU’s K2 building GSHP device. Each has a nominal heating capacity of 120 kW and a cooling capacity of 125 kW. Via a closed device, heat is transported to and from the ground using 159 vertical energy piles that are embedded in the structure’s base and drilled into the London clay. The system's source side consists of energy piles and header pipes to which the HPs supply or extract heat through a pumped heat transfer fluid, exchanging energy between the building and the ground. The GSHP system provides the building's heat and cooling output entirely.

The original system used a DAC designed to work when the heat sink temperature was too high or too low. Therefore, the DAC was used to prevent the heat pump from working outside its protected envelope as a safety system. The DAC was tactically used in the proposed system to increase the efficiency and performance of the heat pump and, thus, the system. Figure 1 below illustrates the simulated system. This shows that to accomplish the best COP, the system is managed to provide heat rejection via the DAC rather than the ground loop. This is based on a theory that the Carnot COP of a heat pump is substantially affected with a 1 K decrease of temperature difference, resulting in a 3 % increase in COP. Therefore, when it provides more favorable heat sink temperatures (and thus a higher COP) compared to those produced by the field, the DAC can be used selectively. The proposed system has the potential to save energy but should not require additional components compared to the existing system, although it is controlled differently. The performance improvement of the proposed system is discussed in the following sections.
3.0 The Simulation Setup.

In order to simulate the experimental observations, a model was built with the simulation software TRNSYS 17, (2010). This allows the construction of a GSHP system simulator that closely resembles and simulates the actual HP installation. The main components of the GSHP system that were used to build the simulation model are the ground heat exchanger (Type 557a), the HP model (Type 668), the circulating pumps (Type 682) as flow stream loads, DAC (Type 511), tempering valve (Type 11), and tee piece (Type 511). The following sections describe how the various system components work, which are replicated by interconnecting a set of models.

3.1 Ground Heat Exchanger (Type 557a).

The ground heat exchanger component (Type 557a) was set up with the appropriate geometrical configuration and relevant ground thermal properties, some of which were derived from the thermal response testing carried out in the GSHP design stage. Type 557a models a set of equal vertical U-tube heat exchangers which thermally interact with the ground. This ground heat exchanger model is most used in GSHP applications. Depending on the temperature of the heat carrier fluid and the ground, a heat carrier fluid is pumped through the ground heat exchanger and either rejects heat or absorbs heat from the ground. In the current work, 159 energy piles are used to exploit the ground’s heating and cooling capacity.

3.2 Heat Pump Model (Type 688).

The HP model (Type 668) relies upon catalogue data readily available from HP manufacturers for the performance measurement related to the HP that is being simulated. At the heart of the component are two data files: a file containing cooling performance data and a file containing heating performance data. Both data files provide capacity and power draw of the HP (whether in heating or cooling mode) as functions of entering source fluid temperature and entering load fluid temperature; these establish the performance envelope of the HP over a range of ground source side temperatures and a range of load side temperatures.
The Type 668 HP is equipped with two control signals, one for heating and cooling. If the heating and cooling control signals are both ON, the model will ignore the cooling control signal and will operate in heating mode. However, the heating mode takes precedence over the cooling mode. The data used to build this HP model were obtained from the manufacturer WaterFurnace.

The HP’s COP in heating is given by equation 1.

\[
\text{COP}_{hp} = \frac{Q_{HP}}{W_{HP}} \quad (1)
\]

The amount of energy absorbed from the source fluid stream in heating is given by equation 2.

\[
Q_{absorbed} = \text{Cap}_{heating} - P_{heating} \quad (2)
\]

The outlet temperatures of the two liquid streams can then be calculated using equations 3 and 4.

\[
T_{\text{Source}, \text{out}} = T_{\text{Source}, \text{in}} - \frac{Q_{absorbed}}{m_{\text{Source}}c_{p_{\text{Source}}}} \quad (3)
\]

\[
T_{\text{Load}, \text{out}} = T_{\text{Load}, \text{in}} - \frac{Q_{absorbed}}{m_{\text{Load}}c_{p_{\text{Load}}}} \quad (4)
\]

The HP’s COP in cooling mode is given by equation 5.

\[
\text{COP}_{R} = \frac{Q_{HP}}{W_{HP}} \quad (5)
\]

The amount of energy rejected by the source fluid stream in cooling mode is given by equation 6

\[
Q_{absorbed} = \text{Cap}_{cooling} + P_{cooling} \quad (6)
\]

The outlet temperatures of the two liquid streams can then be calculated using equations 7 and 8.

\[
T_{\text{Source}, \text{out}} = T_{\text{Source}, \text{in}} + \frac{Q_{rejected}}{m_{\text{Source}}c_{p_{\text{Source}}}} \quad (7)
\]

\[
T_{\text{Load}, \text{out}} = T_{\text{Load}, \text{in}} + \frac{Q_{rejected}}{m_{\text{Load}}c_{p_{\text{Load}}}} \quad (8)
\]

### 3.3 Circulation Pumps (Type 741).

There are two pumps for circulation. The Type 741 pump model may produce any mass flow rate between zero and its rated flow rate; in reality, each pump represents a group of pumps. Similar to the majority of pumps and fans in TRNSYS, Type 741 accepts the mass flow rate as input but only uses it to check the mass balance. Based on its rated flow rate parameter and the current value of its control signal input, Type 741 determines the downstream flow rate. The pressure rise, overall pump efficiency, motor efficiency, and fluid properties are used to compute the pump's power draw.

### 3.4 DAC (Type 511).

A dry air cooler, represented by Type 511, cools a liquid stream by blowing air across the coils holding the liquid. This model assumes that the device can be modelled as a single-pass, cross-flow heat exchanger.

### 3.5 Tempering valve (Type 11b).

Thermal systems frequently require the use of pipe or duct "tee-pieces," mixers, and diverters that are controlled externally. This valve enables the system to be managed according to the fluid's temperature, leaving the heat pump.

### 3.6 Tee piece (Type 511h).

The empirical GSHP system model used to examine various control techniques is schematically depicted in Figure 2. In this application of the Type 511h model, modes 1 and 6 are used to model how a tee-piece would work to thoroughly mix two intake streams of the same fluid at various temperatures and/or relative humidity. Table 1 provides a list of the assumptions used to simulate the TRNSYS system model.

4.0 Model Validation.

The empirical TRNSYS model created was validated using experimental data from the real GSHP system installation at LSBU. The many physical elements of the system have been kept as close to reality as feasible, and numerous experiments have been carried out to validate the model. A comparison of the independently calculated COP values with those anticipated by the model shows a reasonable level of agreement. The maximum variance shown in Figure 3 is approximately 7%.
5.0 Development of Novel Control Strategies Using DAC.

The development of novel control strategies using a DAC is given in this section. When the fluid temperature leaving the HP is higher than a specific threshold, as shown in Table 2, the control methods investigated in this work enable the DAC to activate the various control strategies known as scenarios CS1, CS2, CS3, CS4 and CS5. These conditions have been put to the test and measured against the system’s typical operating state in order to explore the impact of operating the DAC at various temperature setpoints. Examining the annual change in ground temperature, the energy input into the GSHP system, and the output coefficient are all necessary for this (COP). The outcomes of the simulated scenarios are thoroughly explained in Sections 5.1 to 5.4.

Controls that have been properly installed and configured are essential for upholding the necessary performance and safety standards while utilizing minimal energy. It is possible to regulate the GSHP system’s performance by utilizing a DAC to selectively reject heat to the air. The estimated seasonal or daily ground temperature and the anticipated/available energy demand of the building can be used to manage this. Building energy use and carbon emissions could be reduced if the control system is well-designed, implemented, and uses design temperatures that maximize the system’s coefficient of performance (COP).
Table 2: Different control strategy approaches using DAC

**Control Strategy 1 (CS1)**
The DAC is controlled based on the fluid flow temperature exiting the HP. When the DAC is on, then the fluid is cooled down using the DAC; otherwise, the fluid bypasses the DAC and enters the ground.

**Control Strategy 2 (CS2)**
The DAC is controlled based on fluid return temperature leaving the ground. When the DAC is on, then the fluid is cooled down using the DAC; otherwise, the fluid bypasses the DAC and enters the ground.

**Control Strategy 3 (CS3)**
This is a free cooling option; the DAC is controlled based on the difference between fluid return temperature, leaving the ground and outside air temperature. When the DAC is on, then the fluid is cooled down using the DAC; otherwise, the fluid bypasses the DAC and enters the ground. The fluid returning from the ground bypasses the HP and enters the building.

**Control Strategy 4 (CS4)**
In this control strategy, there is an option of cooling the fluid either on fluid flow temperature exiting the heat pump or on fluid return temperature leaving the ground; otherwise, the fluid bypasses the DAC and enters the ground or the HP.

**Control Strategy 5 (CS5)**
The DAC is controlled based on the ground temperature and ambient air temperature, when the ground temperature reaches a certain value then the DAC can either be used to reject heat to the ground or the fluid bypasses the ground and enters the heat pump.

In order to reduce ground saturation, which has an impact on the system's performance, the existing system model was modified to reject heat into the ground. The opportunity was therefore seized...
to explore the effects of various control strategy approaches employing the DAC on HP performance and ground temperature change after developing and establishing a verified empirical TRNSYS system model. The DAC circuit, circulation pumps, and the HP should all be turned on or off at different times according to the control methodologies used in this study. The three categories of HP power, each circulating pump's power, and DAC fan power add up to the total amount of electrical power used by the system. Figure 4 below displays a flow diagram of the examined control techniques.

![Flow diagram of the control strategies](image)

**Figure 4: Flow diagram of the control strategies.**

### 5.1 Effect of DAC on COP.

Figure 5 shows the cooling COP value of the GSHP system at various temperature set points. It should be noted that the COP values for all four of the specified temperature scenarios were quite similar at the start of the season in April to June 2013. Time Period A is the period during which the DAC is not active. In Time Period B, there is a difference in COP between the options, and the DAC is either working fully or partially during the months of June and October 2013. The DAC was used to lower the leaving fluid temperature from the HP by rejecting the heat back to the ground at a lower temperature than the normal operating leaving fluid temperature of the HP, which is the only reason for the difference in COP. The GSHPs COP value decreases continuously with increasing setpoint temperature. For the first year of GSHP system operation, the COP values for cooling are highest for the lowest setpoint temperature.

Setting the temperature setpoint control to 22 °C results in a cooling COP of 6.2, which is 19.2% higher than the average operating scenario. As a result, the cooling COP value is reduced to 5.2 in comparison to the regular operating scenario. An energy and exergy analysis of a GSHP system in Ontario (Canada) by Kizilkalan and Dincer (2015) revealed that the system's efficiency in the heating mode was marginally increased when the fluid temperature entering the HP was greater.
5.2 Effect of DAC on Ground Temperature

Along with looking into how the DAC's operating cycle affects the device's efficiency, a look into how it affects ground temperature is also conducted. The simulation results for ground temperature over the course of a year are shown in Figure 6. The results demonstrate that when the setpoint temperature varies, the four separate setpoint operation temperatures of the DAC cause variations in the ground temperature.

In Time Period A, when the DAC is not operating at the beginning of the cooling season, the ground temperature is similar, and hence changing the ground temperature setpoints does not affect it at all. Therefore, the ground temperature for all scenarios remains constant. However, in Time Period B, the temperature variation between the scenarios becomes clear that the more the DAC is running, the lower the ground temperature variation is. After one year of cooling mode operation, the maximum ground temperature is 23°C for the normal operation duration, compared to 20°C for the lowest set point temperature, which is 15 per cent lower than the normal operation.

This impacted on COP, and therefore by reducing the ground temperature from 23 to 20 °C, the overall system performance has improved by approximately 9 %, and this can be seen clearly in Figure 5 above. If excessive heat extraction rates from or rejection to the ground are tolerated for prolonged periods, then significant changes in ground temperature are likely to occur; such changes in ground temperature may have a significant detrimental effect on the overall COP system, as well as a significant impact on the atmosphere. By using simpler heat rejection or 'free cooling' techniques, Zoi and Constantinou (2012) suggested three control strategies to mitigate this major change in ground temperature. The first one determines the set point at which a cooling tower starts its operation according to the fluid temperature exiting HP, and ambient air wet-bulb temperature exceeds a given set point. The second one activates the cooling tower when the fluid temperature exiting GHX is higher than a specific value. The third one sets the cooling tower on when the fluid temperature exiting HP is higher than a given value.
With the decrease of average ground temperature around the ground heat exchanger, the temperature difference between the ground and the circulated heat carrier fluid decreases; this phenomenon has both advantages and disadvantages for the system. While this gradual shift in temperature increases the COP value during the cooling season, it also decreases the system’s COP value during the heating season.

5.3 Effect of DAC on Heat Pump Energy Consumption.

The total monthly HP energy consumption for scenarios CS1, CS2, CS3 and CS4 are presented in Figure 7. The operation cycle of the DAC can determine whether the GSHP system consumes more energy compared to a GSHP system without DAC. Figure 7 shows that the maximum energy consumption of the HP was 7923 kWh and 7669 kWh, respectively, between the periods of April 2013 and August 2014, both of which occurred while the system was operating without DAC support. Also, when the DAC was controlled at the highest set point temperature of 28 °C, these dynamics can be shown clearly in Figure 6 during Time Period B. Time Period A demonstrates that the performance of the four set points remains unchanged when the DAC is off. Time Period B shows that this zone also illustrates the advantages of decreasing the ground temperature while the DAC was running at various set points, as shown in Figure 6 of the system’s energy input. Reducing the temperature of the ground helps to decrease the temperature differential between the temperature leaving the ground loop heat exchanger and the temperature leaving HP, thus increasing the system’s COP.

Comparisons of the four scenarios in Time Period B between the periods of July and September 2013 showed that the system’s energy consumption decreased by 8% when the lowest control setpoint of 22 °C (CS4) was compared to the system’s usual operating conditions. Likewise, the system’s lowest energy consumption was 267 kWh during the transition period to the heating mode. Zhao et al. (2003) proposed a theoretical and experimental study to investigate the impact of several capacity control techniques on the HP’s energy efficiency, i.e. turning the compressor on/off, regulating on/off times of intake and discharge valves, concentration ratios of the refrigerant mixture, and speed of the compressor.
5.4 Proportion of Energy Utilisation

The total proportion of energy consumption of the HP, circulation pump and the fan are shown in Figure 8 below. It indicates that the compressor accounts for 72 per cent of the total system's annual electricity consumption, followed by the circulation pumps, which use 20 per cent of the system's total energy supply. The DAC's 9 per cent energy consumption is comparatively small compared to the energy input of the compressor.

5.5 Economics of The Control Strategy

The financial and CO2 emission savings for each temperature set point were compared with the regular operation of the system in this section. The additional monthly CO2 emission savings (kgCO2) that can be achieved by enforcing the various temperature control setpoints are shown in figure 8. The graph indicates that a cumulative CO2 emission saving of 420 kgCO2 was achieved in July 2014. This is also the point where the highest COP and highest ground temperature have been reported in connection with Figures 5 and 6. This occurred, notably, at the lowest set temperature point of 22 °C. In addition, the lowest CO2 emission savings were approximately 20 kgCO2, and this occurred at the
28 °C maximum temperature set stage. As shown, the lowest temperature set point can produce a saving of approximately 17 per cent relative to the highest temperature set point. The lowest temperature set point will often achieve cost savings of approximately 18 per cent relative to the maximum temperature set point.

**Figure 8:** Monthly CO2 emission savings from the different control strategies.

Specifically, Figure 9 shows the possible additional cost savings that can be made relative to the standard system operation from the various temperature set points. Figure 9 also shows that using the lowest temperature set point of 22 °C, a maximum cost saving of £110 was achieved in July 2014. In addition, for the same month, the most economical cost savings were around £20, and this happened at the maximum fixed temperature point of 28 °C. Compared to the maximum temperature set point, the lowest temperature set point will achieve cost savings of approximately 18 per cent.

**Figure 9** Monthly cost savings from different control strategies CSI
6.0 Conclusion

During the net cooling cycle for a university building, this paper identified various control strategies for GSHP device optimisation. The investigation centred on the effect of DAC on ground heat rejection, system COP, variance in ground temperature, minimisation of compressor and circulation pump electrical power consumption, assuming certain building load values, and maximum cooling capacity of HP and DAC.

This paper has shown that a substantial reduction in GSHP running costs, electrical power usage, and an increase in the system's COP could be achieved by using and regulating a DAC using different temperature setpoints. However, it is difficult to argue that this is the most economically profitable example, not only because the heating cycle is not tested, but also because unit selection has not considered the investment and maintenance costs. This is the subject of further work.

This paper has established that the best of those tested to control the activity of DAC in the GSHPs is the lowest temperature setpoint control. A comparison of these four scenarios shows that substantial cost and carbon reductions can be accomplished and that all current control methods achieve improved management of system operations, leading to an additional reduction in energy usage, carbon and cost savings. It is possible to use these remarks as guidelines for potential GSHP designers.

Making progress in the decade of heat pumps – status and trends of the European heat pump markets in 2022

Thomas Nowak

European Heat pump Association aisbl, Rue d’Arlon 63-67, 1040 Brussels, Belgium

Abstract

European heat pump sales grew +38% in 2022. With 3.016 million units sold across Europe, this is a new sales. Assuming a life expectancy of approx. 20 years, the current European heating heat pump stock amounts to 16.97 million units, representing nearly 15% of the EU’s building stock of 116 million residential buildings. The main influencing factors for market growth:

- Policy makers focus on heating: 10 years of energy and climate policy is now showing results in national markets.
- Heat pump technology delivers: the needs of new and existing residential and commercial buildings (temperatures up to 75°C) as well as industrial processes (providing between 140°C and 160°C) are met. Solutions are available to fuel the greening of district heating and cooling at temperatures of up to 95°C and capacities of between one and 35 MW.
- Homeowners have focused on upgrading their buildings to improve indoor environmental quality.

The paper explains the underlying market dynamics growth in Europe in 2022 including air-air, air-water, and ground-water heat pumps for heating as well as sanitary hot water heat pumps.

Keywords: heat pumps; market development; sustainable energy system; decarbonisation; Europe; REPowerEU; Renewables; System integration, industrial strategy, heatpump accelerator

1. Background

Over the past decade, the importance of heat pumps has been hailed in the context of climate change. They have been mainly recognized for the highly efficient use of renewable energy and the related much lower emission of CO₂. While the policy framework has been adjusted over time with more ambitious targets for the use of renewable energy, energy efficiency and CO₂ emission reduction, the economic framework has been left untouched until recently [1]. The resulting mismatch between ambition and speed of conversion is observable in the slow transition speed from the use of fossil energy to more renewables as documented by the Eurostat SHARES tool [2]. The average increase of renewables used in heating and cooling has only been 0.6 percentage points for the decade until 2020, far below the target of 1.3 percentage points as set forth in the current European Renewable Energy Directive [3] or the targeted 2.5 percentage points [4] proposed in its future version.

From 2021 onwards, a new momentum was observable.

1. Increasingly recognizable effects of global warming made change urgently necessary, including a more ambitious focus on heating and cooling in legislation. Several European countries have started to discuss and/or to introduce measures that are giving an economic advantage to heat pumps over fossil based solutions.
2. Throughout the COVID pandemic, end users spent much more time in their homes and buildings, realizing the need for good indoor environmental quality.

3. The war waged by Russia on Ukraine has shaken the belief of “gas as a transition fuel” and has destroyed policy makers and end-users trust in Russia as a reliable partner for energy delivery. This recognition has materialized in conceptual papers like the IEA 10 point plan to reduce Europe’s dependence on Russian gas [5] and powerful policy packages like “REPowerEU” [6]. Consequently, end-users are now asking for alternatives to their fossil based heating systems. All three effects trigger additional demand at a level unexpected by industry and installers. The combination of this additional demand and supply shortages of components in a global value chain has led to bottlenecks across the heat pump sector. All three effects will mutually reinforce each other and stabilize the trend away from fossil heating and ensure the necessary exponential growth throughout this decade. Continued policy support both regarding targets and supporting their implementation on all levels is needed to overcome them and to accelerate and stabilise deployment.

2. Status of heat pump market development

The European Heat Pump market has seen positive, uninterrupted growth since 2012. From 2015 onwards double digit growth was observable and 2022 saw a new sales record of +38% (over +34% in 2021). In 2022 more than 3 million heating and hot water heat pumps were installed in the 21 countries covered by EHPA statistics (see figure 1) [7]. This lead to a stock of nearly 20 million units.

The market was dominated by France (626k), Italy (517k), and Germany (282k). Together with Sweden (215k), Poland (203k), Finland (196k), Spain (185k), Norway (156k), and the Netherlands (125k), these countries form a group of nine markets, in which sales exceeded 100k units and which are jointly responsible for 83% of annual sales.

Figure 2 shows absolute and relative change of annual sales in 2022. Italy leads absolute change in sales with an increase of 134k (+37%) while Poland shows the biggest relative increase with doubling annual sales (+102%, + 99k). It is followed by Czech Republic (+99%), the Netherlands (+80%), Belgium (+66%) and Austria (+59%). Regarding year over year sales increase in absolut numbers the top 5 countries are Italy (+134k), Poland (+99k), Germany (+82k), France (+76k) and Finland (+67k).
Growth is expected to continue as national legislation becomes more ambitious, partly as a result of local considerations (e.g., air quality in Poland), partly as a consequence of transposing European legislation. Germany aims at 500k heat pumps to be sold in 2025 supported by a new requirement of a 65% renewables share which is to be met by all heater installations (in new buildings and when replacing an existing heater) from 2024 onwards. Austria has already banned the installation of oil boilers in new buildings in 2020, and followed up with gas boilers in 2023. It aims to ban oil heating by 2035 and gas heating from 2040 onwards [8]. The Netherlands, after having declared the aim to become “gas free” in residential heating, is now mandating hybrid heat pumps as the minimum solution to be installed from 2026 [9]. Denmark has announced a shift of its remaining 400k gas boilers to district heating and individual heat pumps by 2028/2029 [10].

France has banned the installation of new oil boilers in all buildings and the installation of new gas boilers in new buildings from 2023 onwards. Ireland currently discusses the ban of fossil boilers with oil starting this year and gas following in as early as 2025. The European Commission is working on sharpening the regulation on Ecodesign for boilers in a way that would make the installation of fossil-only boilers impossible by 2029 [11]. These measures are fuelling a debate also in countries that have not yet agreed on a specific policy on the matter and their heat pump markets see a positive spill-over from more ambitious neighbours.

This strong increase in sales numbers in 2021 and 2022 is essential to decarbonise heating and to reduce local air pollution. The 2022 heat pump stock to the energy and climate targets is summarized in table 1 [12]. New units with a thermal capacity of 28.18 GW were installed producing approx. 33.95 TWh of useful energy and integrating 19.8 TWh of renewables in heating and cooling.

</tbody>
</table>

Installing and maintaining these heat pumps is estimated at requiring a total of 162k full time equivalent of employment. Obviously real employment related to the heat pump market is larger, as not all employees work full-time on heat pumps only.
The total stock of heat pumps installed since 2003 amounts to 19.9 million units around 18 million of these being for heating purposes and about 1.9 million providing sanitary hot water. With a thermal capacity of 175.2 GW these heat pumps provided 330.7 TWh of useful energy, 208.7 TWh of which being renewable.

The average emission factor for electricity in Europe has declined from 500 g CO\(_2\)/kWh to a value as low as 229 g CO\(_2\)/kWh in 2020 but has bounced back to 275 g CO\(_2\)/kWh in 2021. Assuming a continuation of the downward trend, the emission value for 2030 is estimated at 115 g CO\(_2\)/kWh [13]. The number of heat pumps sold in 2022 have reduced CO\(_2\) emission by 7.6 Mt, arriving at a total annual savings of 53.5 Mt. With the greening of electricity, this number will increase further in the future.

The positive impact of heat pumps on the energy and climate targets is expected to continue, as the technology is not only the #1 heating technology in the new build segment of many national markets but is also making an inroad into the renovation sector. Improved technologies and new business models help the greening of electricity, this number will increase further in the future.

3. Legislative background: From EU Green Deal to REPowerEU

Europe’s energy and climate policy has traditionally been shaped around:
- the promotion of the use of renewable energy, both in electricity and heating and cooling
- the support of energy efficiency measures in buildings and industry
- the introduction of minimum efficiency requirements for products through the Ecodesign directive and the related regulations on performance and labelling
- the reduction of CO\(_2\) emissions through an emissions trading scheme and an effort sharing mechanism
- a re-design of the electricity grid.

Table 2 shows the increase of ambition on the EU level regarding the block’s energy and climate targets. With each revision of the targets on renewable energy, energy efficiency and CO\(_2\) emission reduction arose the need to review the underlying legislation on the EU and the Member State level.

Currently, the legislation on renewables, energy efficiency, CO\(_2\) emission is undergoing its 3rd review round. New proposals related to heat pumps include:

1. a more ambitious Renewable energy Directive (see [17]) with
   - an increased renewables target for 2030,
   - a faster increase of the share of renewables used in heating (forthcoming Renewable Energy Directive), and
   - the recognition of cooling and waste heat, including in industry and district heating through large heat pumps.

2. the phase out of fossil heating in buildings (Energy Performance of Buildings Directive) [20].

3. a synchronised set of planning measures and assessments (National energy and climate plans, Comprehensive assessment, assessment of the potential from renewable sources, the use of waste heat and cold) (see the forthcoming Energy Efficiency Directive [16]).

4. the inclusion of heating and light commercial uses of fossil energy into the EU Emission Trading System (ETS2) [21].

5. a rebalancing of energy carrier taxation levels making the tax rate applied to electricity the lowest (Energy Taxation Directive [22]).
6. change of the accounting method of energy savings and ruling out the counting of savings from the installation of fossil boilers.

While this review was on its way, the war in Ukraine shattered the belief of gas being a bridge to a more sustainable heat supply and of Russia as a reliable trading partner for fossil gas. Both the International Energy Agency and the European Commission published communications on the need to remove Europe’s dependency on Russian gas and both recognised that replacing gas boilers with heat pumps was a suitable approach. Each million of boilers replaced saves around 2 billion cubic meter of fossil gas imports. It hence required about 75 million additional heat pumps to completely remove the amount of gas imported from Russia in 2021 [23].

The European Commission followed up the REPowerEU communication [24] with a proposal for a sharpened legislation to accelerate the deployment of renewable energy [25]. For the first time, heat pump technology was mentioned in the top level communication. This was supported with specific targets on heat pumps, in particular:

1. the installation of 10 million additional hydronic heat pumps until 2026 and a total of 30 million additional units to be installed by 2030.
2. the recognition of renewable energy infrastructure as being of “overriding public interest”. This recognition could then be used to justify simplification of administrative procedures.
3. taking additional measures to decarbonise the heat demand in industry, including through high capacity/high temperature heat pumps.
4. the need for additional 210 billion Euro investment identified as necessary to phase out the dependence on Russian gas. In parallel it was suggested to increase the share of renewables in final energy demand to 45% by 2030.

While these suggestions show a recognised need for higher ambition and action, they are not universally supported by neither the European Parliament nor by the Council. The European Heat Pump Industry assessed the proposals as appropriate and feasible but lacking clarity and detail. Achieving the growth numbers as proposed would require an action plan or a heat pump industrial strategy to ensure end-user trust in the technology, trigger and stabilise demand and increase capacity across all stages of the value chain. New technological solutions would have to be developed both for components and products, manufacturing sites would have to be build/redesigned, and experts would need to be trained on all levels. The latter including higher level education on the university level as well as a focus on mathematics, computer science, natural sciences and technology education in schools and a focus on the vocational training of installers, plumbers, or electricians.

4. A pandemic with an impact on home improvement

Regarding the need for a stabilised demand, the more inward focus of end-users on their own homes led to the realisation, that indoor environmental quality could be and should be improved. In consequence, the pandemic influenced demand for comfort and renewable solutions in electricity and thermal energy demand. And there is some evidence pointing to exactly that: When people were forced to stay home during the different lockdowns and home office obligations of the COVID pandemic, they began observing the shortcomings of their properties. With budget that would otherwise have been spent on hobbies, eating out or holidays now at the end user’s disposal, they were channelled towards home upgrades. Focus areas were home offices, kitchens and living areas but also ventilation and heating systems. Why representative studies are sparse, (An evaluation of Discover Home Loans concluded that the interest in renovating increased dramatically during the pandemic [26].) anecdotal evidence from personal discussions with installers and other experts in the field support the assumption. An additional plausible explanation of increased demand is the aim to reduce the operating cost of a building by investing in modern, efficient, and renewables-based power and heat generation solutions.

5. Using energy as a weapon has shattered the belief in gas as a transition fuel

The Russian invasion of Ukraine on 24th of February 2022 had an additional impact on the energy transition in heating. This war “using energy as a weapon” [27] is directly and heavily impacting energy users and may in the end have been the most decisive for the accelerated energy transition, in particular towards the use of renewables in heating [28]. The sudden and unexpected price increase for gas lead to higher cost for heating and – due to determination of the electricity price by merit order – electricity for most of Europe and lead end users to realise that supply security and affordability are at risk when relying on fossil energy. This realisation
has led to a double effect: several international and EU level communications describing the move away from (Russian) gas to the use of more renewables and the REPowerEU legislative package increasing existing energy and climate targets and introducing legislative measures and financing options to achieve them. The IEA 10 point plan to reduce Europe’s dependence on Russian Gas lists 10 points to reduce demand of gas, two of which highlight the positive impact of a faster deployment and an increase in sales numbers of heat pump based solutions in residential and industrial applications. The REPowerEU plan aims at a similar target (see above) and identifies additional financing needs. This has a double impact on consumers: on top of their personal experience of the cost impact on energy resulting from the war, the need to shift our energy demand from fossil energy to renewables is re-enforce by the positive policy recognition and support systems that are (announced to be) put in place.

6. Concerted action still needed to fast-track heat pump deployment

Figure 3 shows the mutual support and boost for heat pump demand of three parallel developments. Where the continuous review, sharpening and increase of ambition of the different policy files has created a strong and continuous growth in demand, both the COVID pandemic and the war in Ukraine have added momentum on the end-user side.

![Fig 3: Mutually reenforcing impact on heat pump demand from policy, geopolitics, and pandemic. Source: own.](image)

The triple effect has steadied out demand not least through engaging hitherto reluctant end-users in considering heat pumps to ensure personal supply and affordability of heat and activating this target groups financing means. Demand must and likely will grow exponentially throughout this decade and while this is generally positive, it comes with a set of challenges that need to be overcome thorough enhancing energy and climate policy by a concerted heat pump industrial policy.

6.1. Are heat pumps becoming the dominant technology for heating in Europe?

Heat pump based heating can efficiently supply all residential and commercial buildings, both in new and renovation, single and multi-family application. Nearly 60% of all buildings are ready to be equipped and solely heated with heat pumps with the rest either having to undergo energetic renovation or be equipped with hybrid heat pumps, using two or more energy sources. As more than 75% of the European building stock are still heated by fossil energy, the necessary speed of change is far bigger than what can be currently observed.

Based on a previous assessment of around 116 million residential buildings in Europe and annual heater sales of around 7 million units, heat pumps now make up for a share of more than 35% in annual sales and about 15% in the stock of heating solutions. To achieve the target of 10 million additional hydronic heat pumps, as set forth by REPowerEU, exponential, double digit growth will be needed. Available data for 2022 shows that this target is within reach, and even the need for continued growth throughout this decade is within reach. Applying the necessary growth rates under REPowerEU also to air-to-air heat pumps, a category that is used for heating in Norway, Sweden, Denmark and Sweden, the Baltics as well as in the Mediterranean countries and that is responsible for about 33% of annual sales, heat pumps could provide 50% of Europe’s building stock by 2030.
While the benefits of heat pumps for the energy and climate targets will undoubtedly lead to higher demand, the necessary growth is currently limited by supply shortages regarding components (fans, heat exchangers, pumps, semi-conductors and even tanks) and installation capacity. Related to this the need for a larger, skilled workforce, and the need for a competitive economic offering vs the incumbent fossil heating technology puts a limitation to the possibility of future growth. This needs to be overcome by concerted action.

6.2. A heat pump accelerator is needed to quadruple heat pump markets within this decade!

Europe has a strong position in heat pumps. It has a versatile landscape of research institutions and manufacturing sites and an established process of training and educating a skilled workforce. It should build on this strength to maintain this leadership in this new “industrial age” of renewables [29]. Industry has announced investments close to 5 billion Euro over the next three years [30]. For individual manufacturers, that means about a quadrupling of the 2021 production volume. It is the role of governments to back this growth by further shaping policy ambition and devising an industrial strategy along the whole value chain [31][32]. Making such policy continuity visible to developers and investors will allow them with the confidence needed to go ahead and even intensify their investments.

Hence it needs an all-hands-on-deck approach establishing a “heat pump industrial policy” that supports stakeholders on all stages of the heat pump value chain to implement and even enhance necessary investments to increase capacity. Such a heat pump accelerator will have to address the following points:

1. Maintain trust in the future importance of heat pump based solutions for the energy transition in Europe. Heat pumps need to be put forward in public communication on the European and national level. Their importance needs to be mentioned in high level speeches and used as an example of the low hanging fruits to reduce CO2 emission quickly and significantly from heating and cooling. Heat pumps should be included in the overall energy and climate policy as well as in new, short term measures like EU net zero industry act [source]. Obstacles in component supply, administrative procedures and skilled workforce need to be addressed.

2. Cost of the energy transition in heating: The economic framework conditions need to be shaped towards making heat pump based solutions the economically most attractive alternative for private and commercial end-users, including those operating industrial plants and district energy networks. Regarding operation cost, this means improving the relative cost of electricity based heating and cooling solutions vs. their fossil counter parts. Negative external effects of the use of fossil energy need to be internalised, energy taxation needs to give an advantage to electricity and fossil fuel subsidies need to be stopped. Flexibility needs to be given a value, including through offering time-of-use tariffs and at least for the next years, investment cost support needs to be provided through subsidies and advantageous loan offering.

The decision in favour of a heat pump is not only related to direct, but also to indirect cost. Uncertainty and doubt on the right technical solution, quality of offer and installation can be overcome by providing decision and process support through knowledge centres. This can go as far as providing complete support in form of one-stop-shops [33].

3. Legal certainty needs to be established for investors and end-users alike. Legislation should be established with a long term view making investments plannable and profitable. Administrative procedures should be simplified and revised to also allow the provision of new energy services (“heat-as-a-service”) even beyond the individual lot. Similarly, the revision of current legislation such as on the use of refrigerants or Ecodesign should take the necessary accelerated deployment of heat pumps into consideration and simplify, not hinder, the path to this goal. Looking at the current review of the refrigerant regulation, the resulting new bans and phasedown trajectory will significantly shape the future of the heat pump industry. The proposed PFAS restriction proposal to the REACH regulation will limit available refrigerants for the industry. Clarity must be created as soon as possible [34][35].

4. In the foreseeable future, there will be a lack of skilled workers on several levels of the value chain. From architects, designers, and planners to factory workers to electric and heat pump installers. This needs to be addressed by policy makers through joint initiatives that recognize the importance of skills in the HVAC sector and aim at education and training as much as at re-skilling of existing employees. A focus on heat pump installations may allow a simplification of the extent of skills needed, for example by dropping those needed to install fossil based solutions.

5. Heat pump solutions require further research and development to develop residential, commercial, and industrial solutions for enhanced application areas, a reduced footprint, more compact solutions, and units that integrate thermal and energy through sector coupling. Such research can be supported...
vi different vehicles, Horizont Europe, and Life, but could also be positioned inside one or many Important Projects of Common European Interest (IPCEI).

In order to ensure the necessary growth rate is achieved and maintained, the heat pump accelerator or heat pump industrial policy must include a regular progress review to enable adjustment and modification of EU and national legislation.

7. Conclusion

The European heat pump industry has reached a level of maturity perfectly suited for exponential growth throughout this decade. In 2022 the heat pump share in annual boiler sales has reached about 30%. About 16% of all heating solutions installed in Europe are now heat pump based. Demand is triggered from both policy and individual end-user decisions in residential, commercial, and industrial applications. Growing demand encounters limitations in supply in capacity and skills across the value chain. As demand has increased rather surprisingly for many market players, friction between supply and demand is observable in factory construction, component, and heat pump manufacturing as well as installation. Ongoing investments are expected to overcome this friction over the course of the next 12 months.

The outlook for the heat pump sector is positive, but more needs to be done in order to remove the use of fossil energy from heating in Europe. Accelerating its growth even further and stabilizing sales needs strong and visible support by governments including through establishing a European heat pump strategy that addresses and supports all parts of the value chain and coordinates the ambition of member states.

If this is established, heat pumps can become the #1 heating and cooling technology in Europe, meaningfully contributing to the continents energy and climate targets and removing its dependence on Russian gas, making renewable heat available and affordable for all. For the next winter and the winters to come.

Abstract

H$_2$O/LiBr and NH$_3$/H$_2$O are commonly used as working fluids of absorption system in that they present high solubility of refrigerant in absorbent. However, the conventional working fluids need to be substituted considering causticity and toxicity. In this study, a simultaneous cooling and heating absorption system, which is combination of type 1 and type 2 absorption systems, has been analyzed using the numerical methods to improve the coefficient of performance (COP) for heating/cooling applications. The ionic liquid absorbents including imidazole, which has non-causticity and non-toxicity, are utilized as working fluids. H$_2$O and R32 refrigerants are also utilized as working fluids. The thermophysical properties are evaluated by using the non-random two liquid (NRTL) model. The variation of COP is analyzed according to split ratio and generation temperature of each component. It is found that the maximum COP$_{tot}$ of H$_2$O/LiBr, H$_2$O/IL, R32/IL are 0.9000, 0.8481 – 0.9066 and 0.4084, respectively. It is also confirmed that when using H$_2$O/IL, better performance of the absorption system is expected than when using R32/IL, and the crystallization, causticity and toxicity problems are also expected to be solved.

Keywords: Absorption system, COP, H$_2$O, Ionic liquid, R32, Simultaneous cooling and heating.

1. Introduction

The conventional NH$_3$/H$_2$O system has problems with refrigerant toxicity, and the H$_2$O/LiBr system has problems such as crystallization of the absorbent and corrosion with metals. In addition, international regulations are being strengthened step by step to use low global warming potential (GWP) refrigerants after the Montreal Amendment in 1997, the Beijing Amendment in 1999, and the Kigali Amendment in 2016. For this reason, there is a need for research on a new working fluid of absorption type systems.

Ionic liquids have been attracting attention as working fluids due to their unique properties. Kim et al. [1] showed that ionic liquids can maintain a liquid state even at room temperature or below room temperature. Paulechka et al. [2] found that the vapor pressure of ionic liquids is negligible. Domańska et al. [3] confirmed incombustibility and thermal stability, and Trindade et al. [4] confirmed low melting point and high refrigerant solubility, so that it can exist in a liquid state at room temperature. It is expected that these characteristics solve the problems of the previous absorption systems.

However, although there is a demand for a simultaneous cooling and heating absorption system in that waste heat can be recovered, there are not many prior studies. In this study, four different working fluids using an ionic liquid as an absorbent were selected based on the previous studies that resulted in a high COP in type 1 absorption system and they were applied to the simultaneous cooling and heating absorption system. Finally, cooling COP, heating COP and total COP were compared according to the variations of split ratio and generation temperature.

2. Research method

2.1 Selecting working fluid

H₂O and R32 were selected as the refrigerant, and the reasons are as follows. In the case of H₂O, the most commercialized working fluid in the previous absorption system is H₂O/LiBr, R32 refrigerant has a smaller specific volume than H₂O, which is advantageous for miniaturization. R32 is HFC and has greater solubility in ionic liquids than HFO.

As the absorbent, imidazolium (C₃H₅N₂) ionic liquid was selected. Imidazolium ionic liquid is known as the most stable material among the ionic liquids, and it is easier to obtain necessary physical property data than other ionic liquids because physical properties are measured relatively often. [DMIM][DMP], [EMIM][DMP], and [EMIM][BF₄] were selected as the absorbent for H₂O, and [HMIM][Tf₂N] as the absorbent for R32.

2.2 Simulation model

Figure 1 shows the schematic diagram of the simultaneous cooling and heating absorption system. It is a combination of type 1 and type 2 absorption systems. Cooling COP, heating COP and total COP are analyzed under various conditions. To evaluate performance of the system, split ratio and COP were defined as follows;

\[
\tau_g = \frac{m_2}{m_4 + m_7} \tag{1}
\]

\[
\tau_c = \frac{m_{14}}{m_{14} + m_{17}} \tag{2}
\]

\[
COP_c = \frac{q_{eva1}}{q_{gen} + W_{pump}} \tag{3}
\]
\[ \text{COP}_h = \frac{\dot{Q}_{\text{abs}}}{\dot{Q}_{\text{gen}} + \dot{W}_{\text{pump}}} \]  \hspace{1cm} \text{(4)}

\[ \text{COP}_{\text{tot}} = \text{COP}_c + \text{COP}_h \]  \hspace{1cm} \text{(5)}

where \( r_g \) is the split ratio of the generator; \( r_c \) is the split ratio of the condenser, \( \text{COP}_c \) is cooling COP, \( \text{COP}_h \) is heating COP, \( \text{COP}_{\text{tot}} \) is the total COP, \( \dot{Q}_{\text{gen}} \) is the heat absorbed by the generator, \( \dot{Q}_{\text{ev1}} \) is the heat emitted by the low-temperature absorber and \( \dot{W}_{\text{pump}} \) is the pump work. \( \text{COP}_c, \text{COP}_h \) and \( \text{COP}_{\text{tot}} \) are analyzed under various conditions.

In the previous studies, the correlations for the thermal properties of the refrigerant/ionic liquid solution are established using the VLE (vapor-liquid equilibrium) equation and the NRTL (Non-Random Two-Liquid) model. The NRTL model is a chemical model that uses three interaction parameters to obtain an activity coefficient for the phenomenon of deviating from an ideal solution to which the Raoult’s law is applied, and uses it to calculate the VLE equation [5–7].

\[ Y_i p \Phi_i = X_i Y_i p_i^s (i = 1, 2) \]  \hspace{1cm} \text{(6)}

\[ \Phi_i = \exp \left[ \frac{(B_i - V_i^L)(p - p_i^s)}{R T} \right] \]  \hspace{1cm} \text{(7)}

\[ \ln Y_i = X_i^2 \left[ r_{21} \left( \frac{G_{21}}{x_1 + x_2 G_{21}} \right)^2 + \frac{r_{12} G_{12}}{(x_1 + x_2 G_{12})^2} \right] \]  \hspace{1cm} \text{(8)}

\[ \ln Y_2 = X_1^2 \left[ r_{12} \left( \frac{G_{12}}{x_2 + x_1 G_{12}} \right)^2 + \frac{r_{21} G_{21}}{(x_1 + x_2 G_{21})^2} \right] \]  \hspace{1cm} \text{(9)}

\[ G_{12} = \exp(-\alpha r_{12}), \ G_{21} = \exp(-\alpha r_{21}) \]  \hspace{1cm} \text{(10)}

\[ r_{12} = r_{12}^0 + \frac{r_{12}^1}{T}, \ r_{21} = r_{21}^0 + \frac{r_{21}^1}{T} \]  \hspace{1cm} \text{(11)}

where \( Y_i \) is the vapor molar concentration of \( i \)th species; \( X_i \) is the liquid molar concentration of \( i \)th species; \( p \) is the vapor pressure of the solution; \( p_i^s \) is the saturated vapor pressure of \( i \)th species; \( \Phi_i \) is the correction factor for \( i \)th species; \( \gamma_i \) is the activity coefficient for \( i \)th species; \( B_i \) is the second virial coefficient of \( i \)th species; \( V_i^L \) is the saturated molar liquid volume of \( i \)th species; \( R \) is the ideal gas constant (8.314 kJ/kmol·K), \( T \) is the temperature, and \( \alpha, r_{12}, \ r_{12}^0, \ r_{21}, \ r_{21}^0, \ r_{12}^1, \ r_{21}^1 \) are adjustable parameters regressed through data from the experimental studies of each solution.

In the simultaneous cooling and heating absorption system, the generator receives waste heat and generates the refrigerant from strong solution. Generated refrigerant moves to the condenser, and the remaining weak solution moves through the splitter to the high temperature solution heat exchanger and the low-temperature solution heat exchanger. In each solution heat exchanger, heat exchange between the strong solution and the dilute solution is performed. After the heat exchange, the weak solutions move to a high-temperature absorber and a low-temperature absorber, respectively. The condenser condenses the generated refrigerant vapor, and the condensed refrigerant moves to the high-temperature evaporator and the low-temperature evaporator through a splitter. Each evaporator evaporates the liquid refrigerant, and a cooling effect corresponding to the cooling load occurs in the low-temperature evaporator. The evaporated refrigerant moves to the absorber and is absorbed by the weak solution to form a strong solution. The strong solution exits the absorber, passes through the solution heat exchanger, and returns to the generator. The simulation conditions for R32/[HMIM][Tf2N] and H2O/[DMIM][DMP], [EMIM][DMP], [EMIM][BF4] are summarized in Table 1 and 2, respectively.

3. Results

3.1. Effect of split ratio

There are two split ratios in the generator and the condenser, and each value of split ratio has an impact on several performance indicators. The split ratio has an impact on COP_c, COP_h and COP_tot for all four refrigerants/ILs. Simulation results according to the changes in r_g and r_c are shown in Figure 2. The COP trends in H_2O/[DMIM][DMP], H_2O/[EMIM][DMP] and H_2O/[EMIM][BF_4] were compared. As r_g increases, the COP_c, COP_h and COP_tot increase. As r_c increases, the COP_c and COP_tot decrease while COP_h increases. To achieve the reasonable level of cooling and heating effects, it is important to choose r_g and r_c correctly. The COP trends of R32/[HMIM][Tf_2N] were different from those of H_2O/[DMIM][DMP], H_2O/[EMIM][DMP] and H_2O/[EMIM][BF_4]. As r_g increases, the COP_c, COP_h and COP_tot increase. However, as r_c increases, the COP_c, COP_h and COP_tot decrease.

When H_2O/IL applied, cooling effect decreases while heating effect increases as r_c increases. On the other hand, cooling effect increases and heating effect decreases as r_c decreases. When R32/IL applied, the trend of cooling effect is similar to the result of H_2O/IL. However, trend of heating effect is opposite. This is because the factors that influence Q_\text{abs} are different. In H_2O/IL system, increasing enthalpy of refrigerant vapor which is point 16 in Figure 1 is a dominant factor to influence Q_\text{abs} as r_c increases. In R32/IL system, increasing enthalpy of solution liquid which is point 10 in Figure 1 is a dominant factor.

![Fig. 2. Simulation result of COP-split ratio for r_c=0.5.](image-url)
3.2. Effect of generation temperature

Figure 3 shows the simulation result of $T_{\text{gen}}$-$\text{COP}_{\text{tot}}$ when $r_c=0.5$. To show a balanced example of the cooling effect and the heating effect, $r_c$ is set to 0.5. For all four alternative working fluids, $\text{COP}_{\text{tot}}$ increases as the generation temperature increases. As shown in Figure 3, the maximum $\text{COP}_{\text{tot}}$ of H$_2$O/LiBr was 0.90 and NH$_3$/H$_2$O was 0.73. Compared with $\text{COP}_{\text{tot}}$ of H$_2$O/LiBr, H$_2$O/[DMIM][DMP] (COP$_{\text{tot}}$=0.91), H$_2$O/[EMIM][DMP] (COP$_{\text{tot}}$=0.88) and H$_2$O/[EMIM][BF$_4$] (COP$_{\text{tot}}$=0.85) results in similar performances. Compared with COP$_{\text{tot}}$ of H$_2$O/LiBr, R32/[HMIM][Tf$_2$N] (COP$_{\text{tot}}$=0.41) performed 45%.

The trend of increasing or decreasing COP can be explained by the different increasing rates of $\dot{Q}_{\text{gen}}$ (heat transfer rate of generator), $\dot{Q}_{\text{eva}}$ (heat transfer rate of low-temperature evaporator) and $\dot{Q}_{\text{abs}}$ (heat flow rate of high-temperature absorber), respectively. As $\dot{Q}_{\text{gen}}$ increases, the amount of generated refrigerant increases. Naturally, $\dot{Q}_{\text{eva}}$ and $\dot{Q}_{\text{abs}}$ also increase. Therefore, if the rate of increase in the numerators in Eq (3) and (4) are faster than the rate of increase in the denominators, the COP tends to increase, whereas if the rate of increase in the numerators is slower than the rate of increase in the denominators, the COP tends to decrease. For all four working fluids, the rate of increase in the cooling and heating effects is faster than the rate of increase in the amount of heat input to the generator as the generation temperature increases. Therefore, COP$_{\text{tot}}$ increases as the generation temperature increases for all working fluids.

4. Conclusion

In this study, four different working fluids were selected for the simultaneous cooling and heating absorption system, and the COP$_c$, COP$_h$ and COP$_{\text{tot}}$ were compared depending on the variations of the split ratio and generation temperature. From the results, the following conclusions were drawn.

(1) The COP$_{\text{tot}}$ of H$_2$O/IL ranges 0.84–0.90 which is higher value than that of R32/IL.

(2) For all four different working fluids, COP$_{\text{tot}}$ increases as generation temperature increases. Maximum COP$_{\text{tot}}$ of H$_2$O/IL is estimated 0.85–0.91. Maximum COP$_{\text{tot}}$ of R32/IL is calculated 0.41, showing 55% lower performance than H$_2$O/IL.

(3) COP$_{\text{tot}}$ of refrigerant/IL is similar to that of H$_2$O/LiBr. Since it can solve the crystallization phenomenon, which is the weakness of H$_2$O/LiBr, it is confirmed that the ionic liquid will be a strong alternative to the traditional working fluid.

Abstract

Global interest in carbon neutrality is increasing for a sustainable society in response to the climate crisis. Various studies are being conducted for carbon neutrality, and among them, many studies related to unused energy are being conducted. Many studies focused on the waste heat recovery system regarding the use of unused energy. Recently, interest in a chemisorption heat pump capable of performing a cooling based on low-temperature thermal energy has increased. This research conducted an experimental study to understand the performance characteristics of a chemisorption heat pump consisting of a condenser, an evaporator, and two reactors based on a low-temperature heat source (40°C). Experiments were conducted for cases where the adsorption/desorption operation time was 20, 30, and 50 minutes, and the average cooling capacity, COP, and SCP were presented for each condition when performing six alternating operations. As adsorption/desorption operation time went up, average cooling capacity, SCP were reduced and COP was increased.

Keywords: Chemisorption Heat Pump; Waste heat recovery; Adsorbent; Adsorption; Desorption;

1. Introduction

There is a growing interest in carbon neutrality around the world. The governments of some countries around the world, including South Korea, have announced national plans to achieve carbon neutrality in 2050 [1]. Research institutions around the world are conducting research on the use of renewable energy, process efficiency improvement, and waste energy recovery to achieve carbon neutrality. Among these research topics, in the case of waste energy recovery, many studies have been conducted on waste heat recovery. One study showed the amount of waste heat in each EU country and each industry sector [2]. In most cases, thermal energy of more than 100°C is emitted in the form of waste heat, and most studies have focused on utilizing waste heat energy in this temperature band. In addition, since the technical difficulty is high to recover low-temperature thermal energy of about 40 to 50°C, relatively little research has been conducted on technologies that utilize low-temperature waste heat energy of about 40 to 50°C.

The chemisorption heat pump is a refrigeration cycle driven by thermal energy. Fig. 1 shows the basic principle and cycle diagram of chemisorption heat pump [3]. Relatively high-temperature (T_h) thermal energy is supplied to the desorption reactor, medium-temperature (T_m) thermal energy is discharged from the condenser and adsorption reactor, and low-temperature (T_l) thermal energy is supplied to the evaporator. A cooling effect occurs in the process of supplying low-temperature thermal energy to the evaporator. In order to drive the chemisorption heat pump, a high-temperature, medium-temperature, and low-temperature heat source is required, and the combination of this temperature is determined by a combination of a working fluid and adsorbent. According to Yang et al. [3], when the working fluid of the low-temperature driven chemisorption heat pump is NH₃, NH₃Cl, PbCl₂ or NaBr are suitable as an adsorption material. Oliveira and
Generoso [4] conducted an experiment using a chemical adsorption heat pump driven by about 70°C heat energy. Oro et al. [5] conducted an analysis study on a chemisorption heat pump using waste heat of about 70 °C discharged from the fuel cell. Pacho [6] conducted an analytical and experimental study on a chemisorption heat pump driven by thermal energy of 120°C. In addition to these studies, various studies were conducted on the chemisorption heat pump, such as cycle analysis and Clapeyron curve [7-11].

Fig. 1. Schematic and Cycle Diagram of Chemisorption Heat Pump [3].

In this study, a cooling cycle experiment was conducted by using a chemisorption heat pump consisting of an evaporator, a condenser, and two reactors. By performing the alternating operation, cooling performance, COP, and SCP (Specific cooling power) of the system according to the alternating operation time were measured.

2. Experimental Apparatus and Procedures

Fig. 2 shows schematic diagram of chemisorption heat pump. The chemisorption heat pump is operated alternately, and a total of four operation modes are repeated. Each operation mode is implemented using a valve in the system, and the valve’s status under each operation mode is in shown in Table 1. In mode A, the working fluid is adsorbed and desorbed from the adsorbent in reactor 1 and reactor 2, respectively. Mode B is a preparation process for mode C, and the chillers connected to each reactor are changed. In mode C, the working fluid is adsorbed and desorbed from the adsorbent in reactor 2 and reactor 1, respectively. Mode D is a preparation process for mode A, and the chillers connected to each reactor are changed. In this study, experiment was conducted by setting \( T_h, T_m, \) and \( T_l \) to 40, 20, and 15°C, respectively. Chillers 1, 2, 3, and 4 supply cooling water of temperatures of 20°C, 40°C, 20°C, and 15°C to the system, respectively. Mode A, B, C, D were repeated as illustrated in Fig. 3, wherein \( \Delta t_1 \) was set to 20, 30, and 50 minutes, and \( \Delta t_2 \) was set to 5 minutes, and the experiment was conducted. During Mode B and D, Valve 5 was opened at the start of Mode B and D, and closed after 1 minute.

Temperature, pressure, and flow rate were measured using thermocouples, pressure transmitters, and flow meters, respectively, and the specifications of each instrument are as shown in the Table 2.

Ammonia was used as working fluid and NaBr was impregnated in Expanded-graphite and used as an adsorbent.
3. Experimental Results and Discussion

Figs. 4 ~ 9 show experimental results when $\Delta t_1$ was set to 30 minutes, and $\Delta t_2$ was set to 5 minutes. As shown in Fig. 3, Mode A and C were operated 4 and 3 times, respectively. If the alternating operation is repeated continuously, the initial conditions of modes A and C are constant. However, when the alternating operation is first started (0 second of Fig. 3), the initial condition of Mode A is different from the condition when the alternating operation is continuously repeated. Therefore, the data analysis was performed on the conditions under which the alternating operation was continuously performed. The experiment was performed by repeating modes A through D three times. This means that a total of 6 adsorption/desorption operations have been performed.

Each adsorption/desorption preparation and adsorption/desorption operation are defined as one cycle, and the start and end of each cycle can be expressed like the black dotted line in Fig. 4. In the first, third, and fifth cycles in Fig. 4, the working fluid is adsorbed and desorbed in Reactors 1 and 2, respectively. In the second, fourth, and sixth cycles, the working fluid is desorbed and adsorbed in Reactors 1 and 2, respectively. The working fluid was moved from the desorption reactor to the condenser and condensed. Therefore, the pressure of the desorption reactor is slightly higher than the pressure of the condenser as shown in Fig. 4. Meanwhile, the working fluid evaporated from the evaporator moved to the adsorption reactor and was adsorbed into the adsorbent. Therefore, the pressure of the evaporator is slightly higher than that of the adsorption reactor. It can be seen that the pressure of each component shows a repetitive tendency and is maintained during the alternating operation. Fig. 5 shows cooling capacity of evaporator. Cooling capacity was calculated by using temperature difference and flow rate of secondary flow ($Q = mC_p\Delta T$). In Fig. 5, the range 0 ~ 300 seconds is adsorption/desorption preparation operation, and after 300 seconds, it is adsorption/desorption operation. After adsorption/desorption preparation operation starts, the cooling capacity of the evaporator decreases to almost zero, and after adsorption/desorption operation starts, the cooling capacity increases rapidly and then gradually decreases. The cooling capacity was up to about 100 W. It can be found that the cooling capacity shows an almost constant tendency in 6 repeated cycles. Fig. 6 shows heat capacity supplied to desorption reactor. As shown in Figure 6, it can be seen that the heating capacity supplied to the desorption reactor increases rapidly after the start of the adsorption/desorption preparation operation and then gradually decreases. When the adsorption/desorption preparation operation starts, the cooling water of 40°C is instantaneously supplied to the reactor that had previously been supplied with cooling water of 20° C. Cooling water of 40°C is instantaneously supplied while the temperature of the structure (Stainless steel) of the desorption reactor is about 20°C, and the cooling water supplies thermal energy to increase the temperature of the desorption reactor structure. Therefore, the heating energy supplied to the reactor increases rapidly after the start of the adsorption/desorption preparation operation. After the temperature of the structure rises, the heat required for the desorption reaction is supplied to the reactor, and as the desorption reaction progresses, the desorption reaction slows down, so the heat supplied to the reactor gradually decreases over time. Olivera and Generoso [4] calculated COP of chemisorption heat pump based on the time averaged cooling capacity of evaporator and time averaged heating capacity supplied to reactor. In this paper, COP is obtained by dividing time averaged cooling capacity of evaporator by time averaged heating capacity supplied to reactor. Figs. 7 ~ 9 show time averaged cooling capacity of evaporator, time averaged heating capacity supplied to desorption reactor, COP of chemisorption heat pump. Average cooling capacity of evaporator is 73.2 (Cycle 1) ~ 87.3 (Cycle 6) W. Average heating capacity supplied to desorption reactor is 379.9 (Cycle 6) ~ 411.5 (Cycle 1) W. COP of chemisorption heat pump is 0.18 (Cycle 1) ~ 0.23 (Cycle 6) W.

As shown in Fig. 5, $Q_{eva}$ decreases as the adsorption/desorption operation time elapses. Thus, as $\Delta t_1$ increases, $Q_{eva,avg}$ and SCP decrease. Each time an alternating operation is performed, a large amount of heat energy is supplied to the reactor structure. Therefore, when the system is operated for a specific time span, the COP is increased when the number of alternating operations is reduced. For this reason, as $\Delta t_1$ increases as shown in Table 3, COP increases.

4. Conclusion

An experimental study on the refrigeration cycle of chemisorption heat pump system is conducted. Experiment was conducted by using a system consisting of two reactors, a condenser, and an evaporator. Experiment was performed under conditions in which coolant of 40°C, 20°C, 20°C, and 15°C was supplied to the desorption reactor, the adsorption reactor, the condenser, and the evaporator, respectively. Experiments were performed on conditions of 20, 30, and 50 minutes of adsorption/desorption operation time. As adsorption/desorption operation time increases, average cooling capacity, SCP were decreased and COP was increased. Based on this study, it is possible to confirm the performance characteristics of the low-temperature driven chemisorption heat pump system according to the adsorption/desorption operation time.

Abstract

In the project HpCosy the base for a decentralized brine-water heat pump system for flats in multi-family houses is developed and investigated. It encompasses the functions heating, cooling and domestic hot water preparation. Its control shall enable the consideration of availability of on-site produced photovoltaic electricity as a single unit within a swarm of all heat pumps within the building.

The comparison between a centralized and several decentralized heat pump systems clearly shows great advantages of the decentralized solutions (savings up to 31% of electric energy). However, the largest share of the energy saved is due to the elimination of DHW circulation.

The measurement of a HpCosy-unit in realistic and dynamic working conditions showed that an individual adjustment of the control of the individual swarm participants in response to a swarm signal is technically feasible and already leads to a reduction of the grid consumption in the selected and tested week.

The final simulations of the overall system show that - in addition to the savings achieved through the use of decentralized systems - an additional reduction in grid consumption of up to 5% can be achieved by increasing self-consumption by 11% to 17% with a swarm signal, indication whether there is a positive on-site energy production or not.

Keywords: heating; cooling; domestic hot water; multi-family houses; swarm control; photovoltaic self-consumption

1. Introduction

Heat for the provision of domestic hot water (DHW) will become more relevant than heat for heating due to increasingly better building insulation and therefore decreasing space heating demand. Cooling applications will be increasingly realized because of increased comfort demands and not least also due to the advancing climate change. In this context, it makes sense to use the same heat pump to generate both cooling and heating of hot water in the summer, and to operate it as far as possible with self-generated electricity from photovoltaics (PV) or to be able to react to tariff incentives for load shifting (demand side management).

Decentralized heat pump systems for heating and DHW provision in multi-family houses (MFH) with individual units per residential unit offer decisive advantages over central heat pumps. DHW circulation is not required, distribution losses can be avoided, and the lower requirements for DHW storage temperatures in accordance with the Swiss SIA 385/1 [1] standard will increase the efficiency of the provision of DHW. As a result of having several small units, the electrical power drawn can be more finely adjusted to the PV electricity produced.

When combined with geothermal probes as heat sources and heat sinks, the system is expected to have major advantages from both an energetic and an economic point of view.

2. Project goals

The main objective is to develop the basis for a new heat pump system, which has the following characteristics:

- Increased efficiency (30% less electrical energy demand) compared to current solutions with the same hygiene assurance (legionella protection) [2].
- Increased comfort by offering free cooling and/or active heat pump cooling function
- Increased flexibility of the brine circuit, which can be coupled with geothermal probes, energy networks, air heat exchangers or other heat sources.
- Development of a so-called swarm control for skillful consideration of the local PV electricity production.

3. Market potential

In a first step, the market potential for the application was analyzed and the requirements for a decentralized heat pump and storage unit defined, such as the necessary heating and cooling capacities, the power controllability, the necessary communication requirements, and the size of the DHW storage tank.

According to the Federal Statistical Office (FSO), there were a total of around 1.76 million buildings with residential use in Switzerland in 2019 [3]. Of these, around 1.48 million are purely residential buildings, divided into 1.0 million single-family houses (SFH) and 0.48 million MFH, of which around 0.25 million have between 3 and 9 flats. The number of residential buildings with secondary use and 3 to 9 dwellings is about 0.06 million. A first rough estimate for the HpCosy system potential results in about 0.31 million buildings with 6 dwellings on average, which would mean 1.86 million decentralized heat pumps.

A market survey of suitable heat pumps with DHW storage systems showed, that the devices for the application are already available. Of the 27 analyzed models with inverter drives, 13 are with heating powers in the range of 1-10 kW, which is regarded to be sufficient for the individual flats. Heating buffer tanks are not required for part load operation, as the output can be adjusted to a very low demand. The heating power ranges of the 13 selected models are shown in Fig. 1.

4. Comparison of centralized and decentralized heat pump systems

A combination of building simulations with the software TRNSYS and spreadsheet calculations for the heating system was used to compare a central with a decentralized heat pump system in an MFH. The modelling was done with the “Type 56” building model in TRNSYS. The modelled building is a three-storey renovated apartment building with six residential units: three residential units on the east side and another three on the west side [4]. Both the internal loads of the flats and the hot water demand are considered via individual user profiles. The location is the city of Zurich. The total heat demand of the flats is shown in Fig. 2 as the sum
of the space heating (SH) demand with ideal heating to a setpoint temperature of 21 °C and the hot water demand.

![Graph](image)

**Fig. 2: Heat demand in the MFH**

The heat supply of the building is either with a central heating system consisting of an inverter-controlled brine-to-water heat pump, two 600 liter DHW storage tanks and an 850 liter buffer tank for space heating, or six decentralized brine-to-water heat pumps, each with an integrated 220 liter DHW storage tank.

### 4.1. Centralized heating system

In the central system according to Fig. 3, the room heat is distributed by means of a central heating circuit pump and one line per residential unit. Each apartment is equipped with a room temperature controlled thermostatic valve. An overflow valve is integrated into the heating circuit system to keep the pressure constant and prevent the pump from working against closed valves. The DHW distribution is kept warm by hot water circulation.

![Diagram](image)

**Fig. 3: Hydraulic scheme of the centralized heating system**

### 4.2. Decentralized systems

The decentralized systems shown in Fig. 4 were modeled as compact units with integrated DHW storage tanks (220 l) and direct connection to space heating without an SH buffer tank. The set temperature in the DHW tank is 55°C (SIA 385/1:2020 for systems without DHW recirculation), which can be achieved by the heat pump without the use of an electric heating element; the space heating curve can be set individually in each unit according to the preferences of the occupants and the heat loss rate of the apartment, which is higher for apartments just under the roof or in contact with the basement.
The parameterization of the heat pumps for calculating the electricity consumption was carried out according to two models of the company CTA AG:

- Optiheat Inverta 17e for the central system, and
- Optiheat Inverta DHW for the decentralized systems.

The dimensioning of the heat pump for the central heating system was based on the heat demand of the building described above. The aim of the design was a model that can cover the heat demand with 2500 full load hours. The total space heating demand (including losses) in the building is about 58 MWh. Considering the full load hours of 2500 for the heat pump operation, the heat pump capacity is 23.11 kW. The Optiheat Inverta (OHI) 17e model from CTA AG with an output of 25.6 kW at a compressor speed of 70 rps was selected as the basis for the calculations. The COP values of the two HPs were calculated as a function of the condenser outlet temperature and the compressor speed.

The decentralized systems supply the heat directly to the respective heating circuit. For the distribution of DHW, a circulation system with 60/55 °C in the flow and return - and a correspondingly high setpoint temperature in the storage tank - is integrated in the central system; the decentralized systems can operate without the circulation, which is why a temperature of 55 °C in the individual storage tanks is sufficient (SIA 385/1:2020).

Comparing the heat balances of the variants on Error! Reference source not found., the difference between the centralized and the decentralized system is relatively small. For space heating, only 1.5 MWh of losses occur in the central system, with a heat demand of 49.6 MWh. For DHW, the losses from storage and distribution amount to 7.4 MWh, with a demand of 17.3 MWh. For the decentralized systems, the only losses are the heat losses from the domestic hot water storage tanks. These amount to a total of 2.9 MWh, which can be credited to the space heating of the respective zone.

However, the comparison of the electricity demand shown in Fig. 6 discloses a big difference between the centralized system and the 6 decentralized systems. It becomes clear that the greatest difference lies in the DHW preparation and distribution.

With a target room temperature of 21°C in each flat, the decentralized systems could save 12% of the electrical energy used for space heating. For hot water production, the total saving, i.e. including coverage of heat losses from circulation, is as much as 53%.
5. Swarm signal

The comparison of centralized and decentralized systems in a MFH revealed already a significant advantage of the decentralized systems with a control strategy that is based on the individual demand. The next step was to investigate the potential benefits in terms of self-consumption of the locally generated PV power of an aggregation of the 6 HP systems into a swarm. The individual HP system has its own controller which also listens to a guide signal, the so-called “swarm signal” to rather consume electricity or not. Therefore, a signal is to be calculated and communicated to the individual entities, whose reaction to the signal is programmed to their controllers. There are different concepts of guide/swarm signals feasible:

- A locally generated by regarding the PV production and electric consumption of the building itself
- A remotely generated by the electricity supplier (using tariff models, regarding demand and supply)

For the tests, a locally generated swarm signal was used. The central unit records the target value, namely the difference between local PV power generation and the consumption of all participants for household appliances and the operation of the heat pumps. The aim of the swarm control is to minimize this difference. The difference $S$ is transmitted as a unidirectional signal to the individual HP systems. The transmission is linked to the production of the local PV system. Only from a threshold value of 200 W produced PV electricity, the swarm signal processing is enabled. Otherwise, the HP control is purely demand driven.

The signal $S$ is limited to the peak power of the PV plant in kW: $-P_{PV}$ in kW ... $S$ ... $P_{PV}$ in kWp.
6. Laboratory setup and measurements

A sample of a HP and DHW system from the company CTA AG was measured in the FHNW "hardware-in-the-loop" test stand according to Fig. 7 for the provision of DHW, space heating (SH) and cooling; its functionality was tested and its efficiency evaluated. In the background of the HP, the emulators for the building heating and the geothermal probe are visible, which are operated in a simulation-coupled manner. The DHW tapping takes place in real according to the SN EN 16147:2017 tapping profile L [5].

Fig. 7 shows the schematic of the laboratory measurement with the emulators (highlighted with color). The other five heat pump/storage systems of the other flats are just virtual in the simulation. Temperatures for all supply and return lines, tank layer temperatures, volume flows and electrical powers are recorded.

A total of three different dynamic 7 day test sequences were measured with this setup:

- only DHW preparation and tapping for 4 days and standby mode for 3 days
- heat demand for SH and DHW with a purely demand-driven control without PV power
- heat demand for SH and DHW with the specification of a swarm signal for the measured unit

6.1. DHW Storage Tank CTA Optiheat DHW

Fig. 8 shows the storage tank temperatures measured at 400, 700, 1000 and 1300 mm above the bottom of the tank (Tw1 … Tw4) and the volume flows of the heat pump (HP) charging (Vdot_HP) and hot water tapping (Vdot_DHW) during a 24-hour cycle of the measurement. The storage tank has a total height of 1300 mm. The power-weighted mean flow temperature of the HP during this cycle was 44.5 °C; the power-weighted mean flow temperature of the DHW was 51.4 °C.
For efficient DHW production with the HP, it is particularly important to keep the flow temperature of the HP as low as possible by avoiding mixing in the storage tank. Any mixing of fluids of different temperatures means exergy losses, which must be compensated again via the HP, with the corresponding negative effects on the efficiency of the HP. The temperature curve in Fig. 8 shows the unavoidable mixing processes in the lower part of the storage tank due to the internal heat exchanger. However, the temperatures in the upper part of the storage tank remain unaffected during charging.

The HP had to deliver in total 13.2 kWh to cover the heat demand of 11.9 kWh. The average charging temperature was 44.7 °C, the DHW was delivered with an average temperature of 51.5 °C. The electricity demand of the HP was 4.1 kWh, leading to a power factor (PF) of 3.3 respectively 2.9 considering the thermal losses. The source temperature was held at 5 °C throughout the test.

6.2. Testing of the HP system with demand control (Test 007) and swarm signal control (Test 011)

The developed swarm signal control strategy was transferred to the system installed in the laboratory, but not activated/enabled for the initial tests.

As a reference base, the purely demand controlled system setup was tested (Test 007). The whole building was simulated in advance in detail to generate the time series of the five other heat pump systems of the building. The electric power rates of the five simulated heat pump systems were fed into the real-time simulation running during the laboratory test. The data collected from the “hardware-in-the-loop” measured heat pump system were also used to form a swarm of totally six heat pump systems within the simulation.

Further tests were performed to verify the correct function with the swarm signal control (Tests 008, 009 and 010). During Test 011 the swarm signals for power and control enabling were calculated in the real-time simulation and processed by the heat pump controller.

![Compressor electric power and swarm-signal](image)

Fig. 9: Compressor electric power and swarm-signal

Comparing the compressor electric powers of test 007 and 011, it can be seen in Fig. 9, that the compressor of the swarm signal controlled system (green curve) runs higher and more during the times with a positive swarm signal.

The HP controller reactions to the swarm signal were:
- Rising or lowering the SH supply temperature setpoint as an offset +/- 5K of the heating curve value
- Rising or lowering the DHW temperature setpoint up to max. 58°C / down to min. 48°C and rising or lowering the compressor speed during DHW preparation nom/min/max 44/30/65 Hz
Fig. 10 shows the time series of the two test 007 and 011 for the simulated and measured week of 3/24 - 3/30. This week was selected because it had sufficient PV power, days of SH requirements and days without. Shown are the SH, DHW, electric compressor energies and the generated swarm signals during test 011.

6.3. Comparison of the energy consumption from the grid and PV for the tested week

Table 1. shows the final energies and the average COP values after 7 days of testing. Test 011 showed higher energy values for the SH and DHW and lower values for COP. The swarm signal controlled system had higher temperature setpoints for SH and DHW in average, so the efficiencies were in total 13% less compared to the demand controlled system. On the other hand, the swarm signal controlled system reduced the grid consumption from 36 kWh to 31 kWh (-14%) by enhancing the PV power consumption. With the chosen swarm signal concept, yearly results were evaluated with a series of test-validated simulations in paragraph 7.

The influence of the swarm signal control on the operation can be seen in Fig. 11. The tested week has sufficient PV power, so the during the day, the DHW storage was loaded to higher temperatures. Also, the SH supply temperatures were raised in test 011 and the operations shifted to daytimes with PV power.

Fig. 11: Heat pump source and load temperatures
7. Annual simulations

Annual simulations of the selected swarm control strategy of the decentralized units with the aim of using PV electricity as efficiently as possible were conducted with a simulation model that has been re-parameterized according to the performed hardware-in-the-loop measurements to obtain viable results.

Figure 12 shows the energy balances with swarm control for different PV areas on a monthly basis. The goal of the simulations is to minimize the term “GridtoHP”, the electric energy from the grid to the HP, and maximize “PVtoHP”, the electric energy from the PV system to the HP. The term “ELfromGrid” is the electric energy from the grid as an input (IN) to the system, “GridtoHH” is the electric energy from the grid used for the household appliances as an output (OUT), in the sense of where it comes from and what it is used for.

As the swarm signal strength is a function of the PV kWp sizing compared to the totally rated electric consumption of the building, three PV areas 60, 120 and 180 m² of specified PV modules were simulated and compared with the base case of purely demand controlled HPs. The grid consumption could be reduced up to 5% and the self-consumption increased by 11 to 17%. 

![Energy balance](image-url)
Figure 13 shows the grid purchase and the grid feed-in of the systems with swarm control compared to those with purely demand-based control. The comparison was carried out for different PV system sizes. As expected, the reduction of the grid consumption (blue numbers in the graphic) is smaller than the reduction of the grid feed-in (green numbers). This is due to the reduction in efficiency with forced operation at higher supply temperatures. The ratio of saved grid consumption to lost feed-in is between 2.2 (with 60 m² PV area / 11.3 MWh PV yield) and 1.9 (with 180 m² PV area / 23.8 MWh PV yield).

8. Summary and conclusion

The comparison between a centralized and several decentralized heat pump systems clearly shows great advantages of the decentralized solutions, even in a purely demand controlled operation without taking PV electricity or a swarm control into account.

The savings in the base case with a room set temperature of 21 °C are 28% in electric energy. The variation of room set temperatures revealed that the savings could increase up to 31% when only one of the apartments demands a high room temperature. However, the largest share of the energy saved is due to the elimination of DHW circulation.

The measurements showed that an individual adjustment of the control of the individual swarm participants in response to a swarm signal is technically feasible and already leads to a reduction of the grid consumption in the selected and tested week.

The final simulations of the overall system show that - in addition to the savings achieved through the use of decentralized systems - an additional reduction in grid consumption of up to 5% can be achieved by increasing self-consumption by 11% to 17%.

Abstract

Reverse electrodialysis (RED) technology provides a way to harness clean and sustainable energy from salinity gradients. First introduced in 1954 [4], this technology has not been widely applied due to limitations requiring direct access to fresh and seawater. The novel approach of introducing a MultiSource heat pump technology into a RED-based system allows users to take full control of the salinity gradient by dissolving and regenerating the salt in a closed-loop system. The heat pump exploits otherwise wasted low-grade heat energy to simultaneously heat and cool salt solutions to produce electricity and/or hydrogen by reverse electrodialysis process. The untapped potential of excess heat as a source of energy is substantial, with Europe and The United States alone boasting an estimated 5791 TWh of accessible waste heat per year [13, 21, 22]. This innovative approach unleashes the full potential of salinity gradient energy, thus offering a solution to the current bottleneck of the seaside water source dependency. Approximately one-third of the global electricity is consumed by residential buildings [8,9]. The unique combination of the reverse electrodialysis process and MultiSource heat pump technology paves the way to significantly reduce energy consumption as well as greenhouse gases (GHG) emissions on a global scale. In this work, we will explore some of the theoretical aspects in more detail.

1. Introduction

Air conditioning is a process which allows cooling, heating, and ventilation of an environment. Although the term “air conditioning” is predominantly associated with the cooling process, the process of air conditioning systems also involves humidity control and air cleaning as its key functions. Currently, the use of air conditioners and electric fans for cooling purposes represents 20% to 40% of the global building electricity consumption, which is only projected to increase with elevated global temperatures [2,9]. Presently, air conditioning is used in approximately 90% of homes in the United States, whereas in locations such as India, air conditioning is less prevalent, with an average of around 5% of homes utilizing this technology [3]. Worldwide demand for cooling is rising fast [3]. Currently, more than one-third of the electricity generated in the world is consumed in the residential sector and most of this energy is used for water heating, air conditioning, and space heating [8,9]. Earth’s population and global warming are only expected to increase while global energy demand from air conditioners is anticipated to triple by 2050 [3]. In these situations, the demand for air conditioning will surge while imparting a significant impact on the world’s overall energy reliance, putting pressure on the electrical grid, and driving up global greenhouse gas (GHG) emissions. On the other hand, at the 2022 United Nations Climate Change Conference of the Parties (COP27), the United States launched the Net-Zero Government Initiative, inviting governments to lead by example and achieve net-zero emissions from national government operations by no later than 2050 [14]. Therefore, renewable energy resources have been one of the most important, widely researched, and discussed global topics for over a decade. With the ever-increasing problem of global warming, there has been a global effort in steering away from carbon-based fuels. There are a wide variety of natural sources for clean energy including solar and wind energy. While it is crucial that we continue to make a switch to these resources, it is important to note that their availability, such as usage during specific times of the day, and reliability are limited. They also require massive amounts of energy storage for them to be a sustainable solution to our energy crisis. Therefore, if we want to address the issue of global warming and achieve a net-zero objective, we must address both restrictions: the availability of energy and GHG-neutral air conditioners. The untapped potential of excess heat as a source of energy is considerable, with Europe alone boasting an estimated 2860 TWh of accessible waste heat per year [13]. This energy source is widely available and abundant, with the added advantage of being constantly accessible, often in the form of unwanted waste. The convergence of a MultiSource heat pump and enhanced Reverse Electrodialysis (RED) promises to become a solution to this problem. The RED Heat Pump (RED-HP) technology relies on waste heat and low-grade heat energy to produce electricity and/or hydrogen, with the added benefit of being entirely carbon-neutral. This technology promises to cool a structure and convert waste and low-grade heat into usable energy. The game-changing RED-HP technology has the ability to significantly reduce energy usage and GHG emissions on a global scale.

2. Salinity Gradient Power

Salinity Gradient Power (SGP) is defined by Gibbs free energy of mixing between two water sources of differing salt concentrations. The concept of SGP was first proposed by R. E. Pattle in 1954 and has since expanded into a variety of methods by which to harness this chemical potential of mixing two water streams with different salinity [4].

During the uncontrolled mixing, \( \Delta G_{mix} \) (Gibbs energy of mixing) is released into the environment. This released chemical energy represents the maximum potential energy that can be harvested. The Gibbs free energy [J] released per mole during the mixture of two solutions is given below:

\[
\Delta G_{mix} = G_b - (G_c - G_d)
\]  

(1)

Where \( \Delta G_{mix} \) is the free energy of mixing [J/mol], \( G_b \) is the Gibbs energy of the mixture, the brakish water [J/mol], \( G_c \) is the Gibbs energy of the concentrated salt solution (e.g. brine) [J/mol] and \( G_d \) is the Gibbs energy of the diluted salt solution (e.g. fresh water or river water).

\[
\Delta G_{mix} = \Delta H - T \cdot \Delta S = -T \cdot (S_b - S_d - S_c)
\]  

(2)
\[ S = -R \cdot nT \sum_i x_i \ln (x_i \cdot \gamma_i) \]  

(3)

Where \( S \) is the entropy (J/K), \( T \) is the temperature of mixture (K), \( R \) is the universal gas constant (8.314 J/(mol·K)), \( nT \) is total number of moles (mol), \( x_i \) is the mole fraction of component \( i \), \( \gamma_i \) is the activity coefficient of component \( i \), which accounts for the non-ideal behavior of the solution. The change in enthalpy \( \Delta H \) (J) is not taken into account in equation 2. The objective of equation 2 is to calculate the theoretically available energy from mixing two dissolved salt solutions with different salinities.

The three primary means of harnessing salinity gradient power from this extraordinary heat pump assisted close loop process are the reversal of the capacitive deionization (RCD) [10], pressure-retarded osmosis (PRO), and reverse electrodialysis (RED). For the basis of this paper, only RED will be discussed in detail as it is believed to have the greatest potential based on its high efficiency [17, 18].

3. Reverse Electrodialysis (RED)

Reverse electrodialysis was first proposed and demonstrated by Richard Pattle between 1954 and 1955, but it was not until a push from the first and second oil crises in 1973 and 1979 that interest in RED was truly heightened [4]. Today several institutions have committed to the RED technology as a way to harness the salinity gradient power (SGP). SGP is a sustainable energy source with a large worldwide potential of 22776 TWh per year, and it is available at deltas where river flows into the sea [20]. Commonly referred to as “Blue Energy”, this renewable and carbon-free energy source provides a significant advantage over other renewable sources such as wind and solar power, as it is constantly accessible. The current limitation of this technology is that it can only be applied in specific locations where water with different levels of salinity is available, namely areas where there is access to both low and high salt concentration water.

Reverse electrodialysis utilizes the salinity gradient of two water solutions to produce power in the form of electricity (Figure 1). When salt dissociates in water two ions are formed (anions and cations) containing positive and negative charge. Naturally, concentrations of ions dissociated in the water tend to flow from high concentration to low concentration and can also be further explained by the Donnan exclusion principle [7]. Anions migrate through the anion exchange membrane (AEM) toward anode(s) and cations move through the cation exchange membrane (CEM) towards cathode(s). For example, a positively charged cation can only move through a cation exchange membrane however a negatively charged anion would be blocked by repulsion. It is the opposite for an anion exchange membrane as positive cations are blocked and negatively charged anions can pass thorough. This dynamic allows for the controlled mixing of salts in the RED cell which creates an ionic potential. As ions flow from the concentrated to dilute solution, ions from a separate recirculating rinse solution are pulled from one electrode to the other. This overall movement of ions creates a stack potential that can be harvested through an external load connected to both electrodes and can be calculated using the Nerst equation:

\[ \Delta V^0 = N \frac{\Delta RT}{2F} \ln \left( \frac{a_e}{a_d} \right) \]  

(4)

Where \( \Delta V^0 \) is the theoretical stack potential [V], \( N \) is the number of membranes [-], \( \alpha \) is the membrane selectivity [-], \( R \) is universal gas constant [8.314J/(mol·K)], \( T \) is the absolute temperature [K], \( z \) is the electrochemical valence [-], \( F \) is the Faraday constant [96485 C/mol], \( a_e \) is the activity of the concentrated solution [mol/L]

A RED cell can operate in various modes, the flow of the two solutions can be directed in co-flow, counter-flow, or cross-flow. Furthermore, electrodes can be composed of a single part or multiple segments, with studies showing that multiple segmented electrodes can enhance the efficiency of the cell stack and increase the overall power density [6].
Figure 1. Process of reverse electrodialysis.

At auxiliary electrodes (anode and cathode) red-ox couple solution such as hexacyanoferrate(II) and hexacyanoferrate(III) can be used to minimize losses and produce electricity. In addition, it should be noted that hydrogen gas can also be generated through the process of water splitting reactions:

Anode: \[2\text{H}_2\text{O} \rightarrow \text{O}_2 \uparrow + 4\text{H}^+ + 4\text{e}^-\] (5)

Cathode: \[4\text{H}_2\text{O} + 4\text{e}^- \rightarrow 2\text{H}_2 \uparrow + 4\text{OH}^-\] (6)

Numerous publications have covered the topic of hydrogen production using reverse electrodialysis \[16, 19\], and thus our study will not specifically address this area.

The power output of a RED cell stack depends on the stack resistance and electromotive force. The stack resistance \(R_{stack} [\Omega]\) is a function of the cell resistance \(R_{cell} [\Omega]\), the number of cell pairs \(N\), \(A_{mem}\) is the effective membrane area \([m^2]\) and the resistance of the electrode system \(R_{electrode}\).

\[R_{stack} = \frac{N}{A_{mem}} \cdot R_{cell} + R_{electrode}\] (7)

The cell resistance \(R_{cell} [\Omega \cdot m^2]\) is a function of the resistance of the cation \(R_{CEM}\) and anion membrane \(R_{AEM} [\Omega \cdot m^2]\) and the resistance of the concentrate and dilute cell compartments (\(R_{con}\) and \(R_{dil}\)).

\[R_{cell} = R_{AEM} + R_{CEM} + R_{con} + R_{dil}\] (8)

The resistance of concentrate \(R_{con} [\Omega \cdot m^2]\) and dilute solution \(R_{dil} [\Omega \cdot m^2]\) can be calculated as below:

\[R_{con} = \frac{d_c}{\kappa_c}\] (9)

\[R_{dil} = \frac{d_d}{\kappa_d}\] (10)

As shown, \(R_{con}\) and \(R_{dil}\) are a function of the compartment thickness \(d_c [m]\) and solutions conductivity \(\kappa [S \cdot m^{-1}]\).

The maximum power output \([W]\) and power density \([W/m^2]\) can be calculated using the following equation:
Where $A_{\text{total}}$ is the total membrane used and the external load and internal load is assumed to be equal.

4. Heat Pump

Heat pumps offer an energy-efficient alternative to furnaces and air conditioners for all climates. They provide optional year-round cooling or heating utilizing a vapor compression cycle, thermoelectric cooler, and/or chemical absorption process. Heat pumps do not create heat, they redistribute and move heat. Passively, heat moves from hot to cold. With a heat pump, one can actively cool and heat a structure by moving heat from cold to hot. The Coefficient of Performance (COP) of a heat pump can be used to determine a heat pump’s efficiency [1]:

\[
\text{COP} = \frac{\text{Output Capacity (W)}}{\text{Power Input (W)}}
\]

Figure 2 provides a visual representation of the heat pump’s operation process. As shown, with an input power of 1500 watts, 3000 watts of heat equivalent is harnessed from a cold stream. The heat pump is capable to concentrate the heat and multiply it by a factor of 3 to produce 4500 watts of heating. In the present scenario, the COP\text{Heating} is 3, although it should be noted that depending on the season, the COP\text{Heating} can reach values as high as 7 [23, 24, 25].
5. Reverse Electrodialysis Heap Pump (RED-HP)

RED is a promising technology for generating renewable energy from the salinity gradient in natural water sources, such as rivers and oceans, without the need for combustion or fuel consumption. The technology has the incredible global potential of 22776 TWh per year of electricity to contribute to a more sustainable and low-carbon energy system, particularly in coastal regions where there is a significant salinity difference between seawater and freshwater [20].

Several attempts have been made to upscale the RED technology to a commercial level [5]. However, no one has yet managed to bring it to a commercially viable level, partly due to the high price of the ion exchange membrane, which is a significant barrier to commercialization. As a general estimate, the cost of an ion exchange membrane can range from around $20 to $200 per m². To date, the majority of the research and pilot systems have been performed as an open loop system utilizing seawater and freshwater. The dependence on both fresh and seawater not only poses limitations on the applicability of this technology but also restricts the potential locations for implementation. Furthermore, the power output of the system is constrained by the specific types of salts and their concentrations that can be utilized by the technology. Additionally, the use of seawater and freshwater requires large utility costs to pretreat the water. Several steps of microfiltration, ultrafiltration and reverse osmosis filtration is required to remove unwanted sediments, organics and objects out of the natural water streams. This results in the need for large quantities of membranes in order to generate power. Therefore, using closed loop system with a selected salt type and its concentration to deliver the highest available salinity gradient will unlock the potential of reverse electrodialysis globally.

MultiSource heat pump technology utilizes thermal energy and waste heat using proprietary thermal chemical optimization techniques that greatly reduce or eliminate the resulting carbon footprint while providing simultaneous heating and cooling [25]. By introducing MultiSource heat pump technology to a RED-based system, high levels of power efficiency can be achieved in a closed-loop system [25]. Simultaneous heating and cooling provided by the heat pump can be used to create an optimal artificial salinity gradient. Figure 3 shows a schematic representation of the RED-HP closed loop system.

![Figure 3. The closed-loop RED-HP system concept.](image-url)
In this process, a salinity gradient can be regenerated by leveraging the power of a heat pump and using a salt with a steep solubility curve. As shown in the Figure 4 salts such as potassium nitrate and calcium chloride have a steep exponential solubility curve. Consequently, a highly concentrated salt solution can be achieved at temperatures greater than 65°C and a dilute solution can be achieved by precipitation of salt at lower temperatures ranging from 5-20°C. To reduce energy consumption, the heat from the spent dilute solution can be exchanged with the refreshed dilute solution, as illustrated in Figure 3. The main contributor to the energy input is heating up dilute solution from, for example, 10°C to approximately 65°C. The energy required to heat up 1m³ of water from 10°C to 65°C is 63.9 kWh in the absence of a heat pump. However, the use of an efficient heat pump with a COP of 7 reduces the required electrical energy to heat up 1m³ of water from 10°C to 65°C to only 9.1 kWh. Furthermore, during the process, the spent dilute solution can be used as a heat source, resulting in a more energy-efficient system. It is important to note that excess heat is one of the largest untapped energy sources and it can be leveraged by utilization of MultiSource heat pump technology [25]. Moreover, it is highly advantageous to have a closed-loop system as the water pretreatment cost are removed, and various selected salts can be used in a controlled manner.

![Figure 4. Various salt solubilities at varying temperatures.](image)

The results from the modeled data are presented in Table 1. Salinity gradient, which refers to the difference in salt concentration, is a critical parameter for achieving high power density. To reach a highly concentrated solution of potassium nitrate, the RED process should be operated at an elevated temperature of 65°C where 12 mol/L KNO₃ solution can be obtained. On the other hand, dilute solution concentration of 2 mol/L is limited by solubility of KNO₃ at low temperature of 10°C. Both solutions have relatively high molarities above 0.5 mol/L, and therefore, activity coefficients were calculated using the Stokes-Robinson [16]. A higher temperature has a positive impact not only on the potential of the RED stack, which is calculated from the Nernst equation (Equation 4), but also on the membrane resistance, which decreases with increasing temperature [15]. The biggest contributors to RED stack resistance are membranes and dilute compartment resistance, which is related to compartment thickness [11]. Therefore, since we operate at higher salt concentrations and elevated temperatures, we assumed anion and cation exchange membrane resistance of 1 Ω cm². Membranes with resistance of 1 Ω cm² or lower are already commercially available [11]. The thickness of the dilute compartment was set in the RED model to 150µm to limit the dilute compartment resistance. The resistance of the electrodes is assumed to be negligible as a full-size stack will contain at least multiple hundreds of membranes reducing the contribution of the electrode resistance to less than 2%. The average membrane permselectivity is assumed to be 90%. Our RED model, based on equations 4-8, gives a maximal theoretical power density for 400 cell pairs, equivalent to 200m² of membrane area. The maximal achievable power density is 5.3W/m² of membrane area and the power output of a single stack is 1.06kW. It is important to note that the RED stack dimensions are 0.5m width, 0.5m height and 0.25m length (including 0.05m for auxiliary electrodes). These dimensions translate to a power density of 16.9kW per m² of RED stack. However, in practical application of RED,
factors such as spacer shadow effect, current leakage, and concentration polarization phenomenon might limit this power density [15]. Energy spent on pumping dilute and concentrated solution was not taken into account; however, it is estimated to be less than 3-10% of the total power output of the RED system [18].

Dilute and concentrated buffer tanks need to have enough buffer capacity to operate at the most optimal salinity gradient. The theoretical available amount of energy available from the mixing of two salt solutions can be calculated from the Gibbs energy of mixing and thus the theoretical potential of salinity gradient energy can be evaluated. The energy theoretically obtainable from the mixing of 1 m$^3$ of 12 mol/L concentrated solution with 1 m$^3$ of 2 mol/L dilute solution at a temperature of 65ºC, calculated from Equation 1-3, equals 9.1 kWh (32.8 MJ). This allows a 1.06 kW system to operate for multiple hours without the need for dilute compartment regeneration and loss of the salinity gradient. However, there is energy needed to heat up the solution after dissolving KNO$_3$. The enthalpy to dissolve KNO$_3$ in water equals to -34.9 kJ/mol (-9.69 Wh/mol) [16]. This means that potassium nitrate is an endothermic salt and when it dissolves in water, it absorbs heat from its surroundings. If 1 m$^3$ of 12 mol/L concentrated solution is mixed with 1 m$^3$ of 2 mol/L dilute solution, then both solutions end up with a concentration of 7 mol/L. Therefore, to regenerate 1 m$^3$ of dilute solution, 505.5 kg of KNO$_3$ salt (5000 mol) need to be precipitated and dissolved in the concentrated solution tank. The energy required to heat up 1 m$^3$ of concentrated solution is 48.4 kW. This means that in order to harvest 9.1 kWh of electricity, 48.4 kWh of heat needs to be used to heat up 1 m$^3$ of concentrated solution. It is important to note that by using efficient MultiSource heat pump technology with a COP$_{heating}$ of 7, only 6.89 kWh of electrical energy will be spent to compensate for dissolving of 505.5 kg of KNO$_3$ salt. This energy can be transferred from the dilute solution where the precipitation (dilute solution regeneration) process takes place at a low temperature of 10ºC. On the other hand, it is advantageous if an exothermic salt is selected because the concentrated solution will be heated up by the energy during dissolution. In addition, it should be noted that energy recovery from salinity gradient energy in reverse electrodialysis is between 20% and 80% [17]. A reverse electrodialysis system was studied for a period of 30 days using natural seawater and river water, and the energy recovery values ranged between 30% and 37% [18]. The obtainable energy recovery from salinity gradient energy depends mainly on the operational current density and the internal stack resistance, which is dominated by the dilute solution resistance and the resistance of membranes.

6. Conclusions

The potential of excess heat energy worldwide is substantial and could play a significant role in reducing global energy consumption and greenhouse gas emissions if efficiently harnessed. This energy source is widely available and abundant, with the added advantage of being constantly accessible, often in the form of unwanted waste.

This work identifies and quantifies the potential and operating window of RED as a sustainable energy source for excess heat recovery, utilizing heat pump technology to maintain a constant salinity gradient. The closed-loop 1kW RED-HP system concept was presented, and theoretical power output model was made. The theoretical open circuit potential was 36.7V and the theoretical power density was 5.3 W/m² of membrane area and 16.9 kW/m3 of RED stack. To achieve these power density numbers 400 cells pairs of membranes with 0.25m² area per cell are required as well as volume of 1m³ of concentrated (12mol/L KNO₃) and 1m³ of dilute solution (2mol/L KNO₃). Potassium nitrate salt was selected due to its solubility and temperature relationship, which allows for dilute and concentrated solution regeneration at a lower temperature. However, potassium nitrate is an endothermic salt and when it dissolves in water, it absorbs heat from its surroundings, which works against our heat transfer. The ideal salt for this process should be an exothermic salt that releases energy during dissolving and heating up of a concentrated solution, while absorbing energy during crystallization and cooling down the dilute solution at the same time.

The results of this study have significant implications for reducing global energy consumption and greenhouse gas (GHG) emissions. The RED-HP concept is currently in the process of prototype validation to further investigate its practical applications.

Abstract

In Japan, a two-step process is applied to the LCCP evaluation of heat pump-type air conditioners with next-generation refrigerants. This report mainly describes the first step of the process through to the LCCP evaluation methods, together with the concept of the study utilizing field data and hypotheses. In particular, a representative model is selected as an example of general split-type air conditioners, and it is considered in two ways, one of which is only as evaluation for a system drop-in of candidate refrigerants replacement while the other is in terms of system optimization, both using the candidate refrigerants to be examined R290, R32, R454C (and R22, R410A). On the basis of such systems, this report explains a calculation method using the performance simulation that is adopted as a standard tool by the Japan Refrigeration and Air Conditioning Industry Association (hereinafter referred to as “JRAIA”).

The report also presents an overview of a project to establish a new concept and hypothesis for LCCP evaluation in which field data related to air conditioners is adopted.

Keywords: LCCP, Air-to-Air, Heat Pump, Next-Generation refrigerant, COP, Residential A/C

1. Introduction

The main issues of recent urgent environmental efforts to address global warming in relation to air conditioners (hereinafter referred to as “AC”) are the Kigali Amendment to the Montreal Protocol in globally, the F-Gas Regulation in Europe, and the Act on Rational Use and Proper Management of Fluorocarbons in Japan.

The Kigali Amendment is a regulation aimed at gradually reducing the production and consumption amounts of refrigerants used in CO2 equivalents. This regulation is a global warming countermeasure to be promoted worldwide by focusing on a transition to lower GWP refrigerants. For actual global warming countermeasures, it is important not only to reduce the GWP of the refrigerant, but also to improve the performance of equipment by reducing the amount of greenhouse gas emissions derived from power consumption.

Report of IEA gives an overview of the forecast of demand for residential AC cooling by 2050 by country/region based on the Future of Cooling report published by the International Energy Agency (hereinafter referred to as “IEA”) [1]. As can be seen, the chart indicates that the world’s demand for residential AC cooling will expand rapidly by 2050. The use of AC in the United States and Japan will increase at a gradual pace. On the other hand, due to growing demand in India, Indonesia, Brazil, China, and EU countries, the world’s AC demand is projected to rise considerably – by more than three times – by 2050. It is anticipated that such an increase in AC demand will not only cause refrigerants to have a direct impact on global warming but also possibly give rise to an increase in the indirect impact on global warming due to the power consumption of AC equipment. Therefore, in addition to the direct impact of refrigerants, the energy efficiency and power consumption of equipment will become the focus of even greater attention in the years to come.

For this reason, we believe the LCCP evaluation to be studied in Task 3 is an important evaluation for selecting the most suitable refrigerants because it takes into account the transition to lower GWP refrigerants
and the environmental impact of power consumption. To make the evaluation more realistic, based on the concept of S+3E (Safety, Environment Performance, Energy Efficiency, Economic Feasibility) advocated by JRAIA, it is desirable to conduct a comprehensive evaluation from multiple perspectives, including safety, cost, sustainability, and infrastructure development, in addition to environmental assessment through the LCCP evaluation.

The study conducted by JRAIA in December 2008 [2] is introduced as a previous case study relating to the LCCP evaluation. The LCCP evaluation in this case was based on a simplified simulation, with climate and other conditions set in accordance with Japanese Industrial Standards (hereinafter referred to as “JIS”).

There is also a case study concerning IEA-related LCCP evaluation, which was presented by the University of Maryland in the United States (hereinafter referred to as “UMD”) [3]. In this paper, mainstream residential ACs in the United States are evaluated; therefore, it is necessary to conduct an evaluation for the split-type heat pump ACs that are in conventional residential use in Japan and Asia.

Accordingly, in Japan, a new LCCP evaluation is carried out in two steps for heat pump-type ACs that use next-generation refrigerants. The first step (this report) examines the LCCP evaluation methods, and the second step to be implemented in the future will mainly describe a new evaluation applying performance simulation and the concept and hypothesis of the study utilizing market data.

In the evaluation in this report, a representative model of typical split-type ACs is selected, and refrigerants R290, R32, R454C, R454C, R22, and R410A are examined. Since the indirect impact of power consumption varies significantly depending on the market and factors such as climate condition and lifestyle, the first step evaluates this under the standard conditions in Japan. The performance evaluation method verified jointly by JRAIA and Waseda University is used. As the second step, evaluation will be conducted on the basis of the possibility of the application of actual market data that varies according to local climate conditions, and Report 2 will explain the established concept and hypothesis about this approach.

2. Concept of LCCP Evaluation

This chapter explains the concept of the LCCP evaluation. Basically, the calculations of LCCP are carried out in accordance with the guidelines published by the International Institute of Refrigeration (hereinafter referred to as “IIR”) [4]. The components to be evaluated for LCCP are shown in the report of IIR [4].

This chapter describes how to calculate the amount of refrigerant charge and annual energy consumption.

2.1. Concept of Candidate Refrigerants

This section explains the concept of candidate refrigerants for examination in the LCCP evaluation in this project. The candidate refrigerants include R410A, a pseudo-azeotropic refrigerant mixture of an HFC refrigerant, and R32, an HFC single refrigerant, both of which are used in current AC units. In addition, R454C was selected as a zeotropic mixture of HFO and HFC refrigerant with relatively large temperature glide, which is attracting attention as a low-GWP refrigerant. We also selected the natural refrigerant R290, which has a lower operating pressure than R410A and R32, and the HCFC refrigerant R22, which is still adopted in many current ACs in emerging nations and is an important refrigerant for comparison with R290.

Table 1 shows the properties of each refrigerant [5] and Table 2 shows the theoretical COP calculated based on the thermodynamic properties of the refrigerants.

As described above, five refrigerants were selected for the study from the perspective of comprehensively covering the properties of the next-generation refrigerants in relation to system performance: R410A, R32, R454C, R290, and R22.

2.2. Examined AC and Performance Simulation

The AC to be examined is a split-type heat pump AC. Widely distributed ACs are diverse according to the manufacturer and development year; therefore, in this project, we decided to examine a residential AC for which JRAIA defined the standard specifications.
More specifically, the selected AC is equivalent to a high-end unit, and an analysis model (standard model) with a rated cooling capacity of 4kW was created for the examination. An overview of the AC’s refrigerant circuits is shown in Figure 1.

The performance simulation was conducted using the simulation software Energy Flow +M, which was developed by Professor Saito’s Laboratory at Waseda University and is used by JRAIA as a standard tool. Figure 2 shows the refrigerant circuit diagram of the standard model constructed with this performance simulation software.

To examine this standard model with greater accuracy, a comparative verification was made between the performance simulation results and the actual equipment test results for the case where the R410A was used for operation. Table 3 shows a comparison with the actual equipment test results. To implement more advanced performance simulation, each element device consisting of the refrigeration cycle was calibrated so that both the capacity and power input in Table 3 have an accuracy of ±10%.

### 2.3. Performance Simulation Conditions

This section describes the calculation conditions for performance simulation shown in Table 4.

The performance test conditions for ACs have been evaluated by means of JIS C 9612 (2013). Its performance evaluation method is carried out through a relative comparison under the predetermined conditions for the balance point (condensation and evaporation temperatures, suction superheating degree, and subcooling degree), which is the operating status point.

AC performance is evaluated by calculating an Annual Performance Factor (hereinafter referred to as “APF”). To calculate the APF, operation modes are set for each of cooling and heating, and the capacity is set for each of the test conditions and a Coefficient of Performance (hereinafter referred to as “COP”) is calculated. AC performance is evaluated based on a relative comparison using the APF.

These evaluations are conducted for each case of using a single refrigerant and using an azotropic (including pseudo-azeotropic) refrigerant mixture, and for the latter performance is evaluated using a technique called the “cycle midpoint protocol (boiling point/dew point)” as specified in JIS B 8623 (2019), which defines condensation and evaporation temperatures.

In addition, the expansion valve opening degree is adjusted so that the suction superheating degree (= compressor suction gas temperature – saturation temperature in compressor suction gas) is 5°C, and performance is evaluated using the same methods described above. Regarding the subcooling degree, the amount of refrigerant charge is adjusted so that the maximum COP is achieved for each refrigerant.

2.4. Calculation of LCCP

Basically, LCCP is calculated in accordance with the guidelines published by the IIR. The calculation methods for the amount of refrigerant charge, annual energy consumption, and other items are arranged and implemented as follows.

(1) Equipment: JRAIA AC standard model (H/P split type) equivalent to high-end unit with a rated cooling capacity of 4kW
(2) Tool: JRAIA standard tool Energy Flow +M (Prof. Saito’s Lab at Waseda University)
(3) Comparison: Optimization is performed for each refrigerant to calculate the amount of refrigerant charge and the annual energy consumption.
(4) Selection of refrigerant types: Five refrigerants (R410A, R32, R454C, R290, and R22) were selected based on the above-mentioned concept.
(5) Calculation conditions: As described above, the power consumption in a refrigeration cycle with the same capacity is calculated under the conditions shown in Table 4.

3. LCCP Evaluation Conditions and Specifications

This chapter describes the evaluation conditions and specifications for LCCP.

3.1. Definitions of LCCP Equations:

The definitions of the LCCP equations are stipulated as the LCCP evaluation conditions. LCCP is calculated by obtaining the sum of the direct and indirect emissions according to the method proposed by Dr. Hwang of UMD [3]. The method of calculating the direct emissions is shown in Equation (1). Indirect emissions are calculated using Equation (2). The following is a brief summary of the LCCP calculation.

\[
\text{LCCP} = \text{Direct Emissions} + \text{Indirect Emissions}
\]

Direct Emissions = \( C \times (L \times ALR + EOL) \times (\text{GWP} + \text{Adp.GWP}) \)

Indirect Emissions = \( L \times AEC \times EM + \sum (m \times MM) + \sum (m_r \times RM) + C \times (1 + L \times ALR) \times \text{RFM} + C \times (1 - EOL) \times \text{RFD} \)

The symbols in the evaluation equations are shown in Table 5.

3.2. Influential Factors of LCCP:

This section describes influential factors when calculating LCCP.

Table 6 summarizes the calculation items used in Equation 1 for the direct emissions and in Equation 2 for the indirect emissions in the LCCP calculation. Table 6 indicates that LCCP involves various influential factors. Therefore, when evaluating LCCP, it is necessary to clarify its influential factors and parameterize them for the study. There is particular concern that the evaluation may significantly differ depending on the country or region.

For example, with regard to energy conversion, since the power generation systems vary by country or region, the data that comes under Equation 1 for the direct emissions and Equation 2 for the indirect emissions are deemed to be influential factor parameters for energy conversion. By replacing these influential factor parameters as appropriate for each country or region, it is possible to estimate valid LCCP.

3.3. Evaluation Applying Performance Simulation:

To predict the performance of AC equipment, which will have a major impact on the LCCP evaluation, newly constructed performance simulation with improved prediction accuracy is used in the study.

Figure 4 shows the schematic configuration of the standard model used for performance simulation in this study. The standard model was created based on the specifications of a common commercially available heat pump AC.

In this study, to take into account the design concept for actual ACs, the performance is predicted assuming drop-in (hereinafter referred to as “DI”) and soft optimization (hereinafter referred to as “SO”) in the performance simulation. Specifications optimized with greater awareness of AC product capabilities (e.g., size equivalence and energy efficiency equivalence) are also examined. The DI evaluation in this study refers to performance evaluation where the same AC equipment is used but only the refrigerant is replaced. However, regarding equipment mounted with an inverter compressor and electronic expansion valve, the compressor frequency is changed (change of refrigerant mass flow rate) with the same AC capacity, and the expansion valve opening degree is changed with the same suction superheating degree. In addition, the SO evaluation refers to performance evaluation with minor modifications added on the AC’s hardware, such as changing the diameter of the connection pipe so that almost the same pressure drop occurs in the circuit even when different refrigerants are applied. Table 7 shows the concept of the assumed specification changes.

As shown in Table 7, compared with the base AC (a), in (b) the charged refrigerant (R410A) was changed, the refrigerant amount was adjusted to equalize the subcooling degree, and the compressor frequency was also changed to equalize the capacity before comparison. In (c), for the connection pipes of the liquid side and gas side that connect the indoor and outdoor units, the pipe diameter was optimized so that the pressure drop is equal to that of the current refrigerant. In (d), while maintaining the size of the heat exchanger, the path was changed to achieve the maximum efficiency. In (e), the size of the heat exchanger was changed to equalize the energy efficiency.

The refrigerant used for the base model is R410A.

Based on these studies, the values for the refrigerant charge amount, C, and the annual energy consumption, AEC, which are factors affecting the LCCP evaluation, are calculated, and a comparative assessment is made using the obtained values.

Figure 3. Outline of how to apply the LCCP of this study to various product specifications and global areas
4. Application of LCCP Evaluation and Consideration

With regard to the LCCP evaluation, this chapter formulates a hypothesis for the study with a view to the influential factors and the study of regions both in Japan and abroad, and describes a consideration of these.

4.1. Key points of the Project in the LCCP Evaluation:

Firstly, we will explain the key points of the project in the LCCP evaluation.
The LCCP evaluation is basically examined by utilizing field data in addition to the past study by JRAIA [2] and the paper by UMD [3].
The results of evaluation based on the actual operating conditions will be reported next time in the final report.

4.2. Application of the Project’s LCCP Evaluation

The concept of the LCCP evaluation in this project is shown in Figure 3, and the following explains how to apply the evaluation and other matters. The final report of the project will classify and study the regional characteristics of ambient air temperatures and other influential factors in Japanese regions that affect the LCCP evaluation. Therefore, we will study the LCCP evaluation through this task, having in mind that other countries will be able to make broad and general speculation.

(1) Impact of equipment specifications

As explained in Chapter 4, the LCCP values in this project are calculated for the standard model based on a high-end AC unit with a cooling capacity of 4kW that is commercially available in Japan.

However, there is a wide variety of ACs on the Japanese market, and they are even more diversified in other countries. In our view, for such diverse equipment, it is possible to calculate the annual power consumption, namely the indirect emissions in the LCCP evaluation, by modifying the specifications in the refrigeration cycle simulation shown in Figure 2.

(2) Influence of regional characteristics

In addition to the modification of the equipment specifications mentioned in (1), the annual power consumption, namely the indirect emissions in the LCCP evaluation, also requires modifications of the estimation parameters according to environmental characteristics including the temperatures in the region, users’ usage conditions, differences in power generation systems, and other factors.

For reference, Figure 6 shows a comparison of the changes of monthly average temperatures around the world in 2020. Climates vary depending on the assumed regional environment, which results in differences in the ambient air temperatures and humidity, operating hours, and required load. These differences strongly affect the annual power consumption during the use of an AC – the indirect emissions of LCCP. For example, in a region where ACs are required to operate throughout the year, annual power consumption is projected to increase throughout the life of the equipment. Regarding the load on the equipment, the higher the ambient air temperature during the cooling mode, the higher the condensing pressure in the refrigeration cycle, increasing the load on the compressor. The heat load entering the building from outdoors also increases, and the room temperature tends to rise; therefore, it is necessary to select an AC with a higher capacity.

Moreover, larger heat exchangers are required as the load increases, leading to the problem of an increase in the amount of refrigerant used. Therefore, it is anticipated that there will be demand for highly efficient refrigerants suitable for large capacity and other influences.

Figure 5 shows the composition of power generation systems in five countries in 2016. Power resources are classified into fossil fuels, such as petroleum, natural gas, and coal, and non-fossil fuels, such as hydraulic power, other renewable energies, and nuclear power, and they are compared in percentage terms. As indicated in Table 6, according to the resource of power generation means, LCCP is affected by EM, which is the amount of CO2 [kgCO2] generated per unit power consumption [kWh]. The EM varies greatly depending on the major power generation systems in each country. For example, in countries where the major systems are renewable energy power generation, such as hydraulic power, and nuclear power generation, the power consumed by ACs will be unlikely to lead to CO2 emissions, and the indirect emissions will be negligible. On the other hand, in countries where power generation is mainly derived from fossil fuels such as petroleum and natural
gas, CO2 emissions from the use of AC becomes sensitive, and the indirect emissions of LCCP are strongly affected by the equipment efficiency and air-conditioning load.

Concerning the power generation systems, changes in the composition due to changes in power resource demand, shift to renewable energies and other factors may also need to be considered in future predictions. In our view, by studying the basic values required for the LCCP calculation shown in Table 6, it is possible to apply the LCCP evaluation to the influential factors described above.

(3) Impact of the properties of various refrigerants

This section explains the concept concerning the LCCP evaluation methods for diverse candidate refrigerants.

As mentioned in Chapter 4 and this chapter, in this project, by utilizing new performance simulation with high accuracy and market data, the LCCP evaluation is expected to be closer to actual market conditions than

---

Figure 4. Example of Monthly average temperatures around the world

Figure 5. Comparison of non-fossil fuel power resource rates in 2016
the previous evaluation was.

The LCCP calculation for various refrigerants in this project is as described in Chapter 4. The method is to examine the factors that affect the LCCP evaluation of various refrigerants through SO or by optimizing the refrigerant circuit for each refrigerant.

For example, the values for the refrigerant charge amount, C, and annual energy consumption, AEC, which are considered major influential factors, can be calculated with high levels of accuracy. In terms of the calculation conditions, it is expected that LCCP for each refrigerant can be compared by reflecting market data and regional characteristics, such as climate and refrigerant recovery rate, which vary in different countries and regions.

5. Conclusion

In Japan, LCCP, LCCP evaluation is studied in a two-step process, and the concept (hypothesis) of the first step described in this report is summarized in the following bullet points:

• The concept (hypothesis) of the LCCP evaluation in this report was established by focusing on the consistency of the criteria of evaluation indicators.
• In the LCCP evaluation, a performance simulation evaluation will be carried out using JRAIA’s standard tool (performance simulation program developed by Waseda University) to optimize the system in relation to candidate refrigerants.
• Performance evaluation will be carried out through a relative comparison for each refrigerant under the same capacity.
• A residential heat pump mini-split AC with a capacity of 4.0kW was selected as the standard model of AC equipment to be examined, and calculation will be performed.
• For the standard model, mutual correction will be made between the actual equipment test data and the performance simulation data.
• The calculation conditions of LCCP were clarified so as to share the same data recognition.

In addition, in the second step, the LCCP evaluation will be studied by utilizing the market data on ACs.

Finally, the basic concept on the positioning of the LCCP evaluation in the selection of refrigerants is explained as follows.

We believe that the LCCP evaluation to be studied in Task 3 is one of the important criteria for selecting optimal refrigerants. We also feel that in order to make the evaluation more realistic, it is desirable to conduct a comprehensive evaluation from multiple perspectives, including safety, cost, sustainability, and infrastructure development, in addition to the environmental assessment through the LCCP evaluation.

6. Future Plans

Regarding issues and responses to be addressed in the second step in the future, we plan to verify the concept (hypothesis) of the LCCP evaluation described in this report.

Specifically, the study will be conducted based on the results of the performance simulation to optimize ACs. In addition, the utilization of market data will also be examined.

In the second step, we plan to study the LCCP evaluation not only for Japanese regions with a temperate climate but also, by utilizing market data, for other areas in the world such as India, where ACs are used more often.

Terminology

• **Life Climate Performance (LCCP)**: An index to evaluate the global warming impact of a product throughout its life, from manufacture to disposal. Based on the TEWI, the value is calculated by adding energy consumption (indirect emissions) when manufacturing the gas to be used and the leakage of the gas (direct emissions).

• **Global Warming Potential (GWP)**: Indicates the degrees of the global warming impacts of gases released in the atmosphere. On the basis of carbon dioxide (1.0), the same gas weight and same period (100 years) are assumed to allow relative comparisons of the impact of each gas. When the HFC refrigerant used for ACs is considered with the same gas weight, its GWP is generally hundreds to thousands of times greater than that of carbon dioxide; therefore, its significant impact on global warming is regarded as a problem.
• **Optimization**: In performance simulation, compared with the performance prediction made with conventional DI and SO, optimized performance prediction takes into account the design concept of an actual product; optimization is carried out by adjusting the component parts (piping, heat exchanger, etc.) of the refrigeration circuit so that their specifications conform to the refrigerant characteristics.

• **Performance simulation**: A method to estimate the power consumption of the target equipment under various operating conditions using Energy Flow +M (Prof. Saito’s Lab at Waseda University), which is a standard tool of JRAIA. Used to calculate annual power consumption.

• **Coefficient of Performance (COP)**: A factor used as a measure of the energy consumption efficiency of cooling equipment, etc. The value represents cooling/heating capacity per kW of power consumption.

• **Total Equivalent Warming Impact (TEWI)**: A method to evaluate global warming impacts in comprehensive consideration of refrigerant leakage during equipment use, emissions into the atmosphere at the time of disposal, and the amount of carbon dioxide generated from fossil fuel usage due to operating power consumption. TEWI is expressed by the following equation.

\[
\text{TEWI} = \text{Direct CO2 emission equivalent} + \text{Indirect CO2 emission equivalent}
\]

\[
\text{Direct CO2 emission equivalent} = \text{GWP} \times L \times N + \text{GWP} \times M \times (1-\alpha)
\]

\[
\text{Indirect CO2 emission equivalent} = N \times E \times \beta
\]

- **GWP**: Global warming potential per kg on the basis of CO2, 100-year integration period (kg-CO2e/kg)
- **L**: Annual amount of leakage from equipment (kg/year)
- **N**: Service life of equipment (years)
- **M**: Amount of charge to equipment (kg)
- **α**: Recovery rate at equipment disposal
- **E**: Annual energy consumption of equipment (kWh/year)
- **β**: CO2 emissions required for 1 kWh of power generation (kg-CO2e/kWh)

• **CO2 emissions**: Total of the amount of carbon dioxide generated from fossil fuel usage due to power consumption and the equivalent amount of carbon dioxide using GWP to the degree of the global warming impact of the gas released into the atmosphere.

**Acknowledgements (or activity members)**

This project is conducted by the following members and observers of JRAIA LCCP Evaluation Study WG. We would like to express our deepest gratitude for their cooperation.

The Chief is PhD. Shigeharu Taira, Daikin Industries, Ltd., and the Sub-Chief is Mr. Seishi Ititaka, Panasonic Corporation.

Members are as follows: Mr. Itaru Nagata, Sharp Corporation; Mr. Tomoyuki Haikawa, Mr. Hayato Nuno and Mr. Katsunori Murata, Daikin Industries, Ltd.; Mr. Hiroichi Yamaguchi and Mr. Kohei Maruko, Toshiba Carrier Corporation; Mr. Ryoichi Taka-fuji and Mr. Takashi Inoue, Johnson Controls-Hitachi Air Conditioning; Mr. Shunji Itakura, Fujitsu General Limited; Mr. Takenori Nakamura and Mr. Keisuke Mitoma, Mitsubishi Heavy Industries Thermal Systems, Ltd.; Dr. Koji Yamashita and Mr. Yasuhide Hayamaru, Mitsubishi Electric Corporation.

Observers are Professor Kiyoshi Saito and Mr. Yoichi Miyaoka, Chief Researcher, Waseda University; Mr. Takeshi Sakai and Mr. Kazuhiro Hasegawa, JRAIA.

Abstract

To improve heat conversion efficiency in the industrial field, this research has focused on heat pump technology, which has low CO\textsubscript{2} emissions and high efficiency, and has developed a simulator that can easily study the effects of introducing the technology and can be used for a variety of systems. To achieve this goal, we have selected a model with a good balance between calculation speed and accuracy, and have built a simulator that is easy for users to use and can flexibly respond to changes in refrigerants, systems, and operating conditions. In this paper, we show, compare and analyze the results of an environmental evaluation, as well as verification of its accuracy using actual measurement data from a factory using the simplified simulator calculated by classification of basic system configuration patterns and the integrated simulators based on general-purpose analysis logic for the model.

Keywords: Industrial heat pump; Simplified simulator; Integrated simulator; economic and environmental evaluation

1. Introduction

The New Energy and Industrial Technology Development Organization (NEDO)\cite{1} reported that 70\% of waste heat per fuel is generated in boilers, steam pipes, production facilities, and so on, considering the operation of conventional industrial heat systems in factories. Therefore, the introduction of heat pumps as an alternative to conventional combustion methods is attracting attention as a promising method for energy saving. When introducing an industrial heat pump into an existing process, it is necessary to quantitatively evaluate the cost, effectiveness, and desirable configuration of the heat pump system in advance.

However, the hurdles in terms of cost and time are high to determine these factors through actual demonstration construction using heat pumps, and as a result, this has become a factor hindering the spread and expansion of heat pumps. Considering these problems, a simulation-based evaluation method is preferable for quantitatively evaluating the effectiveness of heat pump installation. However, actual processes and systems have complex equipment configurations and are large in scale, and annual performance evaluations must be conducted in response to fluctuating loads and ambient temperatures, etc. This requires complex calculation inputs and a large amount of calculation time. For this reason, the authors have conducted research with the goal of constructing a simulator that is relatively easy to input calculations, has high accuracy, and can significantly shorten calculation time. \cite{2}\cite{3}

This paper reports on two simulators that enable the effects of introducing heat pumps with environmental considerations even in complex systems where multiple devices are installed on factory production lines. Specifically, considering the analysis time and convergence for a large annual calculation in hours, the validity of the analysis results is confirmed by comparing them with field data of heat pump systems obtained...
throughout the year. The primary energy consumption and CO$_2$ emissions of each simulator were evaluated to quantify the efficiency of the heat pump installation system compared to a conventional combustion system.

2. Simulation overview

2.1. Simplified simulator

We suggested the evaluation method of target systems that are classified as 16 basic patterns to evaluate the effects of introducing a heat pump as shown in Table 1, and constructed a simulator that can be handled easily by users with knowledge of heat pumps as a whole to save energy in the entire industrial field. In order to organize a complicated system configuration, patterning methods were proposed based on four indicators (i.e., used equipment, heating method, introduction use) via surveys of heat pump products developed for existing industries.

The conventional “equipment” is set to “boiler” and the introduced equipment is set to the “heat pump” to compare the use of a conventional boiler or burner with a heat pump. We then consider an eco-cute system that supplies hot water as a system that includes a heat pump. Household water heaters are popular although large-scale industrial eco-cutes were developed to generate hot water instead of boilers. This corresponds to an introduction example targeted in the study. In this type of a water heater, there is a difference in the heating method between storing hot water in the tank and temporarily supplying hot water.

Therefore, “heating method” is set to “circulation” and “non-circulation”. Furthermore, the CO$_2$ hot air generation heat pump can be used for complete replacement of conventional boiler or preheating before conventional boiler. “Introduction use” is set as “replacement” and “preheating”.

Finally, heat pumps that can realize applications including cold / hot water generation, hot water supply, and hot water tank heating with a single unit were developed using waste heat recovery technology. The heat pump can simultaneously extract cold and warm heat from the low temperature side and high temperature side of refrigerant. Therefore, the “thermal utilization” is set as “high-temperature heat utilization” and otherwise “Simultaneous utilization of heat and cold” is set.

In the present study, a total of 16 patterns are proposed by combining the aforementioned "used equipment" (boiler, heat pump), "heating method" (circulation, non-circulation), "introduction use" (preheating, replacement), and "thermal utilization" (high-temperature heat utilization, simultaneous utilization of heat and cold).

The user inputs the target system configuration via a combination of the 16 basic patterns. Similarly, it is possible to perform a comparison with the case where the heat pump is introduced by using the basic pattern and to clarify various effects of introduction.

The GUI of the simulator developed using the C++ language is shown in Figure 1. In the simplified simulator, the user first selects one of 16 basic system configuration patterns that correspond to the existing system.

The selected pattern is arranged as the system on the left side shown in Figure 1. The pattern of the heat pump to be newly installed is also selected in the same way, and is placed as the system on the right side shown in Figure 1. Then, input variables for each pattern in csv format (values separated by commas (,)). The input variables are basically the refrigerant type and rated value, as well as the temperature and flow rate at each time point.

Finally, the comparison results are output after running the calculation program. On the screen, the results are displayed in the form of line graphs showing the primary energy consumption during the evaluation period for the input data, and bar graphs and numerical values showing the total primary energy consumption and total CO$_2$ emissions during the evaluation period, respectively.

In addition, a Moriel diagram of the heat pump is displayed based on the pressure and enthalpy data at the selected time. Since all 16 patterns are used as objective systems for comparison, it is possible to compare the performance of heat pumps with each other, and can respond flexibly to changes in the type of refrigerant and the basic configuration pattern of the system. This simulator is also capable of system economic assessment and LCCP evaluation, however, this paper focuses on the calculation of primary energy consumption and CO$_2$ emissions. The simulation models are composed of continuity and energy equation in each equipment and the heat transfer performance of the heat exchangers was analyzed as pinch temperature. Details of evaluation assessment are referred to Jeong.[3]

2.2. Integrated simulator

Figure 2 shows GUI of integrated simulator, which features high ability in analyzing the performance of system with various refrigerants, and simulation environment being familiar to engineers and researchers that do not specialize in a simulation on industrial and scientific fields. This simulator extends the capabilities of the simplified simulator to analyze systems with complex configurations and is fully capable of not only designing large-scale heat pump systems, but also predicting and verifying the effectiveness of heat pump installations. As for the tool for examining the performance of air-conditioning systems, a general-purpose energy analysis simulator “Energy Flow+M” has been developed at Waseda University for steady state, dynamic, and control analysis [4-6]. Vapor compression type of air conditioning system expressed by GUI is shown in Figure 2-(a) as an example of simulation. In Figure 2-(b), system simulation is carried on GUI. Figure 2-(c) shows simulation results as output using CSV file. The simulation models are basically the same with those of simplified simulator.
Figure 3 shows the analysis process of the integrated simulator. First, the components of the system to be built are selected from the module list and placed on the GUI. Each element or combined pattern is treated as a "module" with its own entrance and exit, and each module is connected to each other with "connections" to construct the system configuration as shown in Figure 2(a). For each of these modules, fixed variables for each device, time-series variables such as temperature conditions, and connection information with each module are stored in xml format, and when the system calculation is executed, the information in the xml file is passed to the calculation main core side. The system is then simulated using the necessary physical properties and convergence algorithms. The final result of the analysis is an environmental assessment of the primary energy consumption and CO₂ emissions of the system and an economic assessment of the life cycle cost. In this paper, it focuses on the calculation of primary energy consumption and CO₂ emissions.

3. Simulation example of each simulator

3.1. Objective system

The objective system shown in Figure 4 is a paint drying system in a certain factory. In contrast to conventional combustion-type heating, this system uses a heat pump with CO₂ refrigerant for preheating to generate high-temperature hot air, which is preheated to 90-100°C with the heat pump by the heat pump by taking in outside air at around 15°C, and the heated air is further heated to 170°C by the burner. This system consists of a chiller, a heat exchanger, a burner, and a fan in addition to the heat pump, with multiple heat sources heating and cooling materials in different temperature zones.

Figure 4. Flow of the target factory
Figure 5 shows annual actual operation data for the objective system with a heat pump as shown in Figure 4, including the temperature and airflow rate of the fan on the hot-air process side, the temperature of the heated hot-air from the heat pump at about 100°C, and the temperature of the hot-air provided by the burner to the drying furnace at about 170°C. Compared to a conventional combustion system, the heat pump is used to raise the temperature from the ambient air to about 100°C. When assessing environmental and economic performance using the simulators, the actual operation data shown in Figure 5 are used as input values for analysis, and energy consumption is calculated to evaluate the effect of the heat pump installation. The heat pump installation system operates for approximately 11 hours from 7:00 to 18:00 on weekdays, with system shutdown on weekends and holidays.

\[ \text{Figure 5. Annual actual operation of heat pump installation system} \]

3.2. Analysis by simplified simulator

For analysis of objective system, the simplified simulator enables evaluating the effects of introducing the industrial heat pump proposed above. The classification for simulation described in Table 1 corresponds to Type 4. This type is without hot water circulation between heat pump and tank and heat pump is for use of preheating in front of boiler or burner to get the target temperature into drying furnace. In addition, to operate efficiently this system, cold and hot water are utilized for drying furnace and electrodeposition process by the heat exchanger in Figure 4. Figure 6 shows the setting of input values for conventional type and heat pump introduction type. Power consumptions are calculated by these input values, for example, final target temperature (Tc1, Th2, Tc2, Th3), environmental air temperature (Th1), air flow rate (Gh), cooling water temperature (Ts), chilled water temperature(Tc1), chilled water flow rate (Ge).

\[ \text{Figure 6. System type classification for simplified simulator} \]

3.3. Analysis by integrated simulator

The integrated simulator is based on the concept of modular analysis as a general-purpose analytical theory for energy systems, particularly thermal-fluid systems. This theory enables the numerical analysis of a wide variety of energy systems using a unified method, and Figure 7(a) shows a flow diagram of a chiller and burner used in conventional industrial process cooling and drying processes. To analyse these systems, the modules of each component of the system are arranged on the graphic user interface (hereinafter referred to as GUI) of the integrated simulator, as shown in Figure 7(b). Figure 7(c) shows a flow diagram of a system that simultaneously utilizes cold and heat by introducing a heat pump, in contrast to the conventional system shown.
in Figure 7(a). Figure 7(d) shows this system represented as a module of each element in the GUI of the integrated simulator. As shown in Figure 7(b) and Figure 7(d), the integrated simulator was developed in the C++ language, and the GUI was designed to make the calculation procedure easy to understand. In addition, the code is structured in a calculation core with independent system analysis, module analysis, convergence calculation, refrigerant properties, and other sections, making it easy to modify and add to the code. The code incorporates a new convergence calculation method to increase speed, and maps refrigerant properties based on the latest REFPROP to improve accuracy and increase speed.

3.4. Simulation results by simplified simulator and integrated simulator

3.4.1. Comparison of simulation results and field data

Figure 8 compares the simulated and measured power consumption of heat pump only by simplified simulator and of heat pump and auxiliary equipment by integrated simulator on a monthly power basis. Integrated simulator considered pump and fan power consumption as auxiliary equipment in addition to heat pump power consumption. The actual measured daily power consumption values used for verification are accumulated as kWh, and data for 365 days are shown. For the simulator analysis, calculations are performed at one-hour intervals throughout the year and compared with the actual measured data. The time required for analysis by the simplified simulator and integrated simulator is about 2 minutes (based on Intel(R) Core(TM) i5) and 7 hours (based on Intel(R) Core(TM) i5) respectively. For the integrated simulator, considering the user's environment, it is assumed that the analysis results can be checked when the user finishes work in the evening and starts work the next morning. The accuracy of the calculation was about 10.0% and 4.1% relative error, confirming the validity of the analysis using the simplified and integrated simulator, respectively.
3.4.2. Environmental evaluation

The introduction of heat pumps into the industrial heat system field is expected to save energy in industrial processes. This chapter presents a quantitative comparison and evaluation of the degree to which the introduction of heat pumps can save energy and reduce CO$_2$ emissions for the entire system compared to conventional combustion-type heating equipment such as boilers and burners. The primary energy consumption and converted CO$_2$ emissions are compared between the conventional system and the heat pump system, including the gas consumption by the gas burner. To calculate the primary energy consumption, the energy conversion efficiency of thermal power generation is 36% and that of burners and boilers is 90%. For the calculation of CO$_2$ emissions, the emission factor for electricity is set to 0.000462 [t-CO$_2$/kWh] [7] and that for city gas to 0.00017964 [t-CO$_2$/kWh] [7]. Fig. 9(a) and Fig. 9(b) show the monthly primary energy consumption of the conventional system and the system with heat pumps. In the results, it was found that the calculation results of the simplified simulator and the integrated simulator were almost identical, with the only difference being the presence or absence of power consumption by the auxiliary equipment-pump and fan.

![Comparison of simulation and measurement results on electric power consumption of heat pump installation system](image)

**Figure 8.** Comparison of simulation and measurement results on electric power consumption of heat pump installation system

![Comparison of conventional and heat pump installation system on primary energy consumption and CO$_2$ emission](image)

**Figure 9.** Comparison of conventional and heat pump installation system on primary energy consumption and CO$_2$ emission

(a) Result by simplified simulator  (b) Result by integrated simulator

(a) Result on primary energy consumption by simplified simulator  (b) Result on primary energy consumption by integrated simulator

(c) Result on CO$_2$ emission by simplified simulator  (d) Result on CO$_2$ emission by integrated simulator
As shown in Fig. 9(a) and Fig. 9(b), although the heat pump system provides the chiller's cooling capacity for the conventional system, the heat pump provides heating up to about 100°C out of the heating capacity of the gas burner up to 170°C. Therefore, the reduction effect cannot be said to be large. Fig. 9(c) and Fig. 9(d) show the monthly CO₂ emissions of the conventional system and the system with heat pumps in the simplified and integrated simulatores. It can be seen that CO₂ emissions are reduced by using a heat pump for preheating, which is more efficient than a gas burner, even though the electricity emission factor is about 2.5 times larger than the city gas emission factor.

Based on the above results, it is not important which simulator is better between the simplified simulator and integrated simulator that have been developed so far. The simplified simulator can be effectively used to estimate the effect of installing a heat pump in a short calculation time. The integrated simulator should be used for system design purposes when the energy distribution of the entire system, including auxiliaries, and greater calculation accuracy are required. In this way, we believe that the real strength is found in using different simulators according to the user's application.

4. Conclusions

In this study, we developed a "Simplified simulator" and an "Integrated simulator" that can study the effects of introducing heat pumps from both environmental and economic perspectives in order to help expand the use of heat pumps in the industrial field toward the targeted energy conservation.

As a result of the verification of the accuracy of the analysis, it became possible to calculate with a relative error of approximately 10.0% on simplified simulator and 4.1% on integrated simulator from the annual measured values of the objective system. In addition, a comparison study was conducted between a conventional combustion-type system and a system with a heat pump, and the effects of the introduction were quantitatively compared and evaluated in terms of environmental performance indicators such as energy consumption and CO₂ emissions. This means that the simplified simulator and the integrated simulator can contribute to improving the efficiency of existing systems in the industrial field. Especially, the integrated simulator extends the capabilities of the simplified simulator to analyze systems with complex configurations and is fully capable of not only designing large-scale heat pump systems, but also predicting and verifying the effectiveness of heat pump installations.

Looking ahead, we will continue to develop these simplified and integrated simulators to increase its usefulness and practicality.

Acknowledgements

These results were obtained as a result of the commissioned work (JPNP15007) of the New Energy and Industrial Technology Development Organization (NEDO), and we would like to express our gratitude to all concerned.

Abstract

A design platform, namely Smart Thermal Energy Design Platform (STED platform), for thermal energy-intensive industrial facilities is being developed for any user with an intuitive interface and smart guide during design process. Among design modules in STED platform, the vapor compression heat pump design module gives suitable design results for heat pumps under the given operation conditions. The module can model three heat pump layouts: basic, internal heat exchanger, and injection. To validate the design results from the module, a lab-scale heat pump experimental device, namely heat pump simulator, was made based on the calculation results from the heat pump design module. As a result, the calculated performance from the platform and the measured performance from the simulator had an error of 0.1\% in terms of mean COP for 30 minutes.

1. Introduction

According to the global energy-related CO\textsubscript{2} emissions by sector from IEA data [1], industry sector occupies 23\% of total global CO\textsubscript{2} emissions. In 2021, the sector accounted for 38\% (169EJ) of total global final energy use, and the fraction of fossil fuel energy in the whole industry sector final energy use was about 68\% [2]. To reduce the emissions in the sector, fossil fuel based thermal systems like boilers should be electrified. Reported by Net Zero Roadmap [3], electricity share in light industry should be 76\% to accomplish net zero until 2050. Heat pumps could be a great option to electrify the industrial heat because compared to electric heaters heat pumps can generate a few times of generate process heat by inputting a same electric power. Many previous works reported that energy consumption in the industrial sector could be saved about 40 to 60\% if process heat under 200\(^\circ\)C that is utilized in most industrial sectors is replaced with heat pumps [4] [5] [6] [7] [8]. Despite these benefits of heat pumps, there is a lack of holistic design algorithms for heat pump systems because they involve various combinations of design parameters, such as cycle layouts, specifications of sub-components, refrigerants, and degrees of superheating and subcooling, and so on [9]. Thus, it is hard for small-, and medium-sized enterprises to design their own heat pump systems because they generally have deficient R\&D infrastructure and insufficient capital to pay the license fees of state-of-the-art design platforms to enhance the performance of heat pumps. According to Meng et al. [10], these enterprises approximately accounted for 50\% of CO\textsubscript{2} emissions, so that improving the performance of heat pumps used by small-, and medium-sized enterprises could contribute to reduction of CO\textsubscript{2} emissions in industry sector. To solve the problem, the latest national R\&D technologies should be efficiently disseminated to those enterprises.

Smart Thermal Energy Design platform, namely STED platform could be a solution to provide preliminary design results of the thermal energy-intensive facilities such as burners, furnaces, dryers, heat exchangers, and
heat pumps to the energy consumers or vendors. Among variety of design modules, heat pump design module could treat three kinds of heat pump layouts which are basic, internal heat exchanger, and injection. In this study, the design algorithms of the layouts were suggested, and the design result of basic layout were validated with experimental test loop for heat pump design module, namely heat pump simulator.

2. Design algorithms for various heat pump layouts

At the first step to design heat pump cycle, inputs are applied into specifications of major components in a heat pump system should be inputted as listed in Table 1.

The heat pump design module adopts CoolProp database for utilizing fluid properties [11], but not all fluids are not considered a refrigerant in a heat pump users intend to design owing to the computational resource problem. Instead, the appropriate refrigerants are dynamically selected from the list according to the temperature of process fluid, and the specifications of an evaporator and condenser like approach temperature and LMTD. In the condenser, a refrigerant with high pressure is condensed by the hot-side process fluid such that the critical temperature of the refrigerant is higher than the temperature of the hot-side process fluid considering the pinch point, as shown in Eq.(1). In the evaporator, a refrigerant with low pressure is evaporated by the cold-side process fluid. The refrigerant pressure in the evaporator should be higher than the ambient pressure because of the purity problem in the heat pump system. Thus, the saturation temperature of the ambient pressure considering the pinch point should be lower than that of the cold-side process fluid, as expressed in Eq.(2).

\[
T_{\text{crit}} > T_{\text{ho}} + \Delta T_{\text{pp,cond}} \quad (1)
\]

\[
T_{\text{NBP}} < T_{\text{co}} + \Delta T_{\text{pp,evap}} \quad (2)
\]

This is because heat pumps designed by the module should be a subcritical vapor compression heat pump.
2.1. Basic layout

A heat pump system with basic layout is composed of an evaporator, compressor, condenser, and expansion valve. Initially, low pressure and high pressure of the refrigerant in evaporator should be estimated considering atmosphere pressure, critical pressure, and process temperatures. The saturation temperature in evaporator can be calculated from the estimated low pressure by CoolProp database. Adding the superheat inputted by a user to the saturation temperature, the evaporator outlet temperature (i.e. compressor inlet) can be obtained.

\[ T_{\text{comp.in}} = T_{\text{sat@\text{evap}}} + \Delta T_{\text{sh}} \]  
\[ h_{\text{comp.out}} = \left( 1 - \frac{1}{\eta_{\text{comp}}} \right) h_{\text{comp.in}} + \frac{h_{\text{comp.out\_ideal}}}{\eta_{\text{comp}}} \]  

The saturation temperature in condenser can be calculated from the assumed high pressure of refrigerant in condenser, and the condenser outlet temperature can be obtained by subtracting degree of subcooling from the saturation temperature in condenser as written in Eq.\((5)\). After condenser inlet and outlet temperature are defined, mass flow rate of the system can be calculated by energy conservation between refrigerant side and process fluid side as shown in Eq.\((6)\)\((7)\). The subscripts ‘hot_in,sec’ and ‘hot_out,sec’ mean the inlet and outlet state of hot secondary flow like water and air in condenser. However, the approach temperature point in condenser does not usually exist at the channel inlet or outlet as single-phase heat exchangers do. This is because phase change occurs on refrigerant side in condenser while do not happened in process fluid side. To search the approach temperature in channels, the condenser channel should be divided into finite discrete nodes, and each state can be obtained based on energy conservation equation as shown in Figure 1. Comparing the calculated approach temperature of condenser to the approach temperature inputted by a user, the error can be defined as Eq.\((8)\). If the error is not met under the entered tolerance, the high pressure in condenser is adjusted until satisfying the convergence tolerance.

\[ T_{\text{cond.out}} = T_{\text{sat@\text{cond}}} - \Delta T_{\text{sc}} \]  
\[ Q_{\text{cond}} = \dot{m}_{\text{hot,sec}}(h_{\text{hot.out,sec}} - h_{\text{hot.in,sec}}) \]  
\[ \dot{m}_{\text{ref}} = Q_{\text{cond}} / (h_{\text{cond.in}} - h_{\text{cond.out}}) \]  
\[ \varepsilon > |\Delta T_{\text{pp,cond}} - \Delta T_{\text{pp,cond}}| \]  

![Figure 1. Internal channel calculation of condenser using finite discrete nodes](image)

After the condenser outlet state is obtained, through expansion valve, evaporator inlet state can be calculated through with isenthalpic process of the condenser outlet state to the low pressure as expressed in Eq.\((9)\).

\[ T_{\text{evap.in}} = f(P_{\text{evap}}, h_{\text{cond.out}}) \]
Thus, evaporator inlet and outlet can be determined, and the approach temperature of evaporator is also calculated by the finite discrete nodes method similar to the condenser as shown in Eq. (10)(11)(12). The subscripts ‘cold_in,sec’ and ‘cold_out,sec’ mean the inlet and outlet state of cold secondary flow like water and air in evaporator. The error of evaporator’s approach temperature is a criterion to judge the convergence of low pressure in evaporator.

\[
Q_{\text{evap}} = m_{\text{ref}} (h_{\text{evap, out}} - h_{\text{evap, in}}) \quad (10)
\]

\[
h_{\text{cold, out, sec}} = h_{\text{cold, in, sec}} - Q_{\text{evap}}/m_{\text{cold, sec}} \quad (11)
\]

\[
\varepsilon > |\Delta T_{\text{pp, set}} - \Delta T_{\text{pp,evap}}| \quad (12)
\]

When both the approach temperature errors of condenser and evaporator are under the user inputted tolerance, the cycle design is completed. Figure 2 shows the flow chart for designing a basic layout heat pump.

2.2. Internal heat exchanger layout

The design algorithm of IHX heat pump is basically identical with that of the basic layout heat pump but the evaporator outlet and condenser outlet transfer their heat through IHX, so the superheat at the compressor inlet and subcooling at the expansion inlet is more enhanced by the IHX. In the IHX channels, the phases of condenser and evaporator are both single phase. Therefore, the transferred heat can be calculated based on the effectiveness of IHX inputted by a user. Eq. (13) to (18) show the calculation process of IHX cold side and hot side states.

\[
T_{\text{IHX, ci}} = T_{\text{sat,evap}} + \Delta T_{\text{sh}} \quad (13)
\]

\[
T_{\text{IHX, hi}} = T_{\text{sat,evap}} - \Delta T_{\text{sc}} \quad (14)
\]

\[
q_{\text{ideal}} = \min (h_{\text{IHX, hi}} - h_{\text{IHX, ko}}, h_{\text{IHX, ko}} - h_{\text{IHX, co}}) \quad (15)
\]

\[
q_{\text{actual}} = \varepsilon_{\text{IHX}} q_{\text{ideal}} \quad (16)
\]

\[
h_{\text{IHX, co}} = h_{\text{IHX, ci}} + q_{\text{actual}} \quad (17)
\]

Figure 2. Design algorithm of basic layout heat pump
\[ h_{\text{IHX,ho}} = h_{\text{IHX,hi}} - q_{\text{actual}} \] 

Figure 3 shows the design algorithm of a IHX layout heat pump.

2.3. Injection layout

An injection layout heat pump does not directly expand from the high pressure at condenser to the low pressure at evaporator, but there is a flash tank with intermediate pressure between condenser and evaporator. Thus, when the high pressure fluid expands in flash tank, the subcooled refrigerant at the condenser outlet changes saturated state, so that saturation gas partly appears in the tank in Eq. (19). Bypassing the gas to the middle of compression process in a compressor, consumption work of the compressor is substantially decreased due to the intercooling of the compression process in Eq. (20). Remarkably, as intermediate pressure changes, the injection layout heat pump has optimal performance point as illustrated in Figure 4.

\[ x_{\text{fsh}} = f(P_{\text{inter}}, h_{\text{cond.out}}) \]  

\[ h_{\text{comp2,in}} = x_{\text{fsh}} h_{\text{fsh,\rho}} + (1 - x_{\text{fsh}}) h_{\text{comp1,out}} \]
Figure 5 shows the flow chart of injection layout heat pump.

3. Heat pump simulator

To validate the calculation results from the heat pump design module in STED platform, a simulator was built. The simulator is composed of a compressor, plate type condenser and evaporator, and EEV. The compressor is a twin rotary (two cylinder rolling piston type) with hermetic motor, and PVE oil. Temperatures are measured by RTD with 1/16-inch probe, and pressures of compressor inlet and outlet are measured by high accuracy pressure transmitter with FS ±0.075%. Coriolis flow meter is adopted to obtain the mass flow rate in the system. Figure 5 shows the picture of simulator for heat pump design module in STED platform.

Figure 6. Picture of simulator for heat pump design module in STED platform
The monitoring system of the simulator was implemented by Labview 2020 version. The heat pump design platform was embedded in the Labview, so that the platform results and measurements directly compared on the monitoring system. In Figure.7, the center PFD shows the schematic flow lines of the simulator, and the left side the comparison results of platform calculation and measurements. Especially, the cycle states can be expressed by TS and PH diagrams, and the blue line represents the platform results and red lines shows the measurements from the simulator. They show high agreement between platform and simulator. Moreover, calculating the COPs calculated from the platform and measured from the simulator, the estimated error was only 0.1% with average of 30 minutes. Table 2 shows the differences of major parameters between calculation from the platform and measurements from the simulator. Due to the measurement error of power meter, the compression work showed the largest deviation. Coincidently, the measurement of evaporation heat is also smaller than the calculation so that COP has extremely low error. The difference of subcooling is not reported because the condenser outlet of refrigerant side is in the saturated state so that it is hard to compare the calculation of subcooling to the measurement.

4. GUI of heat pump design module

After the results of the heat pump design module was demonstrated, the platform was visualized by PyQt5 module in Python library. The first step is selecting heat pump layout a user wants to design. At the next step, the user enter the required inputs as listed in Table 1. Finishing the calculation, the results are summarized with the refrigerant states, and essential diagrams.

![GUI of heat pump design module](image)

5. Results

To respond to demands for developing user-friendly design platform, Smart Thermal Energy Design platform was developed. Among the thermal energy-intensive facilities the platform treats, the heat pump module algorithms were discussed in this study. Basic, internal heat exchanger, and injection cycles are dealt with, and basic layout heat pump was validated by the simulator with mean error of 0.1%. Thus, the heat pump design module in the platform can provide accurate design results to users.

Abstract

In order to prevent global warming, there is a strong need to reduce greenhouse gas emissions and energy consumption of refrigeration and air conditioning systems. Various new low-GWP refrigerants are being introduced for air-conditioning equipment, such as residential and commercial air-conditioners. The performance of these new working fluids should be effectively evaluated to select their most suitable implementation case and reduce the environmental footprint of this technological field. The actual operation performance of air-conditioning equipment is substantially affected not only by the system design and the properties of the refrigerant, but also by the climate and load conditions of the specific installation. Therefore, a refrigerant evaluation tool may take advantage from the cost effectiveness and flexibility of a reliable simulation platform but requires standardized calculation conditions for achieving unbiased results. Therefore, a system simulator was hence developed for the analysis of next-generation refrigerants, including zeotropic mixtures. This paper discusses about validity verification results of this evaluation tool based on experimental results and assess the performance of residential air conditioners.

Keywords: air-conditioner; simulator; low-GWP; LCCP; refrigerant;

1. Introduction

In order to curb global warming, it is necessary to reduce greenhouse gas emissions from the refrigeration and air conditioning sector. The operation of such thermal systems leads to both direct and indirect emissions to the environment throughout their life cycle, from manufacturing, through operation, to disposal. In fact, their fundamental functioning is based on the circulation of a refrigerant through various components such as compressors and heat exchangers where heat, mass and momentum transfer take place in order to supply output cooling/heating capacity. The ratio between the magnitude of this output capacity to the corresponding input energy defines the coefficient of performance of the system, which is ruled by the thermophysical and transport properties of the refrigerant. Additionally, the chemical properties define the GWP of the refrigerant, which is commonly used to assess the corresponding direct emissions. Following the Kigali amendment to the Montreal Protocol, research and development of next-generation low-GWP refrigerants and their safety and risk assessment are underway to provide alternative working fluids for refrigerators, air conditioners, and heat pumps. Accordingly, the development of effective refrigerant evaluation techniques is an essential tool for strategizing the decarbonization of this technological field. Contextually, it has been widely recognized that accounting for the sole GWP value cannot comprehensively evaluate the overall environmental footprint of refrigeration and air-conditioning systems. In fact, these systems consume energy during their entire life cycle for equipment manufacturing, operation, and disposal. Energy supply is accompanied by a series of processes that result into corresponding emissions. Under this viewpoint, when selecting optimal refrigerants, LCCP may better represent the performance and environmental footprint of air conditioners and refrigerators. Contextually, the actual operating performance of refrigeration and air conditioning equipment is greatly

influenced not only by system design and refrigerant characteristics, but also by the climate, load conditions, and characteristics of the energy supply of the installation site [1]. Therefore, to broadly investigate this spectrum of operating conditions, it is important for refrigerant evaluation tools to be cost-effective, flexible, and unbiased.

Common procedures for selecting next-generation refrigerants are either based on the experimental assessment of drop-in tests [2], where refrigerants are replaced without revisiting system design and control, or on the numerical thermodynamic cycle simulations that are determined solely by the refrigerant's thermophysical properties and neglect a thorough evaluation of the interrelationship between the transport properties of the refrigerant and the performance of the equipment [3]. An unbiased refrigerant evaluation approach should assess the potential of each refrigerant under representative operative conditions while also considering the transport performance, component features, and control parameters of the actual equipment. Therefore, a refrigerant evaluation tool may take advantage from the cost effectiveness and flexibility of a reliable simulation platform but requires standardized calculation conditions for achieving unbiased results. To this aim, this study presents the development of a refrigerant evaluation tool based on the integration of a reliable simulation platform with standardized calculation conditions. The validity of the simulator is verified by experimental results, and the performance of residential air conditioners is simulated under some conditions.

2. Overview of the refrigerant evaluation tool

To define representative calculation conditions, it was necessary to bring together different standpoints from academia and industry. Specifically, standardized analysis conditions and equipment models of the most common refrigeration equipment [4] were constructed in cooperation with the Japan Refrigeration and Air Conditioning Industry Association (JRAIA). In November 2015, the JRAIA founded the Refrigerant Evaluation Working Group to develop a standardized environment and corresponding methodology for refrigerant performance evaluation, thereby eliminating complementary discussions on measurement setup, method and accuracy, and enabling prompt evaluation of the actual potential performance of new refrigerants. This will help minimize conflicts between different research efforts and facilitate the effective selection of refrigerants and the development of energy efficient equipment.

As for the tool for examining the performance of air-conditioning systems, a general-purpose energy analysis simulator "Energy Flow+M" has been developed at Waseda University for steady state, dynamic, and control analysis [5-7]. Specifically, the features of the developed evaluation tool and the experimental verification of its computational accuracy are hereby presented and discussed.

3. Features of the simulator

The development of the simulator "Energy Flow+M" is based on the modular analysis theory to consistently represent different thermal systems using different refrigerants on the same simulation platform for energy analysis (Figure 1). Fundamental transport phenomena, together with the laws of energy conservation, mass conservation, and momentum transfer, make up the mathematical relationships that define each module. From this point of view, heat exchangers, compressors, expansion valves, and accumulators are represented as sets of functions that relate the inlet and the outlet states of the circulating refrigerant. As a result, it is possible to construct the Jacobian matrix of the entire system by interconnecting modules according to the system configuration and interfacing with the external environment. Newton-Raphson method drives the simulation towards convergence in stationary conditions and non-stationary conditions with dynamic parameter modulations. For mathematical details of the model formulation employed for the fundamental modules [5-7].

The modular analysis theory as a general-purpose analysis method focused on thermal fluid energy system Modular analysis. Consequently, it was clarified that the modular analysis theory facilitated the numerical analysis of various thermal energy systems, for example, vapor compression system, absorption system, desiccant system, solar thermal application system, etc. by unified methodology. For this theory, the concept of engineering control methods is put into analysis of the energy systems. The user can analyze the thermal system without mathematical procedure. Large scale smart energy system can be also easily analyzed and the user’s burden to make the simulation code can be reduced by using this simulator.
4. Model of the Residential Air Conditioner

Here, we will present the model of a residential air conditioner as a representative example. Single-split residential air conditioner generally feature an independent outdoor unit connected to the indoor heat exchanger with refrigerant pipelines as shown in Figure 2. Additionally, the rotational speed of the compressor and the opening of the expansion valve are adjusted using a PI controller to achieve target room temperature and degree of superheat at the suction of the compressor. The corresponding simulation model is built by assembling compressor, outdoor heat exchanger, expansion valve, accumulator, indoor heat exchanger and extension piping modules according to the reference system characteristics (summarized in Table 1).

5. Characteristics of the GUI

Figure 3 shows the graphic user interface (GUI) of "Energy Flow+M" simulator. The simulation environment makes it user-friendly even to engineers and researchers with minimal background experience in technical and scientific simulations. The combination of modules required to simulate a vapour compression type air conditioning system is shown in Figure 3-(a). Figure 3-(b) shows the appearance of the GUI during system simulations. Figure 3-(c) shows the simulation output in a CSV file format.
6.1.1 Background and purpose of the experiment

When introducing next-generation refrigerants into refrigerating and air conditioning equipment, not only the must the safety and environmental GWP (direct impact) of the refrigerant used in the equipment be considered, but also the impact on global warming owing to energy-derived CO2 emissions (indirect impact). Therefore, the actual operating performance of the refrigerant and air conditioning equipment needs to be evaluated. To fully illustrate the potential of low-GWP refrigerants, an optimized air conditioning unit should be fabricated for each refrigerant and employed to conduct accurate performance tests under actual operating conditions. However, there are a number of next-generation refrigerant candidates; the corresponding financial and time costs required to produce a series of specifically optimized air conditioning units is unrealistic. Therefore, in this study, objective [3] “Simulator development and utilization” was pursued to construct various simulators for heat exchangers and air conditioning systems to shorten the period and cost required for system examination and production. Before using such simulators, the validity and accuracy of the calculated values employed in their construction must be verified. Therefore, the R290 and R454C low-GWP refrigerants were dropped-in to air conditioners designed for use with the R22 refrigerant and their performances were evaluated accordingly.

6.1.2 Overview of the air conditioner used in this experiment

Table 2 shows the specifications of the air conditioner operated during the experimental test. The experimental tests are preliminarily conducted at steady-state for an R22 air conditioner and for drop-in tests of R290 within the same unit.

As the production of the R22 air conditioner had already been discontinued about 10 years ago, it was not possible to obtain a new system. Therefore, tests were conducted on a second-hand wall-mounted room air conditioner with a rated capacity of 2.2 kW. Pressure sensors and thermocouples are installed after thoroughly cleaning the heat exchangers of the outdoor and indoor units. Every time the refrigerant is replaced, the inside
of the refrigerant circuit is cleaned and the refrigeration oil is replaced with one suitable for each refrigerant, mineral oil for R22 and PAV for R290. In order to measure the refrigerant flow rate, two Coriolis flowmeters were installed for measurements in both cooling and heating modes. In addition, a compressor and expansion valve drive tools were provided by the air conditioner manufacturer to enable free control of the rotational speed of the compressor and free adjustment of the expansion valve opening in 50 steps. Figure 4 shows the mounting positions of the pressure sensors, thermocouples, and refrigerant flow meters. Further details of the equipment and instrumentation of the testing facility are referred to [8]. Fig. 4 shows mounting locations of pressure sensors, thermocouples, and flow meters. Figure 5 shows test setup in the dynamic performance evaluation facility.

6.2 Experimental results and simulator validation results
6.2.1 Background and purpose of validation
The actual operating performance of refrigeration and air conditioning equipment is the most critical factor in system operation evaluations. As system simulators offer an extremely effective approach for such evaluations, the effects of applying the R290 refrigerants to air conditioners designed for use with the R22 refrigerant, as discussed in previous section, were analyzed using the EF+M system simulator, which is being developed at our university. The differences between the experimental values and simulation results were then evaluated to validate the simulator.

These numbers are in good agreement overall. However, there is a difference compressor suction pressure and degree of subcooling. The reason for these is that although the former is considered to be affected by the refrigerating machine oil in the actual machine, it is not considered in the simulation. One of the reasons for the latter is thought to be that the fins of the air heat exchanger have slits in the actual machine, but are treated as flat plates in the simulation. In the future, we would like to further investigate and improve the accuracy.

6.2.3 Summary of model validation

A system simulator was applied to reproduce the results of a test in which a room air conditioner designed for use with the standard R22 refrigerant was charged with R22, R290, the latter two of which are low-GWP refrigerants. Comparisons of the experimental values and simulation results confirmed suitable simulation accuracy. In the future, we will also consider dropping in R454C.

7. Conclusions

This study presented the recent progresses in simulation platform adopted for the use in refrigerant performance evaluation analyses. The GUI of the simulator was upgraded with precisely structured and completely independent calculation codes, which enables prompt modification of each component and system module. The new GUI and internal code structure constitute a user-friendly simulation platform that does not require technical experience in coding and numerical simulation development to run accurate air conditioning and refrigeration system simulations with different refrigerants. A standard model for a single-split residential air conditioner was developed and validated with dedicated experimental tests conducted on a 2.2 kW R22 air conditioner. Additionally, numerical simulations with R290 were validated with corresponding drop-in tests of the same air conditioning unit. As a result, it was shown that the simulation results accurately represent the operating performance of actual systems with different refrigerants and may be effectively used for evaluating the performance of new low-GWP fluids.

Acknowledgements

The results of ‘6. Experiments to confirm simulation accuracy’ in this paper were obtained as a result of commissioned work (JPNP18005) by New Energy and Industrial Technology Development Organization (NEDO), and we would like to express our gratitude to everyone involved.

Abstract

Recently, as the life quality has been improved, the demand for the refrigeration system has been increased rapidly. Also, the interest in low GWP chiller is increasing, due to the important environmental problem. Here, we have developed a refrigeration system using R-718 refrigerant, water. Considering the large specific volume and surface tension of the water, we have designed heat exchangers and the compressors. We introduce the performance of the new system with the manufacturing process of the system. Moreover, we show the preparation procedures of the test that are necessary for the system operation.

1. Introduction

As the quality of life improves, the demand for cooling systems is increasing rapidly. However, since the increase in the manufacture of cooling devices is generally accompanied by an increase in the amount of chemically synthesized refrigerants, a global environmental pollution problem is greatly emerging at the same time. Through the regulation of refrigerants, the use of HFC refrigerants following synthetic refrigerants CFC and HCFC will be greatly reduced. Accordingly, interest in refrigeration and cooling systems using eco-friendly refrigerants with low Global Warming Potential (GWP) is increasing. Korea is the 5th largest producer of refrigeration/air conditioning machinery in the world, showing some technological superiority in the market. In response to the eco-friendly trend of the refrigeration market, research on refrigeration/air conditioning machines that use low GWP and natural refrigerants instead of existing refrigerants is needed. In this study, we would like to introduce the (R-718) cooling system that uses water with zero GWP as a refrigerant. A study on the water refrigerant chiller have not been conducted in Korea, although it has been carried out several times in developed countries such as Germany and Japan.\textsuperscript{(1,2)} In this presentation, water refrigerant chillers developed with domestic technology are introduced. In addition, we would like to disclose the manufacturing method and operating performance.

2. Cycle and components of chiller

This refrigerator is a two-stage compression system, an intercooler is used between the first and second stage compressors, and is manufactured according to the following cycle diagram.

\* Corresponding author. Tel.: +82-42-868-7840 ; fax: +82-42-868-7338.
\textit{E-mail address: jungchulkim@kimm.re.kr.}
3. Evaporator

Like other turbo chillers, the heat exchanger is designed and manufactured as a shell-and-tube type. Since the pressure difference from outside is not large, the shell is manufactured in an angular shape like an absorption chiller. The evaporator, classified as a falling film evaporator, is driven using a pump and a distributor. Liquid refrigerant is collected at the bottom of the shell, and a pump is installed at the bottom to move the liquid to the top of the evaporator. The liquid, which passes through the distributor, is fallen on the heat transfer tube. The internal pressure is set to 0.9 kpa as a design value, and the internal saturation temperature is set to about 5.4 °C. The inlet temperature of the cold water is 12°C. Since it is higher than the saturation temperature, the droplets, supplied on the heat transfer tube, is immediately evaporated and turned into steam, which is supplied to the first stage compressor. Here, to prevent moisture from entering, an eliminator is installed, as shown in Fig. 2.
In order to decide the type and number of tubes, evaporator experiments in lab scale test are performed prior to manufacturing the prototype. A 10 kW evaporator is prepared as shown in the photo, and four (Notched corrugated, Notched floral, Low fin, End cross tubes) different heat transfer tubes are tested. The internal pressure is set to 0.9 kpa, similar to the design pressure. The cold water supply temperature is 12 degrees. As for the evaporator, Notched corrugated tube showed the best performance, but Notched floral tube was the best in terms of low flow stability. So, we decided to use a combination of them. When designing the prototype, at least 130 heat transfer tubes (based on 3 meters) were required in consideration of the cooling capacity. But for stable operation, we installed about additional 50% more, and 204 tubes were installed.

![Fig. 3. Images of the 10kW evaporator(left) and condenser(right)](image)

4. Condenser

The internal pressure of the condenser shell is 6.11 kpa, and the saturation temperature is about 36.5 degrees. In the design, the inlet temperature of the cooling water is about 30 degrees, so the refrigerant vapor supplied from the compressor is turned into liquid droplets. The droplets, formed on the upper tubes, fall to the lower ones and are collected at the shell bottom. The liquid moves to the evaporator or intercooler by gravity. Like the evaporator, in order to decide the type and number of heat transfer tubes, lab scale condensation experiments were performed. A 10 kW condenser was prepared as shown in the picture, and 6 different heat tubes (Bare, Corrugated, Floral, Low fin, Notched corrugated, and Notched floral tubes) were employed. The internal pressure is set to 6.1 kpa, similar to the design pressure. The cooling water supply temperature is 30 degrees. Even though the Notched corrugated tubes show the best performance, we decide to use the corrugated, since there was no significant performance difference. Unlike the evaporator which is mainly related to the phase change, the condenser includes the condensing section but also the superheated section, as can be seen in the ph diagram in the figure. Thus, a larger number of heat transfer tubes than for the condensation only are required. Since single-phase heat transfer under vacuum conditions requires a larger heat transfer area, about 4 times more heat transfer tubes were used for cooling the superheated section. Totally, 630 heat transfer tubes are installed. In the overall structure, the condenser should be located at the rear end of the two-stage compressor. But if the connecting parts are arranged in a line, there is a problem that the size becomes excessively large. We also note that the space for the distribution of steam must be added to the front of the condenser, which greatly increases the length of the device. In order to resolve this problem, we erected the condenser, where the refrigerant is supplied vertically to the upper part of the condenser.

5. Intermediate cooler

Since the chiller of this project is a two-stage compression system, an intermediate cooler that cools the vapor that has passed through the first-stage compressor is required. There are two types of intercoolers: an indirect intercooled type and a flash tank type. In this study, the latter is selected to reduce the overall size and
the amount of pressure drop. A nozzle is installed on the top of the intercooler and used to change the refrigerant delivered from the condenser into mist. A small reservoir is installed at the bottom of the intercooler and an additional pump is installed to circulate the refrigerant. The refrigerant vapor passing through the first stage compressor (Lp) meets this mist to exchange heat and mass, and the generated vapor enters the second stage compressor (Hp). At this time, the direction of nozzle injection must be carefully determined so that the droplets do not enter the compressor. (Hp) As shown in the design, the temperature of the refrigerant entering the intercooler is approximately 120 °C, and the temperature of the refrigerant entering the two-stage compressor approximately 24 °C, but the exact temperature could not be measured in this experiment.

The liquid refrigerant collected at the bottom of the condenser moves through a pipe. Part of the refrigerant goes into the reservoir of the intercooler, and the rest moves to the evaporator shell. At this time, using the U-trap, (U shaped pipe) the liquid are collected at the lower end of the pipe. Due to the pressure difference, a liquid column is formed in the U-trap, and the column separates the condenser and the other sides, the evaporator and the intercooler. Because of this device, the evaporator and intercooler can maintain a different pressure environment than the condenser. The column height is determined by the pressure difference between both ends and the hydrostatic pressure due to gravity.

6. Compressor

This prototype is a two-stage compression system, and both compressors are of centrifugal type. Since water vapor has a large specific volume and the compressed environment is in a vacuum state, considerably large impellers are required. The diameter of LP is about 970 mm, and the diameter of Hp is about 650 mm. All of the impellers were made of aluminum, and were manufactured with a 5-axis processing machine as shown in Fig. 4. The two compressors are arranged side by side and operated independently. The compression ratio of LP is about 2.8, and the compression ratio of Hp is 2.6. The compressor efficiencies are 76% and 75%, respectively. Bearings are ball bearings and roller bearings. A cooling fan is installed at the rear end, and a cooling line using water connected to the outside is installed to cool the motor. (See Fig. 5)

Fig. 4. Lp(left) and Hp(right) impellers
Fig. 5. Structure of the compressor (Lp)

Fig. 6. Image of the prototype

Fig. 7. Temperature change during the operation
7. Performance of the system

Prior to operating the prototype, (See Fig. 6) we created a vacuum environment and injected water into the evaporator, condenser, and the intercooler. Cold water and cooling water were set to flow at 1,000 lpm and 1,200 lpm. It was operated while increasing the number of revolutions of LP (primary compressor) and HP (secondary compressor) step by step. If the vibration increases or the internal bearing temperature increases while increasing the number of revolutions, we immediately stop the operation. Finally, it was driven up to LP: 10,000 rpm and HP: 16,300 rpm.

As the phase change occurred in the evaporator, the temperature of the cold water was dropped, resulting in a temperature difference of about 5.11 °C at the inlet and outlet. (See Fig. 7) In the condenser, as shown in Fig. 8, condensation actively occurred on the surface of the heat transfer tubes, and the temperature of the cooling water was increased by about 4.38 °C. The total heat capacity was measured as 359.83 kW and 366.60 kW for the evaporator and condenser, respectively. Considering that the total power used by the compressor is 50.48 kW, the calculated heat capacity of the condenser should be about 410.3 kW, but condensation on the inner wall due to conduction occurs together (the amount of condensation on the inner wall was not calculated), resulting in low performance of the condenser.

Upon reaching equilibrium, the average cooling water inlet/outlet temperatures are 16.48 °C and 11.36 °C, and the average cooling water inlet/outlet temperatures are 28.90 °C and 33.27 °C, as shown in Fig. 7. The temperature change is shown in the graph in the figure. The COP considering power consumption and cooling heat was calculated as 6.80, and the overall heat transfer coefficient of the evaporator at this time was calculated as 5,596 W/m²°C. In the case of the condenser, considering the condensing part includes the single phase heat exchange in the superheated and supercooled sections, we derived the overall heat transfer coefficient, 4,596 W/m²°C.

8. Conclusions

In this study, the evaporator, condenser, and compressor were studied in detail to develop the specifications to be applied to the R-718 refrigerator, and the entire system was manufactured by applying them to the prototype. In addition, performance evaluation and analysis were performed by connecting and operating electric devices. For actual product development, several factors, including a huge size, have to be improved, through additional research. We believe that this study has a significant meaning in that it the development direction of the R-718 refrigerant system was investigated through this study.

Abstract

Supercritical CO$_2$ is receiving increased interest as a heat transfer fluid, particularly in heat pump applications, due to some favorable physical properties. While supercritical CO$_2$ is traditionally circulated via compressors, it may be possible to use centrifugal pumps as an alternative. This could lead to substantial energy and cost savings. The design and evaluation of a pumped supercritical test loop is reported in this work. Upon verifying supercritical CO$_2$ could be circulated with the pump in the given setup, conditions were varied to understand the behavior of the pump and the potential for acting as a heat transfer loop between an outdoor heat pump and the indoor space. These results are presented along with suggestions for improved performance and problems that were encountered in the work.

Keywords: Pumped Supercritical CO$_2$; HVAC; Low GWP

1. Introduction

There are two interrelated trends in the power and energy industries to meet climate stabilization goals. The first is the electrification of fossil fuel-based end use technologies and the second is the decarbonization of electricity generation. The technology of choice for electrification of heating is generally the heat pump, which can replace fossil fuel-based furnaces and water heaters. The trend of using heat pumps to replace these technologies is likely to increase with next generation heat pumps capable of handling colder ambient conditions.

While heat pumps offer a route to electrify heating technologies, they rely on refrigerants that can have orders of magnitude larger global warming potential (GWP) than CO$_2$. With this, the Heating, Ventilation, and Air Conditioning (HVAC) industry is experiencing a push to low GWP refrigerants. The American Innovation and Manufacturing (AIM) Act has directed the Environmental Protection Agency (EPA) to *phase down production and consumption of hydrofluorocarbons* (HFCs), due to their high global warming potentials (GWPs) [1]. This planned reduction in production and consumption, while not directed at air conditioners and heat pump systems is consistent with the transition towards more environmentally friendly refrigerants. From a system designer and manufacturer perspective, what options are available? There is a large interest in natural refrigerants such as ammonia (R-717), CO$_2$ (R-744), and propane (R-290) which are low GWP but *tend* to be more toxic and/or flammable. The synthetic refrigerant alternatives such as R-32 and R-454B have lower GWPs but are still orders of magnitude greater than that of the mentioned natural refrigerants and are more costly. Given the trend towards lower GWPs, facility and plant managers in commercial buildings, and industrial and commercial refrigeration may be faced with decisions of cost and compliance (if it comes to that point) on which systems to utilize to meet their building cooling and heating and/or their refrigeration needs.

Previous research done at the Electric Power Research Institute (EPRI) investigated technologies that can provide solutions/options for low GWP heating and cooling. EPRI performed a laboratory evaluation of a 35
kW (10 RT) ammonia chiller that used CO₂ as the heat transfer fluid to the indoor units [2]. Ammonia was selected as the refrigerant due to its performance and low GWP. The major drawback of this selection is the toxicity of ammonia which requires the ammonia side of the system to be contained outside, requiring a secondary heat transfer loop. Typically, a water-glycol mixture would be used as the working fluid in the secondary loop, however, the work showed the benefits of using liquid CO₂ as the working fluid between the indoor and outdoor units. The main advantage was due to the large latent heat of vaporization of CO₂, taking advantage of phase changes. This resulted in the ability to use smaller diameter pipe and low mass flow rate to transfer heat between indoor air handling units (AHUs) and the ammonia chiller.

This paper presents a novel concept of utilizing a CO₂ secondary loop for space cooling and heating with an ammonia based outdoor unit. Specifically, the ability of a CO₂ pump to circulate supercritical CO₂ is investigated, because the critical temperature of CO₂ (304.25 K) is lower than the temperature typically delivered to heating coils (assuming the volume is such that the pressure is beyond the critical pressure; a likely scenario in HVAC applications).

Centrifugal pumps and compressors both move fluid by accelerating it through vanes in a spinning impeller and then increasing the pressure at the outlet by converting part of the kinetic energy imparted. In a pump the fluid is usually a liquid whose density remains approximately constant, while in a compressor the working fluid is a gas whose density is increased. There are substantial differences between impeller designs in centrifugal compressors and pumps. For supercritical CO₂ applications near the critical point, the working fluid is closer to a liquid than to a gas. Nevertheless, the geometry for optimal pumping of supercritical CO₂ is not the same as for an incompressible fluid, and it is a function of the thermophysical properties of the CO₂. A number of studies investigated these issues in connection with applications in oil and gas, and in power generation. Through a CFD analysis, Cubas et al. [3] conclude that typical hydrodynamics similarity laws of pumps used with liquids can be used to evaluate performance when pumping a supercritical fluid. Kim et al. [4] compare experimental and numerical results and conclude that CFD can yield insight into the performance of liquid pumps used for supercritical CO₂, and moreover that liquid pumps can pump supercritical CO₂ effectively. Bergamini et al. [5] provide similar conclusions, namely that centrifugal pumps are efficient means of pumping supercritical CO₂, provided that certain conditions of temperature and pressure are met. While the pump used in this application is much smaller than what would be considered for oil recovery, CO₂ sequestration, or power generation, we too expect the performance in pumping supercritical CO₂ to be similar to the rated performance of the pump for liquid CO₂ applications.

There are numerous benefits of pumping supercritical CO₂ for the current ASHP design, mainly because a CO₂ compressor will not be required. The pumped solution offers lower electrical power consumption, reduces the total cost of the system, and provides a simpler overall design.

This paper presents the testing of a CO₂ pump to circulate supercritical CO₂ in EPRI’s Knoxville Thermal Laboratory. The following sections describe the setup that was used to test the idea, the results from the tests that were performed, and a discussion on areas for improvement and further study for this application.

2. Experimental Setup

The experimental setup was designed to mirror the conditions that the supercritical CO₂ would experience in the secondary loop that transfers heat from the condenser to heating coils inside a building. In particular, a test loop was constructed to mimic the heating mode of an ASHP that is connected to the indoor space by a CO₂ loop. The CO₂ is pumped into the condenser of the ASHP where it is heated, routed to the indoor AHUs where it heats the air and then pumped back to the condenser of the ASHP. The test loop is a scaled version of this loop. Heat exchangers (HXs) are paired with valves to simulate behavior of the real heat exchangers, namely heat transfer with pressure drops. The layout of the test loop is explained in detail below.
2.1. Test loop hardware details

The test loop is composed of the CO₂ pump, two compact plate HXs, needle valves to provide controlled pressure drops, a receiver to act as a buffer for the pump, measurement devices (flow meter, digital pressure transducers, analog pressure transducers, and thermocouples), and valves for charging, venting, and vacuuming the system. A schematic of the system is shown in Figure 1 and a part list is presented in Error! Reference source not found. The CO₂ pump is a dual stage centrifugal pump where the impellers are magnetically coupled to the motor. The pump was selected because it is designed to pump liquid CO₂ and is rated for pressures suitable for handling supercritical CO₂. The tubing connecting the components is copper-iron (Cu-Fe) tube rated for 13 MPa and can be brazed using standard equipment and a high silver content braze rod. The fluid is first circulated through a MicroMotion Coriolis flow meter rated at 10.3 MPa which measures the flow rate and the density of the fluid. The fluid then goes into the part of the loop acting as the condenser of the ASHP. First the fluid passes through a stainless-steel needle valve to simulate pressure drop along the heat exchanger. The CO₂ is then heated in a brazed plate heat exchanger (BPHE) referred to as the heating HX. The heating HX’s heat source is 0.15 m³ (40 gallon) electric water heater coupled with a small circulating pump. The heated CO₂ then passes through the section of the test loop acting as the indoor AHU. The CO₂ passes through another needle valve, providing a controllable pressure drop, and is then cooled by another BPHE, referred to as the cooling HX. The cooling fluid is provided by a water loop in the laboratory, which is cooled by a chiller and heated by electric heaters, following a given setpoint. After the CO₂ is cooled it is collected in a receiver. The receiver has two functions. First it adds additional volume for a fluid reservoir to be available for the pump, ensuring that the pump doesn’t run out of fluid to pump. Secondly, the receiver helps ensure that the pressure head requirement for the pump is met. The amount of pressure drop between the receiver and the inlet of the pump is also minimized per the manufacturer recommendation. The CO₂ pump operates on 208 VAC three-phase and a variable speed drive (VSD) is used to control the speed. A bypass was added to the loop in the scenario when not enough fluid is being returned to the pump to cool the motor. This condition has

Figure 1: Schematic of test loop for evaluating supercritical CO₂ pumping. T and P indicate location of temperature and pressure measurements, respectively. CV1 and the heating heat exchanger act as the heating portion of the ASHP while CV2 and the cooling heat exchanger act as the indoor air handling unit (AHU).
not been observed with the testing so far. A pressure relief valve was added to protect components and safely reduce the pressure, if exceeded. The system was pressure tested and the pressure relief valve set to 9.75 MPa (1,414 psia). Considerations must be taken with the pressure relief valve if it were ever to exhaust. High pressure CO₂ when rapidly expanded can cause dry ice to form, potentially blocking the exhaust path. Because of this, connecting tubing on the exhaust of a pressure relief valve with CO₂ systems should be avoided. Instead, the CO₂ is allowed to exhaust into the laboratory space where CO₂ sensors are integrated with exhaust fans.

Figure 1 also indicates the measurements being taken and their locations. Temperature is measured using T-type thermocouples and two NI USB-9213 thermocouple modules. 32 temperature measurements are monitored with important measurements (in and out of the heat exchanger, for example) being made with multiple thermocouples. The thermocouples are taped to the pipe and the piping is insulated. The thermocouples were calibrated in a temperature bath prior to installation into the system. Pressure is measured by digital and analog pressure gauges. The four digital sensors output a 0-10 VDC which is read by an NI USB-6001. The flow meter and power meter provide a Modbus over RS-485 interface that the data acquisition computer queries for measured values. Figure 2 shows the completed test setup with major components identified.

Figure 2: The supercritical CO₂ pump test loop as-built. The insulated lines are the CuFe tubes that contain the CO₂. The water lines, hot and cold, are plumbed in PEX (white pipes in figure).
2.2. Charging of the test loop

The mass of CO$_2$ to be added to the system (commonly called the charge) was based on the density of supercritical CO$_2$ at 309 K and 8.5 MPa, and an estimate of the volume of the system. The particular value chosen is a compromise between maximizing the specific heat, $c_p$, and the stability of $c_p$ at the particular fluid conditions. Figure 3 illustrates this tradeoff as $c_p$ of supercritical CO$_2$ is plotted as a function of temperature for different pressures with the black vertical line showing the desired temperature of the fluid going into the indoor AHUs (design condition). As the pressure increases the specific heat decreases but the curves also flatten out, making $c_p$ more stable. It was decided that if we could operate around the 8.5 MPa curve, that would be a reasonable balance between stability and large $c_p$. For reference, $c_p$ of saturated liquid water at 309 K (4.2 kJ/kg-K) is also shown on Figure 3. The mass required is given by,

$$ m = \rho V $$  \hspace{1cm} (1)

where $\rho$ is the density at the design condition and $V$ is the volume of the system. The system volume is estimated to be 3.4E-3 m$^3$ and the density is 568 kg/m$^3$ at the design condition. The required mass to be fill the system is 1.9 kg. The actual charge of the system was 2.2 kg to provide a slight additional charge for the system in-case of uncertainties in volume estimates. The filling process begins with pulling a vacuum on the system. When the vacuum is sufficient, a CO$_2$ cylinder with a dip tube is placed on a scale and connected to the fill valve and liquid CO$_2$ is pulled from the bottom of the cylinder. CO$_2$ is pressure fed into the system until the correct mass has been reached. If the pressure between the system and the cylinder balances before the required mass is in the loop, heat can be applied to the cylinder to increase the pressure in the cylinder, thereby pushing more liquid CO$_2$ into the loop.

3. Test Method

The primary goal of testing was to see if it would be possible to pump supercritical CO$_2$ effectively using a pump designed for liquid CO$_2$. If pumping was possible, a series of tests would be conducted to examine the performance of the pump over a range of conditions. In particular the following are held constant over the course of a test:

- Temperature entering pump
- Temperature exiting heating HX
- VFD frequency
- Position of CV1 and CV2
The temperatures in the first two bullets were held constant by adjusting valves on the water side of the associated heat exchangers. The frequency of the VFD was set on the drive’s front display and the control valves were set before the start of a test. To get the test loop to test conditions (supercritical CO₂ flowing) the cooling water loop and heating water loop were operated until steady state was reached for their control setpoint. The CO₂ pump was started at about 10 Hz with the cooling water valve closed and the heating water valve about a quarter turn open. The temperature and pressure begin to rise in the system until the CO₂ pressure and temperature go beyond the critical point. At this point, the VFD is adjusted to the test’s frequency and the cooling water valve is partially opened. The cooling and heating valves are adjusted until the temperature setpoints for the test are met. The test condition is ran for at least 15 minutes while at steady state.

Referring to Figure 1 (numbers in red circles) the rate of heat added to the system, \( \dot{Q}_{in} \), can be calculated by

\[
\dot{Q}_{in} = m(h_3 - h_2)
\]

where \( m \) is the mass flow rate measured by the flow meter, \( h_3 \) is the specific enthalpy of the CO₂ leaving the heating HX, and \( h_2 \) is the specific enthalpy entering the heating HX. The specific enthalpy is determined using REFPROP [6, 7] and the measured temperature and pressure at the location. The rate of heat leaving the system through the cooling HX, \( \dot{Q}_{out} \), is given by

\[
\dot{Q}_{out} = m(h_5 - h_4)
\]

where the \( h_5 \) and \( h_4 \) refer to the specific enthalpy leaving and entering the cooling HX, respectively. The rate of work on the fluid performed by the pump, \( W_p \), is determined by

\[
W_p = m(h_1 - h_6)
\]

where the specific enthalpy is calculated at the outlet of the pump, location 6, and at the inlet of the pump, location 1. The electrical power consumption of the pump, \( P_p \), is calculated assuming a balanced three phase load,

\[
P_p = \sqrt{3}VIpf
\]

where \( V \) is the applied voltage, 208 VAC, \( I \) is the measured current, and \( pf \) is the nominal power factor of the pump, 0.67. The work done by the pump and the amount of electrical power are related through the efficiency,

\[
\eta = \frac{W_p}{P_p}
\]

which has a nominal value of 72.5%. Heat engine sign convention is used in this study where heat into and work out of the system are considered positive. At steady state, by the First Law of Thermodynamics,

\[
\dot{Q}_{in} + W_p = \dot{Q}_{out} + \dot{Q}_{lost}
\]

where \( \dot{Q}_{lost} \) is the rate at which heat is lost to the environment.

### 3.1. Uncertainty analysis

Error propagation due to uncertainty in measurements begins with examining Eqns. 2 and 3. In particular, there is a difference in enthalpy which is then multiplied by the mass flow rate. If uncertainties are independent and random, the uncertainties associated with addition and subtraction is given by [8],

\[
\delta \Delta h_{3-2} = \sqrt{\delta h_3^2 + \delta h_2^2}
\]

where \( \delta \Delta h_{3-2} \) is the uncertainty that results from taking the difference in enthalpy between points 3 and 2. \( \delta h_3 \) and \( \delta h_2 \) are the uncertainties associated with the enthalpies. These uncertainties are determined by passing through the uncertainties in the thermocouples and the pressure sensors into the enthalpy calculation.
performed by REFPROP. In particular, an upper, \( h_u \), and lower, \( h_l \), estimate is made of the enthalpy from the upper and lower bounds of the temperature and pressure. The uncertainty is then determined by

\[
\delta h = (h_u - h_l) / 2.
\]  

(9)

Given a temperature measurement with associated uncertainty, \( T = T_{\text{best}} \pm \delta T \), and a pressure measurement, \( P = P_{\text{best}} \pm \delta P \), \( h_u \), and \( h_l \) are determined by examining the pressure-enthalpy diagram which shows that the upper value of the enthalpy is given by,

\[
h_u = f(T + \delta T, P - \delta P)
\]  

(10)

and the lower bound of the enthalpy given the uncertainties in temperature and pressure is,

\[
h_l = f(T - \delta T, P + \delta P)
\]  

(11)

where \( f \) is the function for enthalpy provided by REFPROP. It should be noted that this is the worst-case scenario and may be overly conservative. From calibration, a fractional uncertainty of 0.0028 was determined and is assumed for all thermocouples [9]. The pressure sensors have a stated uncertainty of 0.07 MPa. The Coriolis flow meter has a percent uncertainty of 0.25% (assumed for our supercritical case) and a density uncertainty of 0.2 kg/m\(^3\) for liquids.

The next consideration is which temperature is used for enthalpy calculations. Multiple measurements of temperature are done at each location, so an average is used. The uncertainty from each measurement is added in quadrature (Eqn. 8) and scaled by \( 1/N \) where \( N \) is the number of measurements in the average. For example, the uncertainty of the average of three thermocouples is, \( \delta T_{\text{avg}} \),

\[
\delta T_{\text{avg}} = \frac{1}{N} \sqrt{\delta T_1^2 + \delta T_2^2 + \delta T_3^2}
\]  

(12)

where \( \delta T_1 \), \( \delta T_2 \), and \( \delta T_3 \) are the associated uncertainties with thermocouples 1, 2, and 3, respectively, and \( N \) is 3. The relationship between fractional uncertainty, \( x_{\text{frac}} \), and uncertainty, \( \delta x \), is

\[
x_{\text{frac}} = \frac{\delta x}{|x_{\text{best}}|}
\]  

(13)

where \( x_{\text{best}} \) is the measurement made. Using Eqn. 13, Eqn. 12, with constant fractional uncertainty, can be rewritten as,

\[
\delta T_{\text{avg}} = \frac{x_{\text{frac}}}{N} \sqrt{T_{\text{best,1}}^2 + T_{\text{best,2}}^2 + T_{\text{best,3}}^2}
\]  

(14)

The final uncertainty consideration is how the error from the mass flow meter and the difference in enthalpy combine. This is straightforward because the fractional uncertainty of products and quotients, is the square root of the sum of the squares of the given fractional uncertainties [8].
4. Results

The first test was to verify that the test loop could circulate supercritical CO₂. Initially the CO₂ is two phase mixture at room temperature. The VFD was operated at a low frequency to circulate the liquid CO₂ while adding heat, to ensure uniformity while avoiding excessive stress on the pump produced by circulating two-phase fluid. The temperature and pressure increased while the density decreased. When enough heat was added the temperature and pressure surpassed the respective critical points. At this point the density stabilized and the VFD frequency was increased. This showed that the pump could circulate supercritical CO₂ and testing could continue, studying how the pump performed in different conditions.

Figure 4 is an example of a test performed with the pump inlet temperature set to 308.15 K and the heating heat exchanger outlet set to 313.71 K. CO₂ goes supercritical after the red transparent rectangle when the temperature and pressure pass their respective critical point values, \( T_{Cr} \) and \( p_{Cr} \).

Figure 4: An example of a test performed with a pump inlet temperature of 308.15 K and heating heat exchanger outlet set to 313.71 K. CO₂ goes supercritical after the red transparent rectangle when the temperature and pressure pass their respective critical point values, \( T_{Cr} \) and \( p_{Cr} \).
setpoints were varied the density changed slightly between tests which yielded insight into how the CO$_2$ pump performed with a varying fluid density, although the changes were minor. Error! Reference source not found. illustrates the performance of the pump as the density changes (slightly) and as the VFD frequency is adjusted. For reference, liquid CO$_2$ at 20 °C has a density around 773 kg/m$^3$. This performance shows that the mass flow rate is a strong function of the VFD frequency, as expected, and does not vary significantly with the variation in density experienced during these tests. The nominal volume flow rate for this pump when used for liquid CO$_2$, at 60 Hz, is between 12.1 and 20.8 liters/minute for 19.8 to 13.7 m of head, respectively. The maximum volume flow rate for supercritical CO$_2$ at the same pump speed was approximately 17.8 liters/minute, confirming expectations that the pumping of supercritical CO$_2$ would be similar to that of liquid CO$_2$. Error! Reference source not found. also shows the effect of increasing the pressure drop through the test loop by closing the needle valves a given amount. The blue, red, and black horizontal lines are the average mass flow rates with the needle valves fully open, for 40, 50, and 60 Hz, respectively. Both the heating and

Figure 6: The rate of heat delivered to the cooling heat exchanger as the product of the mass flow rate and change in temperature is varied.
cooling HX valves are closed in equal amounts; first 2 turns and then 3 turns. The decrease in flow rate is seen, again, as expected, by the four points that are away from the averages.

The ultimate purpose of the pump is to deliver heat between the indoor AHU and the ASHP. Figure 6 shows the amount of heat that the pump was delivered as a function of the product of the mass flow rate and temperature difference between the heating HX output and the pump inlet temperature. The rate of heat delivered behaves as expected, increasing as the mass flow rate and/or temperature difference increases.

5. Discussion

The presented results show that circulation of supercritical \(\text{CO}_2\) is possible with an appropriately pressure rated/designed \(\text{CO}_2\) pump. The mass flow rate varied between 0.07 kg/s at 40 Hz to about 0.12 kg/s at 60 Hz. The electric power provided to the pump for these flow rates is between 150 W and 200 W. The alternative to using the \(\text{CO}_2\) pump is a \(\text{CO}_2\) compressor. The compressor selected for the current project is estimated to draw about 6.5 kW to operate, running at part load. This is a significant difference between using the pump and compressor. The designed heating load is between 35.2 and 70.3 kW which, by inspection of Figure 6, indicates that multiple pumps will be needed if the maximum output is 7 kW, requiring at least 5 pumps. If 5 pumps were being used at 200 W, the total power draw is about 1 kW. This is still significantly less power consumption than the compressor but increases the initial cost of the system. However, from the results presented there are opportunities for increasing the heat output. These include increasing the temperature difference, lowering the mass charge of the system to allow for higher temperature at equivalent pressures, and running the VFD at frequencies greater than 60 Hz.

During the course of the experiments the pressure of the system was a concern. The system was pressure rated to 9.75 MPa and at the time it was not well understood which temperature in the system would dictate the pressure. Understanding the process from subcritical to supercritical and how the cycle executes along with experimental results shows that the system pressure is mainly dependent on the pump inlet temperature. Figure 7 shows the relationship between the system pressure and pump inlet temperature. This indicates that as long as the \(\text{CO}_2\) can be sufficiently cooled by the cooling HX, the pressure of the system can be kept at safe operating conditions while increasing the temperature of \(\text{CO}_2\) leaving the heating heat exchanger. The result would be a larger temperature difference, leading to an increased heat output. The current setup can be used to test this but is limited by the temperature output of the hot water loop and the HXs. Assuming that the maximum temperature leaving the heating HX is 336 K, and the loop is able to cool this \(\text{CO}_2\) to 319 K, just below the maximum pressure condition, the temperature difference is 17 K. If this is done at 60 Hz, the mass flow rate is about 0.12 kg/s. From the fit in Figure 6 the heat output is about 17 kW, more than doubling the heat output that was measured in the experiments, reducing the number of pumps.
Another possible option is to decrease the amount of CO$_2$ in the system. If the mass present in the system is decreased, the CO$_2$ could be heated to a higher temperature at the same pressure. This would become an optimization problem in itself because the specific heat also decreases with temperature; what mass charge gives the maximum heat output over the range of temperatures considered? This is not fully understood so an estimate of the benefit cannot be made.

The final opportunity considered for improvement is running the VFD at frequencies greater than 60 Hz. If the effect of density changes is assumed negligible (reasonable assumption by Figure 5, a) a linear fit between the mass flow rate and the VFD frequency can be made (Figure 5, b),

$$\dot{m} = 0.002 f_{VFD} + 0.001.$$  \hspace{1cm} (15)

If the VFD is operated at 75 Hz, the mass flow rate is expected to be 0.151 kg/s, according to Eqn. 15. If this mass flow rate is performed for the same temperature differences, the performance can be estimated by the fit given in Figure 6, and this estimate is given in the figure shown by the black wireframe squares. An increase in maximum output of 1.5 kW is estimated which is about a 13% increase from 60 Hz. If the pump is operated at 75 Hz and the temperature difference is increased to the previously stated 17 K, the heat output is estimated at 20.5 kW. The required number of pumps is now 2 for our purposes with this increased performance.

Finally, some of the challenges encountered in this work are acknowledged, in particular, problems that were faced with the CO$_2$ pump and with the uncertainty in the measurement are discussed.

The CO$_2$ pump was designed for liquid circulation but modified by the manufacturer to endure the higher working pressure of supercritical CO$_2$. Unfortunately, the initial design did not consider the aspect of a gas-like fluid being present in the pump and potentially being trapped in any of the internal components. When the system was operated and then vented, gas was trapped in a sleeve in the impeller, which expanded and plastically deformed when the system was vented. The solution was to provide vents on the components that can potentially trap gas.

The final consideration that should be mentioned are the large error bars on the heat calculations (Figure 6). Performing an uncertainty analysis on the measurements it was a surprise that the uncertainty was so large (about 1.5 kW) on the measurements given that calibrated thermocouples were used. Figure 8 gives insight into how slight uncertainty in temperature measurements can lead to large uncertainties in the heat transfer calculations (Eqns. 2 and 3). A number of the experiments were performed between 308 and 313 K where small changes in temperature can lead to large change in enthalpy and thereby increases the uncertainty in the heat transfer calculations. This should have been expected considering the known instability of the specific heat in this temperature and pressure range.
6. Conclusion

This work showed that given an appropriately designed CO₂ pump, supercritical CO₂ can be circulated effectively with a centrifugal pump. The work presented on the ability of the pump and supercritical CO₂ to be used as a secondary loop between a heat source (ASHP) and heat sink (indoor AHU) in a test loop setup. While the amount of heat that was transferred between the source and the sink was somewhat below the requirement for the full scale ASHP, the testing gives indications of how many pumps would be needed if the heat transfer loop was operated as is. More importantly the research showed that there exist opportunities for improvement which included increasing the temperature difference while maintaining system pressure, increasing the VFD frequency, and adjusting the system mass charge. The two former points of improvement could be estimated with the work done and showed that there is a potential to more than double the capacity of the output by appropriate changes in operating conditions. Further work should focus on investigating the concept of optimal charge for pumped supercritical CO₂ systems.

Abstract

A numerical investigation was conducted on a high-temperature heat pump (HTHP) that can supply heat at 200°C and two types of thermal energy storage (TES) systems. The HTHP cycle employs a multistage water vapor compression process to achieve a high-temperature lift. Concrete was used as the sensible heat storage (SHS) system, while strontium bromide/water (SrBr$_2$/H$_2$O) was used as the working pair for the thermochemical energy storage (TCES) system. The multistage HTHP cycle was first analyzed based on an enthalpy balance with specific temperature conditions, and then the performance of both the SHS and TCES systems connected to the HTHP cycle was estimated.

The HTHP cycle achieved a COP of 4.41 with an evaporation temperature of 90°C and a condensation temperature of 160°C. During storage, 500 kW of heat was supplied at 200 °C for 8 hours. The TCES system required 45% and 68% less mass and volumetric size, respectively, in storage mode. During discharge operation, the TCES system was able to supply heat at a temperature of over 200°C under all conditions, while the SHS system had a maximum cycle output temperature of 180°C. The TCES system also had a heat output rate of ~500 kW and round-trip efficiency (RTE) of 0.82.

Keywords: High-Temperature Heat Pump, Multistage Vapor Compression Cycle, Thermal Energy Storage;

1. Introduction

The global greenhouse gas (GHG) emissions have steadily increased over the past few decades. Among the various emission sectors, the industrial sector is responsible for 34.8% of global GHG emissions after reallocating to the final energy consumption sectors, and the industrial sector is becoming increasingly important [1,2].

In 2019, 120944 PJ of energy were consumed in the industrial sector, and fossil fuels accounted for over 58% (70544 PJ). Thermal energy is the dominant energy carrier in the industrial sector and each industrial sub-sector has a different main temperature level respectively [3].

Waste heat recovery is an excellent solution for improving the efficiency of existing industrial processes [4,5]. However, heat recovery at low temperatures is generally not feasible. Another efficient option for recovering waste heat from industrial processes is to use highly efficient thermal power thermodynamic engines and heat pumps. Heat pumps are widely used in domestic applications and are applied to some niche industrial processes. Electrically driven heat pumps have proven to be suitable for supplying process heat effectively; however, industrial heat pumps can deliver heat at a maximum temperature of 150°C, mainly because of component limitations [6,7]. Despite this shortcoming, there have been several research and development efforts to push the sink temperature of industrial heat pumps to 200-250°C thus extending their availability for a larger proportion of industrial processes [8,9].
Thermal energy storage (TES) systems can store heat or cold to be used later at different temperatures, places, or power is mainly used to overcome the mismatch between energy generation and demand [10]. There are three types of TES systems: sensible heat storage, latent heat storage, and thermochemical storage. Sensible heat storage (SHS) is stored by increasing or decreasing the temperature of the storage material. Latent heat storage uses the phase transition of materials, usually a solid-liquid phase change. Upon melting heat is transferred to the material, storing large amounts of heat at a constant temperature. Thermochemical energy storage (TCES) is produced when a chemical reaction with high energy involved in the reaction is used to store energy. TES technology is considered an effective system that can maximize the efficiency of heat pumps [11].

The temperature distribution of the thermal energy demands for individual end-uses can vary substantially. This study focused on a high-temperature heat pump (HTHP) cycle that can supply heat at approximately 200°C. The HTHP consists of a two-stage water vapor (R-718) Rankine cycle with intercooling (IC), and is expected to provide process heat at temperatures ranging from 100°C to 200°C. This temperature range is primarily required in the paper and printing industries and in other non-classified sectors [12]. Additionally, this study numerically evaluated and compared the performance of two different types of thermal energy storage systems, sensible and thermochemical energy storage, when connected to the HTHP.

2. Modeling of HTHP and TES systems

2.1. Multistage water vapor compression cycle

A two-stage water vapor compression cycle with intercooling was introduced as the HTHP cycle, Fig. 1. First, the working fluid, water/steam, is compressed to an intermediate pressure and then cooled close to its condensation temperature. The resulting slightly superheated steam is recompressed to the condensation pressure, which corresponds to the aimed condensing temperature. The International Association for the Properties of Water and Steam, based on the industrial formulation 1997 (IAPWS-IF97), was adopted to calculate the water/steam properties in the HTHP cycle.

The temperature of the heat source, $T_{source}$, which corresponds to waste heat, was fixed at 120°C. The evaporation and condensation temperatures, $T_{evap}$ and $T_{cond}$, were set to 90°C and 160°C, respectively, with a temperature difference of $\Delta T_{lift} = 70$ K. The intermediate pressure was determined to have the same pressure ratio between the first and second stages because the two-stage cycle showed the highest coefficient of performance (COP) when both compressors had the same pressure ratio in previous work. Additionally, all the temperature differences between the hot and cold sides after the heat exchangers were assumed to be 10 K ($T_{sup\&sub} = 10$ K).

The heat sink flow, which flows through the intercooler and condenser, was designed to supply constant thermal energy to the TES system. It has the same pressure as the condenser, $P_{sink} = P_{cond}$, and the temperature of the sink inlet and outlet, $T_{sink\ in}$ & $T_{sink\ out}$, were fixed at 25°C and 200°C respectively. The amount of thermal energy obtained from the intercooler and condenser, $Q_{sink}$, was determined to be 500 kW.

2.2. Thermal energy storage system

Sensible heat storage involves the use of a material to store thermal energy by increasing or decreasing the temperature of a storage medium. This energy storage method is widely used and is the most common type of TES technology. Many materials can be used for SHS materials such as water, air, oil, rock beds, brick, concrete, and so on. An SHS system using concrete is considered in this study. Concrete can withstand cyclic stress at temperatures of up to 500°C during numerous consecutive charging and discharging periods [13]. Therefore, concrete is suitable for storing sensible heat over long lifetimes.

The SHS system consists of two tanks: a hot tank containing concrete and a cold tank that stores air as a heat transfer fluid (HTF). The operating strategies are shown in Fig. 2. The low-temperature air, $T_{\text{amb}} = 25$°C, is heated by high-temperature steam in the HTHP cycle, $T_{\text{sink}} = 200$°C for 8 hrs, during storage mode, while high-temperature air transfers heat to low-temperature water/steam in the heat sink during the discharge mode. The state of water/steam in the heat sink flow was also calculated using IAPWS-IF97, and the performance of the SHS system was calculated based on the concrete properties at 200°C (Table 2) [14,15].

Thermochemical energy storage (TCES) systems use reversible chemical reactions and have the advantages of a high storage density and long storage times without dissipation. Generally, reversible chemical reactions of TCES occur at high temperatures between the solid and gas phases. There are various types of chemical reactions for TCES, such as hydration, carbonation, and oxidation, and each reaction working pair has different working temperature and pressure characteristics. The strontium bromide and water (SrBr$_2$/H$_2$O) system was selected as the working pair for the TCES system in this study based on its promising performance at temperatures above 150°C [16,17]. The monohydrous SrBr$_2$ and SrBr$_2$$\cdot$H$_2$O can store heat via dehydration, and the hydration of anhydrous SrBr$_2$ releases heat, as given in Eq. 1.

$$\text{SrBr}_2(s) + \text{H}_2\text{O}(g) \rightleftharpoons \text{SrBr}_2 \cdot \text{H}_2\text{O}(s) \quad \Delta H = 71.98 \text{kJ/mol} \quad (1)$$

The operation of the TCES system with a packed bed reactor is shown in Fig. 3. During the heat storage mode, the dehydration of SrBr$_2$$\cdot$H$_2$O is caused by a heat sink at 200°C, and the produced water vapor condenses in a water reservoir at 35°C, which is 10 K higher than the ambient temperature. The heat for the hydration, $Q_{\text{evap}}$, is assumed to use waste heat from industrial processes, in the same way as a heat source for the HTHP cycle, therefore, $T_{\text{hyd}}$ is lower than 110°C. Additionally, the molar mass, $M$, and density, $\rho$, of anhydrous and monohydrous SrBr$_2$ are shown in Table 3 [18].

3. Methods and results

3.1. High-temperature heat pump cycle

The HTHP cycle operated at 90°C and 160°C for $T_{\text{evap}}$ and $T_{\text{cond}}$, respectively, during storage for 8 hrs. It is assumed that the obtained thermal energy, 500 kW, is fully converted into a TES system, then 14400 MJ will be stored. The thermodynamic heat and energy balance of the multistage high-temperature heat pump cycle were estimated based on the IAPWS-IF97 standards. The intermediate pressure was defined from the suction and discharge pressures, with the assumption that each compression stage had the same pressure ratio. The overall thermodynamic properties, such as the pressure, temperature, and enthalpy, of each point of the HTHP cycle were determined. The important parameters are available from Eq. 2-3. Mass flowrate of the HTHP main cycle, $m_{\text{main}}$, was induced as 0.19 kg/s, and the power consumption of two compressors, $W_{\text{comp}}$, was estimated to be 113.36 kW; the isentropic and mechanical efficiency, $\eta_{\text{iso.}}$ and $\eta_{\text{mech.}}$, are 0.78 and 0.90 respectively. From the obtained thermal energy from the condenser and IC, $\dot{Q}_{\text{sink}} = 500$ kW, and calculated $W_{\text{comp}}$, COP of the HTHP cycle was defined to 4.41, Eq. 4. Additionally, efficiency of the system was compared to that of an ideal cycle by introducing the thermodynamic efficiency, $\eta_{\text{carnot}}$, in Eq. 5 and 6. The Carnot efficiency, $\text{COP}_{\text{carnot}}$,
represents the maximum energy efficiency of an ideal process that converts power to heat between two different temperatures, $T_1$ and $T_2$ [19]. The $\eta_{\text{carnot}}$ value was calculated as 0.71.

$$\dot{m}_{\text{main}} = \frac{\dot{Q}_{\text{sink}}}{\eta_{\text{mech.}}}$$ (2)

$$W_{\text{comp}} = \left(\frac{(\dot{Q}_{\text{out}}-\dot{Q}_{\text{in}})}{\eta_{\text{mech.}}} + \frac{(\dot{Q}_{\text{out}}-\dot{Q}_{\text{cond}})\times\dot{m}_{\text{main}}}{\eta_{\text{mech.}}}\right)$$ (3)

$$\text{COP} = \frac{\dot{Q}_{\text{sink}}}{W_{\text{comp}}}$$ (4)

$$\eta_{\text{carnot}} = \frac{\text{COP}_{\text{carnot}}}{\text{COP}}$$ (5)

$$\eta_{\text{carnot}} = \frac{\dot{Q}_{\text{out}}}{\dot{W}_{\text{pump}}}$$ (6)

According to the assumption in section 2.1, the mass flow rate of heat sink flow, $\dot{m}_{\text{sink}}$, has the same pressure as $P_{\text{amb}}$ and it was calculated from the capacity of water/steam, $c_p$, and enthalpy, $\Delta H$, of vaporization at 160°C, 2081.9 kJ/kg. Eq. 7. Because the $c_p$ is variable by temperature, averaged specific heat capacities for the liquid and gaseous state, $c_p^\text{liquid}$ and $c_p^\text{gas}$, was adopted for the precise estimation. As a result, $\dot{m}_{\text{sink}}$ of the HTHP cycle is estimated to be 0.18 kg/s.

$$\dot{m}_{\text{sink}} = \frac{\dot{Q}_{\text{sink}}}{(T_{\text{cond}}-T_{\text{sink in}})\times c_p^\text{liquid} + (T_{\text{sink out}}-T_{\text{cond}})\times c_p^\text{gas} + \Delta H\text{vap}\times T_{\text{cond}}}$$ (7)

### 3.2. Sensible heat storage (SHS)

In storage mode, the HTHP cycle supplies 500 kW of heat for 8 hrs ($\tau_{\text{st}} = 28800$ s). Both TES systems stored thermal energy without any heat loss. The required concrete amounts for the SHS system can be calculated from Eqs. 8-9 based on material properties in Table 2, $m_{\text{concrete}} = 96647$ kg and $V_{\text{concrete}} = 43.0$ m$^3$. As aforementioned in section 2.1, the temperature of the HTF in the TES was defined as 10 K lower than the heat sink out temperature, $T_{\text{st}} = T_{\text{sink out}} - 10$ K, and the required airflow rate was obtained from Eq. 10, $\dot{m}_{\text{air,stor}} = 2.82$ kg/s.

$$m_{\text{concrete}} = \left(\frac{\dot{Q}_{\text{sink}} \times \tau_{\text{st}}}{c_p\text{concrete,200°C} \times (T_{\text{stor}} - T_{\text{amb}})}\right)$$ (8)

$$V_{\text{concrete}} = \frac{m_{\text{concrete}}}{\rho_{\text{concrete}}}$$ (9)

$$\dot{m}_{\text{air,stor}} = \frac{\dot{Q}_{\text{sink}}}{c_p\text{air,190°C} \times (T_{\text{stor}} - T_{\text{amb}})}$$ (10)

On the discharge mode, the SHS system can have various cycle out temperatures, $T_{\text{cycle out}} < T_{\text{st}} < 10$ K, by controlling heat output rate from the SHS system, $\dot{Q}_{\text{SHS-dis}}$. The required $\dot{Q}_{\text{SHS-dis}}$ According to the target $T_{\text{cycle out}}$ can be obtained from the enthalpy balance of heat sink flow and corresponding mass flowrate of air, $\dot{m}_{\text{air-dis}}$, on the SHS system are induced from Eq. 11. Additionally, the operation of the SHS system involves an air pump working, unlike the TCES system, for delivering the heat consecutively, Eq. 12. The values of differential the head, $h_{\text{air pump}}$, acceleration of gravity, $g$, and efficiency of the pump, $\eta_{\text{air pump}}$, are 20 m, 9.81 m/s$^2$, and 0.7 respectively. For what concerns the air mass flow rate, $\dot{m}_{\text{air}}$, and densities, $\rho_{\text{air}}$, is changed according to operation modes and conditions.

$$\dot{m}_{\text{sink}} \times (H_{\text{cycle out}} - H_{\text{amb}}) = \dot{Q}_{\text{SHS-dis}} = \dot{m}_{\text{air-dis}} \times (T_{\text{stor}} - T_{\text{cycle out}})$$ (11)

$$W_{\text{air pump}} = \frac{\dot{m}_{\text{air}} \times h_{\text{air pump}} \times g \times \rho_{\text{air}}}{\eta_{\text{air pump}}}$$ (12)

While the SHS system constantly consumes 3522.77 W for air pump work on storage mode, $\dot{Q}_{\text{SHS-dis}}$ and $W_{\text{air pump-dis}}$ are changed on discharge mode by target cycle out temperature, Fig. 4. Because heat sink flows have the same pressure to discharge pressure, $P_{\text{amb}}$, of HTHP main cycle, it has the same evaporation temperature of 160°C, and mass flow rate, $\dot{m}_{\text{air-dis}}$, is increased drastically to satisfy the increase $\dot{Q}_{\text{SHS-dis}}$ over the evaporation temperature. It was also found that the power consumption of the air pump increased consistently despite the heat output rate from the SHS system becoming stabilized over 160°C.
\( m_{\text{air-dis}} \) increased from 22.8 kg/s to 45.9 kg/s on 170°C to 180°C of \( T_{\text{cycle in}} \) while \( Q_{\text{SHS-dis}} \) shows stable values 487.45 kW and 497.68 kW.

![Diagram](image-url)

**Fig. 4.** Change of \( Q_{\text{SHS-dis}} \) and \( W_{\text{air pump-dis}} \) by cycle out temperature on discharge mode.

### 3.3. Thermochemical energy storage (TCES)

The Gibbs free energy change of a reaction, \( \Delta G \), is obtained from the reaction enthalpy change, \( \Delta H \), and the entropy change, \( \Delta S \), as shown in Eq. 13.

\[
\Delta G = \Delta H - T\Delta S
\]

(13)

where \( \Delta G \) has the following relationship with the reaction equilibrium constant, \( K_{\text{eq}} \), for the gas-solid reaction assuming ideal gas properties Eq. 14. The reversible reaction condition is established at around \( K_{\text{eq}} = 1 \) and the linear form of the Van’t Hoff plot is obtained.

\[
\ln K_{\text{eq}}(T, P) = \ln \left( \frac{P}{P_0} \right) = \frac{\Delta G}{RT} = -\frac{\Delta H}{RT} + \frac{\Delta S}{R}
\]

(14)

From the reaction enthalpy, \( \Delta H \), molecular mass and density of \( \text{SrBr}_2 \cdot \text{H}_2\text{O} \), \( M_{\text{SrBr}_2 \cdot \text{H}_2\text{O}} \) and \( \rho_{\text{SrBr}_2 \cdot \text{H}_2\text{O}} \), in Table 3, the necessary amounts of \( \text{SrBr}_2 \cdot \text{H}_2\text{O} \) for the storage mode can be estimated as a mass, \( m_{\text{SrBr}_2 \cdot \text{H}_2\text{O}} \), of 53101 kg and volume, \( V_{\text{SrBr}_2 \cdot \text{H}_2\text{O}} \), of 13.6 m³ from Eqs. 15-16, in terms of anhydrous \( \text{SrBr}_2 \), 49500 kg and 11.7 m³.

\[
m_{\text{SrBr}_2 \cdot \text{H}_2\text{O}} = \left( \frac{Q_{\text{sink}}}{\Delta H} \right) \times M_{\text{SrBr}_2 \cdot \text{H}_2\text{O}} \times \tau_{\text{stor}}
\]

(15)

\[
V_{\text{SrBr}_2 \cdot \text{H}_2\text{O}} = m_{\text{SrBr}_2 \cdot \text{H}_2\text{O}} / \rho_{\text{SrBr}_2 \cdot \text{H}_2\text{O}}
\]

(16)

Fig. 5 shows the Van’t Hoff diagram of \( \text{SrBr}_2 / \text{H}_2\text{O} \) solid-gas reaction, \( \Delta H = 71.98 \text{ kJ/mol} \) and \( \Delta S = 143.93 \text{ J/(mol·K)} \) given in the NBS table. This TCES system possible to store heat by the accomplishment of dehydration at a certain temperature, \( T_{\text{dehyd}} \) and achieve a higher output temperature than dehydration temperature, \( T_{\text{hyd}} > T_{\text{dehyd}} \), particularly, since \( T_{\text{hyd}} \) is controllable from hydration pressure. Therefore, the discharge mode of the TCES system is also known as the temperature upgrade operation of a chemical heat pump [20].
In this study, during the heat storage operation, monohydrous SrBr₂, SrBr₂·H₂O, was decomposed at 190°C, 10 K lower than $T_{\text{sink}}$, and the produced water vapor was condensed at 35°C, 10 K higher than $T_{\text{amb}}$. Because it was assumed that waste heat from the industrial process was used for evaporation, the temperature for evaporation, $T_{\text{evap}}$, was limited to 110°C. Four different evaporation temperatures were selected, $T_{\text{evap}} = 80°C, 90°C, 100°C, and 110°C$, and hydration temperatures, $T_{\text{hyd}} = 206°C, 217°C, 227°C, and 238°C$, were obtained from the corresponding saturated water vapor pressures of 47.4 kPa, 70.2 kPa, 101.4 kPa, and 143.4 kPa. The heat output rate of the TCES system, $\dot{Q}_{\text{TCES-dis}}$, is obtained from the first half of Eq. 9, and Table 4 shows the cycle out temperature, $T_{\text{cycle out}}$, operable discharge time, $\tau_{\text{dis}}$, and $\dot{Q}_{\text{TCES-dis}}$ by evaporation temperature, $T_{\text{evap}}$.

3.4. Comparison of both TES systems

The heat output rate and operable discharge time of both the TES systems are compared in Fig. 6. Generally, the TCES system has a higher heat output rate, $\dot{Q}_{\text{dis}}$, and cycle out temperature, $T_{\text{cycle out}}$, than the SHS system. The SHS system has a maximum cycle output temperature, $T_{\text{cycle out}}$, of 180°C because the stored temperature, $T_{\text{store}}$, is 190°C; however, the $T_{\text{cycle out}}$ of the TCES system obtained from equilibrium pressure on Eq. 12 is higher than 200°C. Additionally, the $T_{\text{cycle out}}$ of the SHS TES system has been decreased rapidly for below 160°C of $T_{\text{cycle out}}$, since the saturation pressure of the heat sink is assumed to have the same condensation temperature as with HTHP main cycle.
The round-trip efficiency (RTE) of the thermal energy storage system is expressed as the ratio of the energy output to the energy input, as shown in Eq. 17; the power consumption of the air pump, $W_{\text{air pump}}$, is considered only for the SHS system.

$$\eta_{\text{RTE}} = \frac{(\dot{Q}_{\text{dis}}-W_{\text{air pump}}) \times \tau_{\text{dis}}}{(\dot{Q}_{\text{sink}}+W_{\text{comp}}+W_{\text{air pump}}) \times \tau_{\text{stor}}}$$ (17)

On the RTE, on the other hand, the TCES system has a constant value, 0.82, since the TCES system can be utilizing waste heat from industrial processes for evaporating, $Q_{\text{evap}}$, without additional mechanical power, the RTE of SHS are decreasing from 0.79 to 0.72 with increasing heat output rate. Dramatically increased air mass flow rate on discharge mode, $m_{\text{air-dis}}$, brings low RTE of SHS system at high cycle out temperature, $T_{\text{cycle out}}$, and heat output rate, $\dot{Q}_{\text{dis}}$. Compared to the concrete SHS system, SrBr$_2$/H$_2$O TCES system only requires 45% and 68% less amount of mass and volume for storage; the TCES system also has 4-14% higher round-trip efficiency, Table 5.

4. Conclusion

The performances of a multistage high-temperature heat pump (HTHP) and two different thermal energy storage (TES) systems connected to the HTHP cycle were investigated. The HTHP cycle had temperatures of 90°C and 160°C for the evaporator and condenser, respectively, and its performance was analyzed using a thermodynamic enthalpy balance. It was assumed that the HTHP cycle would supply 200°C and 500 kW of thermal energy for 8 hours during storage operation. The heat sink flow transferring thermal energy to the TES system is constrained to have the same pressure as the discharge pressure of the HTHP main cycle, $P_{sink} = P_{dis}$, and a constant flow rate, $m_{sink}$.

The thermochemical energy storage system (TCES) has a higher discharge temperature and heat output rate, >200°C and ~500 kW, compared to the sensible heat storage (SHS) system. This is because the SrBr₂/H₂O TCES system release higher temperature than assumed waste heat by considering the equilibrium pressure, whereas the SHS system does not allow for an upgrade in temperature. In particular, the heat output rate of the SHS system was significantly reduced when the cycle out temperature was lower than the condensation temperature, $T_{cycle\ out} < T_{cond}$. In terms of physical requirements, The TCES system has 45% and 68% lower material weight and volume requirements than the SHS system, and its round-trip efficiency is also higher because of the reduced power consumption of the air pump. These results confirmed the advantages of the TCES system for high-temperature thermal energy.

This approach will not only aid in the development of efficient HTHP and TES integration systems but also their effective development. Further study is possible through a detailed analysis of the HTHP cycle with various temperature ranges and different TES system configurations.

Abstract

A flooded evaporator configuration is common in large central air conditioning or process cooling systems. It is basically a shell and tube heat exchanger, in which a secondary fluid (brine or water) circulates inside the tube bundle and is cooled by the vaporization of the refrigerant on the outside surface of the tubes. The enhanced pool boiling process enables the compact design of flooded evaporators, which substantially reduces the refrigerant charge. High-porosity metal foam, with a large surface-area-to-volume ratio, could provide an extended heat transfer area and a high-density of nucleation sites. This study experimentally investigated the pool boiling heat transfer and flow characteristics on metal-foam enhanced tube bundles. The enhanced bundle consists of four aluminum tubes with aluminum foam brazed around the outer surface, which are horizontally mounted in a staggered arrangement. The results showed that the metal-foam enhanced tube bundles improved the heat transfer coefficient by 100-160% with a lower wall temperature difference of 1-10°C, compared to the baseline. In addition, the tube pitch played a significant role in determining the pool boiling behavior of the tube bundles.

Keywords: Tube bundle; metal foam; pool boiling; heat transfer; flow visualization

1. Introduction

Tube bundles have been widely employed in flooded evaporators for air-conditioning and refrigeration, desalination, and absorption chiller industries. In order to reduce the size of heat exchangers and maintain a lower temperature difference between the tube wall and working fluid, improving the pool boiling heat transfer is pivotal. In this regard, several enhanced tube geometries have been developed for industrial applications, such as GEWA, TURBO, and HIGH FLUX tubes. Ayub and Bergles [1] demonstrated 1.5- and 1.75-times heat transfer enhancements for the R-113 pool boiling using GEWA-K and GEWA-T tubes, respectively. Thome [2] demonstrated a 4-10 fold improvement in GEWA-TX tubes compared to the plain tubes.

Recently, utilizing open-cell metal foam to enhance the pool boiling heat transfer has gained significant attention due to its larger area-to-volume ratio and liquid replenishment ability through capillary action. These features of metal foam structures could aid in improving the heat transfer rate and delaying the critical flux. Nosrati et al. [3] studied the flow boiling of R-134a in metal foam filled tubes (metal foam on the tube side). They reported a 220% improvement in the heat transfer coefficient. Similarly, Hu et al. [4] tested the wettability effect of metal foam filled tubes during the flow boiling using R-134a. In their study, they compared the flow boiling behavior of hydrophilic, hydrophobic, and uncoated metal foams. The results showed that the hydrophobic coating offered a 6-30% enhancement in heat transfer compared to the uncoated one, whereas the hydrophilic coating reduced the heat transfer by 2-18%. Manetti et al. [5]
performed the pool boiling experiments on a copper metal foam surface (flat surface) using HFE-7100. They suggested that the metal foam surfaces can overcome the temperature overshoot problem associated with electronic cooling due to their interconnected porous structure that increases the wetted surface area and nucleation site density. Shi et al. [6] analyzed the behavior of a flat copper foam surface under pool boiling conditions for different wettability’s. They reported that the superhydrophilic coated foams offered a higher heat transfer rate when the heat flux was above 20 W cm$^{-2}$, whereas the superhydrophobic coatings outperformed the superhydrophilic ones when the heat flux was below 20 W cm$^{-2}$. The recent developments in phase change heat transfer in metal foam structures are summarized in [7, 8].

In summary, the pool boiling behavior of metal foam structures is widely studied for the flat surface configuration, and the flow boiling characteristics are analyzed for the metal foam filled tubes (i.e., metal foams are placed inside the tubes). In our previous study, the pool boiling heat transfer over an externally embedded metal-foam tube was experimentally investigated [9]. Yang et al. reported that the effective heat transfer coefficient of the metal-foam enhanced tube was 2.1–4.8 times higher than a bare aluminum tube. However, the studies that pertain to the pool boiling behavior of externally embedded metal-foam tube bundles (i.e., shell side) are limited in the open literature. Therefore, the current study aims to develop a metal foam tube bundle to improve the shell side heat transfer rate. The performance of the metal foam tube bundle is compared to the bare tube bundle. In addition, a visualization study is carried out to understand the bubble dynamics on both bare and metal-foam enhanced tube bundles.

2. Experiments

The schematic of the pool boiling apparatus for tube bundle experiments is shown in Fig. 1 (a). It consists of a pool boiling chamber, a heat transfer test section, a condenser coil, and a cooling system. The pool boiling chamber is made of clear polycarbonate, and its internal dimensions are 222.3 mm × 212.7 mm × 222.3 mm. The chamber is charged with 4 Liters of dielectric liquid at atmospheric pressure, and the heat transfer test section is submerged in the liquid pool. The system pressure is monitored with an Omega absolute pressure transducer with an accuracy of ±0.2% Upper range limit (URL) ranging from 0 to 103.4 kPa. The bulk temperature of the liquid pool is measured with T-type thermocouples at two different locations. A coil condenser located at the upper part of the chamber is designed for condensing the dielectric vapor generated through the pool boiling process. The evaporated vapor rises and condense on the outer surface of the coil. The condensed liquid is dropped and returned to the pool to create a natural circulation. The cooling water for the coil is supplied by a recirculating chiller with a cooling capacity up to 7.5 kW (Thermo Scientific, ThermoFlex 7500).
The heat transfer test section of the lab-scale tube bundle experiments has four 3/8” OD aluminum tubes in a staggered arrangement. As demonstrated in Fig. 2(a) and (b), the baseline case consists of bare tubes, whereas the enhanced tube bundle comprises metal-foam tubes. Fig. 1(b) provides the detailed geometry of the tested tube bundles. The tubes have an inner diameter $D_i = 6.22$ mm and an outer diameter $D_o = 9.525$ mm. Two tube pitches of the bundle are investigated in this study. The externally enhanced tubes (metal foam tubes) have a 2.54 mm thick layer of open cell aluminum foam brazed around the outer surface. The aluminum foam used in this study is 40 PPI Duocel foam made of 6101 alloy with heat treated to T6 condition from ERG Aerospace Corporation. The porosity of the metal foam is 81%, estimated through X-ray computed tomography (XCT) 3D scanning. The tested tubes are 76.5 mm long, and they are horizontally mounted to two end plates. One is made of PTFE, while the other is made of transparent polycarbonate for visualizing the boiling process. Two brass pieces are fastened to the end plates as additional weight to ensure the heat transfer test section is submerged. More details of the tube assembly can be found in the work of Yang et al. [9].

For each tube, a Watlow cartridge heater with 579W heating capacity is inserted to provide the heat. The outer diameter and the heating length of the heater are, 6.22 mm and 63.5 mm, respectively. To be noted that epoxy is applied to the end of the cartridge heaters to reduce the heat loss in the axial direction. The power to the cartridge heaters is controlled using pulse width modulation, and different outputs can be approximated over a time span of 1 second. The actual heating power is measured using a watt transducer ranging from 0 to 3 kW (Ohio Semitronics, #PC5-020X5Y25). The wall temperatures for each tube are measured at four locations with T-type thermocouple probes. Four holes with the diameter of 1.02 mm are drilled alongside the tube wall at 90 degrees apart. The first 25.4 mm of the thermocouple probes stays inside the tube wall,
and the remaining portion that is directly exposed to the dielectric fluid is insulated with a PVC sleeve. All the thermocouple probes were calibrated against a NIST-certified precision thermometer with an accuracy of ±0.05°C, and all the data are collected and recorded with a Campbell Scientific CR1000 measurement and control datalogger accompanied with an AM25T thermocouple multiplexer.

For the pool boiling experiments of the tube bundles, 3M Novec engineered fluid HFE-7000 is used as the working fluid. HFE-7000 is a type of clear, colorless, thermally stable dielectric fluid with 34°C boiling point under atmospheric pressure. Prior to the experiments, the pool boiling chamber is charged with 4 Liters of the HFE-7000, which provides around 25.4 mm liquid level above the heat transfer test section. At the beginning of the experiments, the cartridge heaters are set to 10% of its maxin heating capacity to heat up the liquid pool to reach saturation temperature. The liquid pool is heated with the same power setting for an additional hour to remove the non-condensable gases dissolved in the fluid. The power of the cartridge heaters is then reduced to 5% to start the heat transfer measurement. Once the steady state is reached, the data is collected and recorded for 10 mins. The experiments are repeated by increasing the heater power with 5% increments.

3. Data Reduction

The effective pool boiling heat transfer coefficient (HTC) on the outside of the tube is calculated as the ratio of the heat flux to wall superheat.

\[
HTC = \frac{q^*}{\Delta T_{sup}}
\]

(1)

The heat flux \(q^*\) is estimated based on the outer surface area of the bare tube:

\[
q^* = \frac{\dot{Q}_{elec} - \dot{Q}_{loss}}{\pi D_o L_h}
\]

(2)

where \(D_o\) and \(L_h\) are the outer diameter and the effective heating length of the tested tube. The effective heat transfer rate from the tube wall to the dielectric fluid is determined by the electrical power delivered to the heater, \(\dot{Q}_{elec}\) subtracting the conduction heat loss in the axial direction, \(\dot{Q}_{loss}\). The conduction heat loss in the axial direction is estimated using a special tube, in which the thermocouple holes alongside the tube have two different depths.

\[
\dot{Q}_{loss} = k A_{cs} \frac{T_{wall,R} - T_{wall,L}}{\Delta x}
\]

(3)

where \(k\) and \(A_{cs}\) are the thermal conductivity and the cross-sectional area of the tube material, respectively. \(\Delta x\) is the depth difference between the two thermocouple holes in the axial direction. The subscript of the wall temperature shows the location of the thermocouple probe, and \(R\) and \(L\) represent the right and left, respectively.

The wall superheat, \(\Delta T_{sup}\), is the temperature between the tube wall temperature and the saturation temperature of the dielectric fluid.

\[
\Delta T_{sup} = T_{wall} - T_{sat}
\]

(4)

The saturation temperature \(T_{sat}\) is determined by the average values of the two T-type thermocouple probes located at the top and bottom of the pool boiling chamber. During the experiments, the pool temperature is maintained within 0.3°C. The wall temperature \(T_{wall}\) for each tube is the mean temperature of the four thermocouples inserted into the holes alongside the tube wall and corrected using the 1-D heat conduction equation.

\[
T_{wall} = T_{m,avg} - \left(\frac{\dot{Q}_{elec} - \dot{Q}_{loss}}{2\pi k L_h} \right) \ln \left(\frac{r_o}{r_m}\right)
\]

(5)

where \(r_o\) is the outer tube radius, and \(r_m\) is the mean value of inner and outer tube radius, which is the location of the tip of thermocouple probes.

The overall heat transfer coefficient for the tube bundle is estimated based on the average value of four
single-tube heat transfer coefficients calculated using Eq. (1).

The experimental uncertainties of the effective heat transfer coefficient, the heat flux, and the wall superheat are estimated following the error propagation analysis documented in the work of Moffat [10]. The root-sum-square combination of the effects of the individual measurements gives the overall uncertainty of the target parameter. All the uncertainties are based on a confidence level of 95%.

\[
\delta U(X_1, X_2, \ldots, X_N) = \sqrt{\sum_{i=1}^{N} \left( \frac{\partial U}{\partial X_i} \delta X_i \right)^2} \tag{6}
\]

4. Results and Discussion

4.1. Validation of experimental setup

The pool boiling experiments are first performed on a single bare tube to validate the experimental facility. The experimental data are compared against the Cooper [11] and Cornwell and Houston [12] correlations, as shown in Fig. 3. The Cooper correlation and the Cornwell-Houston correlation are given in Eqns. (7) and (8), respectively.

\[
HTC_{\text{Cooper}} = 90 M^{-0.5} \left(q^*\right)^{0.67} \left(-\log\left(P_r\right)\right)^{-0.55} \left(P_r\right)^{0.12-0.20\log\left(R_p\right)} \tag{7}
\]

where \(M\) and \(P_r\) are the molecular weight and reduced pressure. \(R_p\) is the average surface roughness of the plain tube, and \(1 \, \mu m\) was used in the current study.

\[
HTC_{\text{Cornwell-Houston}} = 9.7 P_c^{0.5} \Re_b^{0.67} Fr^{0.4} \left(1.8 P_r^{0.17} + 4 P_r^{1.2} + 10 P_r^{10}\right) \left(\frac{k_i}{D_o}\right) \tag{8}
\]

Noted that \(P_c\) is critical pressure in bar and \(k_i\) is the thermal conductivity of dielectric liquid. \(\Re_b\) is boiling Reynolds number, which is directly related to the heat flux under the saturated pool boiling, as follows.

\[
\Re_b = \frac{GD_m}{\mu_l} = \frac{qD_m}{\mu_h h_{fg}} \tag{9}
\]

where \(\mu_l\) is the dynamic viscosity, while \(h_{fg}\) is the latent heat of vaporization.

Fig. 3 shows the variation of heat transfer coefficient of HFE-7000 against heat load ranging from 5 to 100 kW/m². Similar to the trend predicted by the correlations [11][12], the heat transfer coefficient increases with heat flux. In addition, the Cooper [11] correlation predicts the heat transfer coefficients within a 7% deviation when the heat flux is below 50 kW/m². At higher heat fluxes (\(q > 50\) kW m²), the deviation between experimental and predicted data grows. In contrast, the Cornwell-Houston [12] correlation showed better agreement at higher heat fluxes with a maximum deviation of 7% and exhibited a larger deviation at smaller heat fluxes with a maximum deviation of 13%. Overall, the experimental data matches well with the standard correlations, which validates the experimental setup.
4.2. Performance assessment of bare and metal foam tube bundles

The performances of a bare single tube and a metal foam tube bundle are characterized in terms of heat transfer coefficient and wall temperature. Note that the results presented in this section pertain to a tube pitch of 19 mm. The experiments are performed for a heat flux range of 5-100 kW m$^{-2}$, and the corresponding average heat transfer coefficient values are presented in Fig. 4. The HTC of the bare tube bundle is almost 3-5% higher than that of the single bare tube. It indicates that the bundle effect caused by the vapor flow induced convection is minimum for this tube bundle configuration as it only has three rows. However, it can be seen in Fig. 4 that the metal foam tube bundle exhibited a superior performance over the bare tube bundle. The trend of the metal foam tube bundle is consistent with that of the single metal foam tube published in the earlier work [9]. The heat transfer coefficient of the metal foam tube bundle is about 100-160% higher than that of the bare tube bundle for the tested heat flux range. The improvement in the metal foam tube bundle is primarily attributed to the increased surface area. Besides, the metal foam structures possess many active nucleation sites compared to the plain tube, as shown in Fig. 5. The large number of active nucleation sites in metal foam tubes could ameliorate the nucleate boiling heat transfer compared to the bare tube, which in turn increases the heat transfer coefficient.

Fig. 3. Validation of experimental facility through comparing single tube pool boiling data against Cooper [11] and Cornwell-Houston [12] correlations.

Fig. 4. Performance comparison of bare and metal foam tube bundles.
The photographic comparison of the pool boiling behavior in bare and metal foam tube bundles can be seen in Fig. 5. At lower fluxes (q < 10 kW m$^{-2}$), the wall temperature is close to the saturation temperature of the working fluid (i.e., HFE-7000), as shown in Fig. 6. At this stage, the number of nucleation sites is relatively low, as shown in Fig. 5(a). When the heat flux is increased, the nucleation sites get activated, leading to more bubble formation, as shown in Fig. 5(b). This leads to a bubble coalescence and forms local vapor blankets on the tubes, which hinder the heat transfer from the tubes to the fluid. As a result, the wall temperature keeps increasing with heat load, as shown in Fig. 6. It can be noted that the wall temperature of the bottom tube (i.e., tube 4) is higher than that of other tubes for both bare and metal foam configurations. This is because of the bubble flow pattern. The bubble or vapor column’s departure from the bottom tube is mainly impeded by the top (i.e., tube 1) and side (i.e., tubes 2 and 3) tubes. However, the vapor column leaving the bottom tube mainly passes through the gap between tube 2 and tube 3, and finally hits the bottom of tube 1, as shown in Fig. 5. This phenomenon enhances the convection induced heat transfer in tubes 1, 2, and 3. As a result, tubes 1-3 experienced a lower wall temperature compared to that of the bottom tube, as shown in Fig. 6. When comparing Fig. 6(a) and (b), it can be understood that the wall temperature of the metal foam tubes is almost 4-10°C lower than that of the bare tubes. The lower wall temperature of metal foam tubes is attributed to the combination of the following effects: The metal foam on the outside of the tube increases the surface area and thereby the active nucleation site density, which leads to increased latent heat transfer (i.e., pool boiling). Additionally, the open cell metal foam structure could lead to a smaller bubble departure diameter even at the higher heat fluxes, which can potentially delay the local vapor blanket formation. Furthermore, the porous structure of the metal foam can act as a capillary wick to locally feed the liquid to the tube wall due to the capillary action. The combined effect of the above causes could result in a lower wall temperature for the metal foam tubes, as shown in Fig. 6(b).

</table>

Front view

Side view

Fig. 5. Visualization of pool boiling behavior in bare and metal foam tube bundles.
4.3. Effect of tube pitch on tube bundle performance

To understand the influence of the tube pitch on the heat transfer performance of the tube bundle, two tube pitches, 19 mm and 25.4 mm, are experimentally analyzed for both bare and metal foam tube bundles. The tube pitch effects on heat transfer coefficient are presented in Fig. 7. For both bare and metal foam tube bundles, the heat transfer coefficient value reduces marginally when the tube pitch is increased from 19 mm to 25.4 mm. A maximum of 10% reduction in HTC is observed with an increase in pitch for the bare tube bundle, whereas the same for the metal foam tube bundle is about 14%. In other words, the two-phase flow is more intensive for the tube bundle with lower pitch, and this trend is in agreement with that reported in the
work of Fujita and Hidaka [13] and Swain et al. [14]. Since the increased tube pitch creates a larger gap between the tubes, the vapor column leaving the bottom tubes may not shear along the side tubes. Similarly, the vapor column leaving the side tubes may not shear along the top tubes. As a result, the HTC enhancement caused by the convection effects deteriorates and lead to a lower HTC at a larger tube pitch.

(b)

Fig. 7. Effect of tube pitch on heat transfer coefficient (a) bare tube bundle and (b) metal foam tube bundle.

5. Conclusions

In this study, open-cell metal foam tubes are proposed to enhance the shell-side performance of the flooded evaporators. The performance of the bare tube bundle is compared against the proposed metal foam tube bundle under pool boiling conditions. The experiments are carried out for a heat flux range of 5-100 kW m\(^{-2}\) and two different tube pitches (19 mm and 25.4 mm). Based on the experimental results, the key outcomes of the study can be outlined as follows:
• The heat transfer coefficient of the bare tube bundle is just 3-5% higher than that of the single tube.
• As compared to the bare tube bundle, the metal foam tube bundle reported a 100-160% enhancement in heat transfer coefficient.
• The wall temperature of the metal foam tubes is about 4-10°C lower than that of the plain tubes due to the combination of increased surface area and nucleation sites, reduced bubble departure diameter, and enhanced liquid suction to the tubes’ wall through capillary action.
• The tube pitch played a significant role in determining the pool boiling behavior of the tube bundles. When the tube pitch is increased from 19 mm to 25.4 mm, the heat transfer coefficient values decrease by a maximum of 10% and 14% for the bare and metal foam tube bundles, respectively.

Abstract

An efficient heating system for the cabin of electric-driven vehicles (xEVs) is required to minimize the reduction in the driving range. However, studies regarding heat pumps that use waste heat from fuel cell stack, PE (Power Electronics) and battery in xEVs are limited. In this study, the heating performance of dual coolant-source heat pump using waste heat in xEVs is investigated by varying coolant temperature, and coolant volumetric flow rate to have enough capacity in severe ambient conditions. A developed triple-fluid heat exchanger is introduced to recover waste heat from the fuel cell stack and PE with high level and battery with relatively low level at different temperatures. The heating performance of the coolant-source heat pumps using one coolant and dual coolants shows different characteristics owing to the different temperature levels of the coolants and heat transfer between two coolants. This study suggests optimum heat pump system of xEVs with respect to driving range characteristics under severe ambient conditions.

Keywords: dual coolant-source heat pump; heating performance; triple-fluid heat exchanger; coolant temperature; coolant flow rate;

1. Introduction

In response to regulations pertaining to fossil fuels for addressing environmental concerns [1], automotive companies have developed zero-emission vehicles as an alternative to internal combustion engines (ICEs). Accordingly, numerous studies regarding the development of “green cars,” which do not use fossil fuels, have been conducted. The most prominent zero-emission green cars include battery electric vehicles (BEV) and fuel cell electric vehicles (FCEVs) [2–4]. Their power sources are batteries, a hybrid battery system charged by an ICE, and electricity generated by a stack of fuel cells, respectively. All three types of vehicles, so called xEVs, are considered promising, based on the development undertaken by major automotive companies [5,6]. However, laboratory and on-road tests reveal various engineering short-comings of xEVs, including their system efficiency, stack performance, thermal-management technology, and compatibility with other components under high-voltage conditions. These inadequacies must be solved to achieve a performance similar to that of ICE vehicles [7].

Recently developed electric vehicles generally have maximum driving ranges of approximately 400 km for battery-only vehicles and approximately 600 km for FCEVs. However, these driving ranges can be reduced by over 40% when the heating system of a vehicle is operated under cold ambient conditions [8–11]. Conventional positive temperature coefficient (PTC) electric heaters have been widely used in electric vehicles owing to their simple utility. However, it can consume a significant amount of power from the battery because of its low energy transition efficiency (90%–95%) from electricity to heat, resulting in a significantly reduced fuel economy. The efficiencies ranging from 90% to 95% may seem to be enough; however, be-cause a typical heat pump has a heating efficiency of more than 300%, the PTC electric heaters have significantly lower efficiencies than the heat pumps. Therefore, an efficient heating system for the cabin of electric vehicles must be developed to minimize the reduction in the driving range.
In this study, the heating performance of dual coolant-source heat pump using waste heat from the fuel cell stack and PE (high temperature level) and battery (low temperature level) in xEVs was measured and analyzed by varying coolant temperature and coolant volumetric flow rate using developed triple-fluid heat exchanger.

2. Experimental Method

Fig. 1 shows a schematic illustration of the test setup used to measure the performance of a coolant-source heat pump with a triple-fluid heat exchanger for use in xEVs. The heating performance of the coolant-source heat pump was measured in psychrometric chambers. The psychrometric calorimeter in the indoor chamber was designed to precisely maintain the temperature and humidity settings using a cooling coil, heating coil, and humidifier. The temperature and humidity conditions in the outdoor chamber were controlled using an air-handling unit.

The tested coolant-source heat pump comprised an electric compressor, an inner condenser, triple-fluid heat exchangers (evaporator), and an electronic expansion valve (EXV). An electrically driven scroll compressor with a displacement volume of 33.0 cm$^3$ rev$^{-1}$ at 360 V was adopted along with an inverter driver. The inner condenser, which simulates the cabin of the vehicle, was a parallel-flow type louvered-fin brazed-aluminum heat exchanger measuring 232.0 mm in width, 144.0 mm in height, and 54.0 mm in depth. An EXV with an orifice diameter of 1.6 mm was used to regulate the refrigerant mass flow rate. In addition, an accumulator was installed at the compressor inlet. Table 1 lists the specifications of the coolant-source heat pump with a triple-fluid heat exchanger.

A triple-fluid heat exchanger was developed to enable heat exchange between the refrigerant (R-134a) and two types of coolants, where different operating temperatures were considered for the fuel cell stack and PE (Power Electronics, such as driving motors, converters and inverters) (High temp. side) and battery (Low temp. side). The triple-fluid heat exchanger was a counter-flow-type aluminum plate heat exchanger measuring 190.0 mm in width, 225.0 mm in height, and 80.0 mm in depth. Fig. 2 shows the configurations of the triple-fluid heat exchanger. In this heat exchanger, 63 rows (35.0%) were used for high temperature coolant cooling, and 117 rows (65%) were used for low temperature coolant cooling. In the preliminary experiment, excessively high condensing temperature was observed when the channels were equally assigned for high temperature side and low temperature side, because the triple-fluid heat exchanger was used as a heat sink of the heat pump for cooling mode. Accordingly, for high temperature side, the number of channels in the triple-fluid heat exchanger was decreased to 35% owing to higher temperature difference between a coolant and a refrigerant.

Table 2 lists the test conditions used in the study. The test conditions were set based on the actual coolant temperature profiles of the stack (or PE) and battery under cold ambient conditions under the designed driving pattern, as shown in Fig. 3. The air temperature on the interior side was varied from -20 °C to 0 °C at intervals of 10 °C, and the relative humidity was 50.0%. The air flow rate on the interior side was fixed at 300 m$^3$h$^{-1}$. The stack coolant temperature was maintained within 20 °C–40 °C at intervals of 5.0 °C, whereas the volumetric flow rate at the stack side was varied from 5 to 20 L min$^{-1}$ at intervals of 5 L min$^{-1}$. The electric device coolant temperature was maintained within -20 °C to 0 °C at intervals of 10 °C, whereas the volumetric flow rate at the electric device side was varied from 5 to 20 L min$^{-1}$ at intervals of 5 L min$^{-1}$. Meanwhile, the compressor speed was varied from 2000 to 4000 rev min$^{-1}$ at intervals of 1000 rev min$^{-1}$.

### 3. Result and Discussion

#### 3.1. Single coolant-sourced heat pump system

Fig. 4 shows the heating capacity and COP of the coolant-source heat pump in the high temperature level’s coolant mode with respect to the coolant temperature and volumetric flow rate. Only the high temperature level coolant was used in the high temperature level coolant mode. As the coolant temperature and volumetric flow rate increased at a fixed compressor speed and EXV opening, the heating capacity increased because of the increase in the evaporating pressure. However, the heating COP decreased as the coolant temperature and volumetric flow rate increased owing to the increase in the compressor power consumption. The coolant temperature significantly affected the heat capacity, whereas the heating capacity became constant as the coolant volumetric flow increased beyond 15 L min⁻¹.

![Fig. 4 – Heating capacity and COP in high temperature level coolant mode with respect to (a) temperature and (b) volumetric flow rate of high temperature level coolant.](image)

Fig. 5 shows the heating capacity and COP of the coolant-source heat pump in low temperature level’s coolant mode with respect to the coolant temperature and volumetric flow rate of battery cooling. The heating capacity and COP increased with lower-side coolant temperature and volumetric flow rate at a fixed compressor speed and EXV opening. As the coolant temperature increased from -20 °C to 0 °C, the heating capacity increased by 100%, whereas the compressor power consumption increased by 50%, resulting in an increase in the COP. This was attributed to a lower increase in the refrigerant flow rate with respect to the
coolant temperature in the lower temperature coolant mode compared with that in the high temperature coolant mode. Additionally, as shown in Figs. 4 and 5, the low temperature coolant mode exhibited a relatively lower heating capacity than the high temperature level coolant mode. Accordingly, the operation mode in the coolant-source heat pump should be determined based on the heating load under actual driving conditions.

![Fig. 5. Heating capacity and COP in low temperature level coolant mode with respect to (a) coolant temperature and (b) volumetric flow rate.](image)

### 3.2. Dual coolant-sourced heat pump system

The hybrid coolant mode, which uses both coolants as heat sources, was investigated to utilize all possible waste heat in xEVs. When driving under cold ambient conditions, the coolant temperatures in two kinds of coolants remained at -10 °C and -20 °C to 50 °C, respectively. Therefore, the low-side coolant temperature in the hybrid coolant mode was set to -10 °C at various high-side coolant temperatures and EXV opening percentages. As shown in Fig. 6, in the hybrid coolant mode, the EXV opening percentage did not significantly affect the heating capacity and COP of the coolant-source heat pump. However, the heating capacity in the hybrid coolant mode decreased by 50% and 12% compared with that in the high temperature level and low temperature level coolant modes, respectively. This was because the heat was transferred from the higher temperature of the stack (or PE) coolant to the lower temperature of the battery cooling coolant. Owing to a similar reason, as shown in Fig. 6, the heat capacity and COP of the coolant-source heat pump in the hybrid coolant mode were not affected by the high temperature level coolant temperature.

![Fig. 6. Heating capacity and COP in hybrid coolant mode with respect to (a) EXV opening and (b) high temperature level coolant temperature.](image)
4. Conclusion

In this study, the heating performance of a coolant-source heat pump using waste heat from the fuel cell stack and PE(high temperature level) and battery(low temperature level) in xEVs was measured and analyzed by varying the inlet air temperature, compressor speed, coolant temperature, and coolant volumetric flow rate. A developed triple-fluid heat exchanger was developed to recover waste heat from battery and fuel cell stack (or PE) which have different temperature levels. The coolant-source heat pump indicated a higher refrigerant flow rate than the air-source heat pump owing to the higher evaporating pressure and higher heat source temperature. Accordingly, the superheats at the compressor inlet and outlet in the coolant-source heat pump were lower than those in the air-source heat pump. The heating performance of the coolant-source heat pump was significantly affected by the compressor speed, and the heating capacity was inversely proportional to the COP.

Additionally, the effects of the coolant temperature on the heating performance of the coolant-source heat pump were investigated in the stack and PE(high temperature level), battery(low temperature level), and hybrid coolant modes. In the high temperature level coolant mode, as the coolant temperature and volumetric flow rate increased, the heating capacity increased owing to the increase in the refrigerant flow rate, whereas the heating COP decreased owing to the increase in the compressor power consumption. However, in the low temperature level coolant mode, both the heating capacity and COP increased with the coolant temperature and volumetric flow rate owing to a lower increase in the refrigerant flow rate. Furthermore, the hybrid coolant mode was inferior to one coolant-source mode in terms of performance; this was because in the hybrid coolant mode, heat was transferred from the stack and PE(high temperature level) to the battery coolant(low temperature level).

Abstract

Industrial energy consumption is extremely high. Thermal power plants contribute to approximately 40% of total water withdrawal in the US but dissipate a large amount of vapor and heat energy. Transport membrane condensers have been demonstrated to have great potential to recovery waste heat and water as a combination of membrane condensers and heat exchangers. In this study, a laboratory membrane heat exchanger system was developed using plate ceramic membrane and hollow fibers. The heat and water recovery performances were studied to estimate the heat and mass transfer characteristics of membrane heat exchangers. The operating conditions show significant effects on the recovery performances of system. A computational fluid dynamics (CFD) model was developed using experimental data to consider the heat and mass transfer. The simulation model shows great agreements with experimental results. The temperature distribution as well as vapor mass fraction were analyzed to have an insight about the condensation and mass transfer of water vapor.

Keywords: Transport membrane condenser (TMC), heat exchanger, heat recovery, water recovery, computational fluid dynamics (CFD)

1. Introduction

Freshwater sources are steadily decreasing over this decade due to the population growth and living standards \cite{1}. The energy industry consumes an enormous amount of fuel resources. Flue gas in the power plant unit consists of water vapor up to 13\% volume fraction and take 50 – 80\% heat loss from boiler which accounts for 3-8\% total energy of the units \cite{2}. Several efforts have been done to reclaim energy and water from the waste gases. By recovery the heat loss and wastewater, not only the boiler efficiency can be greatly improved but the feed consumption can be significantly reduced \cite{3}. Typically, transport membrane condenser (TMC) is a promising method to recovery the wasted sources and enhance the industrial thermal process efficiency. By the mean of using a proper membrane, the recovery efficiencies of TMC are particularly improved. It has been demonstrated that the TMC can supply 30\% of feed water in boiler unit under a proper working condition. In this work, transport membrane condensers with two types of membranes were studied experimentally and numerically.

2. Methodology

The experimental scheme of a hollow fiber transport membrane condenser is shown in figure 1. The dense alumina hollow fibers were assembled in an acrylic round tube. A water boiler was used to generate vapor and control the gas temperature. The air compressor was incorporated with the mass flow control (MFC) to control humid gas circulating though membrane condensers. The cooling water was controlled by a pump and cooling
bath to flow inside the hollow fiber. Thermocouples and humidity sensor were installed to measure the operating conditions. The mass of water transport to water side was measured by a water level sensor.

Similarly, a plate membrane was applied in the experiment system for comparison. The humid air and cold water were supplied onto two side of membrane. The velocity and temperature of inlet gas and water were modified to evaluate the recovery behavior. The water and heat recovery can be obtained as following:

\[ J = \frac{\Delta m}{\Delta tA} \]  
\[ Q = \frac{C_p m_1 \Delta T + m_1 \tau E_w}{A} \]

3. Numerical study

Fig. 2. (a) Schematic and (b) meshing of hollow fiber heat exchanger (c) Schematic and (d) meshing of flat membrane heat exchanger
A CFD code in ANSYS Fluent was used to conduct a simple 2D model of plate membrane condenser, as presented in figure 2c and 2d. The numerical model of a hollow fiber membrane condenser was then developed in 3D configuration. The simulation model consists of three computation zones which are gas, water flow and membrane. The model geometry and parameters were built based on the experiment setup. The simulation conditions are presented in Table 1. The species transport in Volume of Fluid (VOF) multiphase model was utilized with gas mixture as the primary phase and water liquid in the secondary phase. The condensation of water vapor was solved using the evaporation-condensation Lee’s model. The condensation rate of vapor was considered as the mass transfer between water liquid and vapor phases. The mass transfer is solved by the following equation:

\[
\frac{\partial}{\partial t} (\alpha_v \rho_v) + \nabla \cdot (\alpha_v \rho_v \vec{V}_v) = m_{lv} - m_{vl}
\]  

For the mass transport through the membrane, the permeation of fluid through the ceramic membrane was considered as a laminar flow and solved by the porous media model. A momentum sink comprised of viscosity loss and inertial loss was added as following:

\[
S_i = - \left( \sum_{j=1}^{3} D_{ij} \mu v_j + \sum_{j=1}^{3} C_{ij} \rho^2 |v| v_j \right)
\]

4. Results and discussions

Fig. 3 shows the comparison between experimental and simulation results with different operating conditions. The simulation results were found to have a great agreement with experimental data. The temperature distribution and vapor mass fraction were studied at different conditions. The temperature and vapor mass fraction of hollow fiber condenser model are presented in Fig. 4 and Fig. 5, respectively. It can be observed that the gas flow temperature decreases along with the flow direction. The decline in gas temperature demonstrated the heat retrieval in the gas stream. On the other hand, the vapor distribution shows a reduction of mass fraction in company with the gas direction. The vapor mass fraction was obtained approximately 0.53 in the gas outlet. Obviously, the moisture content was recaptured into the water side.
5. Conclusion

In this work, a membrane heat exchanger is proposed for application of heat and wastewater recovery from flue gas using ceramic hollow fiber membranes. A 3D CFD model was developed based on experimental data. A great agreement was found between numerical and experimental results. The simulation results such as temperature contour and mass fraction of vapor in the gas phases have given an insight into the mechanism of the membrane condenser.

Performance evaluation and optimization of lower GWP refrigerants in a residential heat pump

Jethro Medina\textsuperscript{a}, Joshua Hughes\textsuperscript{a}

\textsuperscript{a}The Chemours Company, 201 Discovery Boulevard, Newark, DE 19713, United States

Abstract

R-410A is the prevailing fluid in stationary air conditioning and heat pump applications. Its global warming impact, however, has garnered attention for lower GWP options. Existing alternatives include R-32 and R-454B, which provide notable GWP reductions from R-410A (AR4 GWPs of 2088 vs. 675 and 465 respectively). Although R-454B may prove to be a long-term solution, system optimizations, such as variable speed compressor use and heat exchanger changes, enable the use of even lower GWP fluids.

This paper explores the performance of several low GWP refrigerants (<300 GWP) in stationary air conditioning and heating applications. A commercial, residential R-410A heat pump was modified, per OEM guidance, with a suitable variable speed compressor. The heat pump and corresponding evaporator were placed in a pair of environmental chambers. The evaluated refrigerants consisted of blended HFO-based compositions. Variable speed compressor use allowed each fluid to match R-410A air-side capacities.

Presented data will include the following: air-side capacities, energy efficiencies, compressor speeds, and operating parameters. These performance metrics and operating conditions will be compared to those of R-410A. Performance will consist of both air-conditioning and heating environmental conditions, following the guidelines of AHRI 210/240. These blends further extend the potential options of low GWP alternatives, utilizing optimization technologies such as a variable speed compressor.

Keywords: Residential heat pump; Performance; Refrigerant; R-454A; R-454C; Low GWP; R-1234yf; HFO; Variable Speed Compressor

1. Introduction

The phase out of CFC and HCFC refrigerants, due to the Montreal Protocol, has been completed. Consequently, the transition to non-ozone depleting HFC refrigerants resulted in the continued use of high Global Warming Potential (GWP) fluids. With recent regulations, such as the Kigali Agreement to the Montreal Protocol, requiring the phase down of HFC refrigerants, came the advent of hydrofluoro-olefin (HFO) refrigerants, such as R-1234yf. With a GWP of <1, R-1234yf and R-1234yf containing refrigerant blends offer significant GWP reductions relative to incumbent HFC refrigerants.

The residential air conditioning and heating space predominantly uses R-410A (GWP 2088) in heat pump systems. Refrigerant blends containing R-1234yf, such as R-454B (GWP 467), are approved for new equipment use and offer significant GWP reductions. In preparation for future regulations calling for further GWP reductions, additional refrigerant blends were studied in a residential heat pump system. Refrigerants R-454C (GWP 146) and R-454A (GWP 288) are binary refrigerant blends consisting of R-32 and R-1234yf. Both fluids are in commercial use in stationary freezer applications. They each have potential in residential heat pump systems with some system optimizations, such as single-speed compressor changes, variable speed compressor use, or heat exchanger adjustments.
2. Fluid Overview, System Architecture, and Thermodynamic Cycle Model Study

2.1. Fluid properties and test system

A comparison of the physical and chemical properties of several lower GWP alternatives to R-410A are shown below in Table 1. Fluids in the comparison include R-410A, R-454B, R-454A, and R-454C.

Table 1. Physical and chemical properties of R-410A and lower GWP alternatives

The alternatives above offer significant GWP reduction relative to R-410A. Each are binary refrigerant blends of R-32 and R-1234yf at differing compositions. Saturated vapor pressures for R-454A and R-454C indicate lower operating pressures in a heat pump system. Normal boiling points of the two fluids indicate capacity differences, which can be mitigated with system optimizations.

Test system architecture consisted of a residential heat pump designed for R-410A, which was an 8.79 kW, 16 SEER ducted, split system heat pump. The single-speed compressor native to the system was replaced with a variable speed compressor with comparable system performance at 60 Hz. The POE 32 centistoke lubricant used for each refrigerant was identical to what was specified for R-410A use. Architectures for both the cooling and heating modes are shown below in Figure 1.

![Fig. 1. Heat pump setup and schematic](image)

The test heat pump was comprised of two heat exchangers, a variable speed scroll compressor, a mass flow meter, and a suction line accumulator. The indoor and outdoor room heat exchangers have an electronic expansion valve (EEV) and adjustable thermostatic expansion valve (TXV) respectively. A pair of environmental chambers was used to control the temperature and humidity of the indoor and outdoor units to applicable test conditions. Chamber test conditions are listed below in Table 2, which are compliant with ANSI/AHRI Standard 210/240-2023 and ISO Standard 5151-2017.

Refrigerant charge optimizations were performed for each fluid at the Cooling A and H1 conditions for cooling and heating respectively. As the system was designed for R-410A, a singular charge optimization was performed for R-410A at the Cooling A condition. Optimized refrigerant charges were different between the modes for both R-454A and R-454C.

2.2. Thermodynamic cycle modelling

Thermodynamic cycle analyses were completed, comparing relative performance of R-454A and R-454C to R-410A at representative air conditioning and heating conditions. Cooling cycle model results are shown below in Table 3. Cycle conditions were as follows: 10°C evaporator, 46.1°C condenser, 11.1 K superheat, 8.3 K subcooling, 70% compressor efficiency, and equivalent compressor displacement. Heating cycle model results are below in Table 4, performed at the following conditions: 0°C evaporator, 55.0°C condenser, 10.0 K superheat, 3.0 K subcooling, and 70% compressor efficiency.

</table>

For both cooling and heating conditions, R-454A and R-454C exhibited notably lower capacities than R-410A but similar COPs. Compressor discharge temperatures and pressures were decreased with both alternative refrigerant blends. Both R-454A and R-454C are zeotropic refrigerant blends, having higher temperature glides than R-410A.

Lower cooling and heating capacities indicate system optimization for use in a residential heat pump. For this work, a variable speed compressor, as described earlier, was installed to compensate for the lower...
capacities of R-454A and R-454C. By adjusting refrigerant mass flow rate, cooling and heating capacities can match those of R-410A. Increased compressor speeds will impact total system energy consumption, therefore, impacting efficiencies.

The test system was optimized with a comparable variable speed compressor. The inherent heat exchangers, designed for R-410A use, were unchanged. By optimizing the heat exchangers, the increase in heat transfer area will further account for lower fluid capacities and the increased pressure drop in the heat from lower density refrigerants. Additionally, optimized heat exchangers can better account for fluids with higher temperature glides and greater optimized refrigerant charge sizes relative to R-410A.

3. Results and Discussion

3.1 Air conditioning test results

As specified in the above section, performance evaluations were conducted in a split system residential heat pump designed for R-410A use. A variable speed compressor of similar performance at 60 Hz to the single speed compressor native to the commercial system was installed. The system was installed in a pair of environmental chambers. Testing was conducted following ASHRAE Standard 37, with chamber temperature and humidity set according to ANSI/AHRI Standard 210/240-2023 and ISO Standard 5151-2017, as shown previously in Table 2.

Refrigerant charge size optimizations were performed for both cooling (Cooling A) and heating (H1) modes. For the optimization, R-410A was run at 3600 RPM (60 Hz) to mimic the performance of a single speed compressor. The optimal refrigerant charge yielded the highest COP at the singular compressor speed with appropriate subcooling. The refrigerant charge optimizations for R-454A and R-454C involved adjusting compressor speed to match R-410A capacity at Cooling A and H1, depending on the selected mode. Table 5 displays the results for cooling mode, along with an expected refrigerant charge estimated from liquid densities of each refrigerant.

<table>
<thead>

</tr>
</tbody>
</table>

Optimized refrigerant charge for R-454A was similar to its estimated charge. The estimated refrigerant charge of R-454C was 2% less than R-410A. However, the optimized refrigerant charge was about 9% greater than that of R-410A. At the lower refrigerant charge, the refrigerant was not fully subcooled entering the expansion valve. The increased refrigerant charge provided the optimal COP and adequate subcooling.

R-454A and R-454C performance was evaluated twice at each condition specified in Table 2. One evaluation was with using a compressor speed of 3600 RPM and matching evaporator superheat of R-410A. The second evaluation had an adjusted compressor speed to match the capacity of R-410A at that temperature condition. Evaporator superheat was also adjusted to better match the evaporator temperature of R-410A for the matched capacity conditions. Figures 2 and 3 depict cooling capacity and COP, relative to R-410A.
With compressor speed adjustment, the R-454A and R-454C cooling capacities were within 1% of R-410A capacities at the evaluated conditions. Cooling capacities for both fluids were similar to the thermodynamic cycle model when studied at 3600 RPM compressor speed. Relative COPs at the matched capacity conditions were lower than expected. The lower capacities of R-454A and R-454C required an increase in compressor speed, subsequently increasing energy consumption. The energy penalty is larger than expected considering the comparable COP of both fluids relative to R-410A from the thermodynamic cycle models. Discharge pressures for R-454A and R-454C in the matched capacity tests were higher than cycle models would suggest, indicating a potential penalty from high refrigerant charge. Particularly for R-454C, refrigerant charge was about 9% higher than R-410A with an expected charge being less than R-410A. Additional system optimization or using a system designed for use with one of the alternative refrigerant blends would likely mitigate this issue. Energy and compressor speed increases are shown below in Figures 4 and 5.

With lower volumetric capacities, compressor speed increases for R-454A and R-454C are shown above in Figure 4. From Figure 5, relative energy consumption for both fluids at 3600 RPM were about 20% and 30% lower than that of R-410A. Upon increasing speed to match R-410A capacity, increase in energy consumption was greater than the cooling capacity increase, resulting in lower relative COPs shown in Figure 3. This could also be mitigated with further system optimizations or by using a system designed for use with one of the alternative refrigerant blends. Figures 6 and 7 illustrate discharge temperature and refrigerant mass flow rate trends for the testing.
Compressor discharge temperatures follow the expected trend from cycle model evaluations. R-454C yielded the lowest discharge temperatures, followed by R-454A. The same trend was observed with refrigerant mass flow rate. R-454C relative mass flow rate was greatest due to its lower volumetric capacity among the fluids tested. R-454A and R-454C had flow rates about 8% and 24% higher than R-410A, which accounted for cooling capacity increases of about 23% and 33% respectively. Evaporator superheat and EEV inlet subcooling temperatures are below in Figures 8 and 9.

Evaporator superheat was maintained at about 10 F for the 3600 RPM evaluations and adjusted to match the average evaporator temperatures of R-410A at in the matched capacity studies. The higher temperature glide R-454C required more superheat adjustment to match R-410A evaporator temperature. Subcooling values for R-454A and R-454C, though low, were the measured values for the optimal refrigerant charges for both fluids. There is a sight glass on the system before the EEV to visually confirm phase of fluid entering the EEV. For each test, fully subcooled liquid was entering the EEV.

3.2 Heating test results

Performance evaluations in heating mode are in progress. Evaluations for R-454A and R-454C will be complete in 2023.

4. Conclusions

Lower GWP alternatives to R-410A in stationary applications are available in the form of HFO containing refrigerant blends, such as R-454B, and other solutions. The potential for further reducing global warming impact in such systems exists with options such as R-454A and R-454C. Such refrigerants will require optimizations to common designs, such as a variable speed compressor, to achieve comparable cooling.
capacities to the incumbent HFC. Evaluations in a R-410A residential heat pump showed the potential of even lower GWP alternatives. Comparable cooling capacity was achieved with R-454A and R-454C. Relative COPs can be improved with further system optimization or choosing a system better suited for use with the alternative refrigerants. The incurred energy penalties can be reduced with these changes. Refrigerant flow increase can compensate for lower capacity fluids, enabling further reductions in GWP.

Abstract

This research is intended to evaluate a “hybrid refrigeration cycle” which is combining an absorption process driven by utilizing low-temperature waste heat with a compression process in one circulation cycle. A compressor is installed between an evaporator and an absorber in a hybrid refrigeration cycle. In this research, HFO or HCFO refrigerant and an organic solvent were used as a working pair for the absorption process.

The absorption equilibrium solubilities of the working pairs were measured when the experimental temperature and pressure conditions were changed. The parameters of NRTL model were determined by the experimental absorption equilibrium solubilities, and the \(PTx\) lines of the working pairs were calculated. Further, the enthalpy-concentration diagrams of the working pairs were calculated by using the material properties of the refrigerants and the absorbents.

It was confirmed that there are the conditions that the estimated cooling COP based on the power in the hybrid refrigeration cycle can be more than twice as high as that in the compression refrigeration cycle.

Keywords: hybrid refrigeration cycle; compression; absorption; low-GWP refrigerant; waste heat

1. Introduction

Utilization of waste heat is regarded as one of the effective means to achieve carbon neutrality by 2050. This research is intended to evaluate a “hybrid refrigeration cycle” which is combining an absorption process driven by utilizing low-temperature waste heat (lower than 100\(^\circ\)C) with a compression process in one circulation cycle.

Figure 1 shows the schematic flow diagram of the hybrid refrigeration cycle. A compressor is installed between an evaporator and an absorber. Although the power of a solution pump is necessary, the power of a compressor is reduced more than the increased power for a solution pump. Therefore, it is said that cooling COP of the hybrid refrigeration cycle based on power is significantly improved.

Recently, the use of HFCs in air conditioning and refrigeration equipment has been phased out due to their high GWP, and the transition to low GWP refrigerants HFO and HCFO is progressing. As for absorption chillers, working pairs using low GWP refrigerants are being developed, and HFO and ionic liquid working pairs have been proposed [1-2].

In this research, HFO refrigerant (GWP=1 or less) and an organic solvent (glycol ether) were used as a working pair for the absorption process for the purpose of improving the circulation ratio. The absorption equilibrium solubilities of the working pairs were measured when the experimental temperature and pressure conditions were changed. The parameters of Non-Random Two Liquid (NRTL) model were determined by the experimental absorption equilibrium solubilities, and \(PTx\) lines of the working pairs were calculated.
Further, enthalpy-concentration diagrams of the working pairs were calculated by using the material properties of refrigerants and absorbents to estimate cooling COPc of the hybrid refrigeration cycle.

**2. Property of equilibrium state**

**2.1. Refrigerant and absorbent**

R1234yf (GWP < 1) is used as a refrigerant. Tetraethylene Glycol Dimethyl Ether (C10H22O3, Kishida Chemical) is selected as an absorbent. The physical property of the absorbent used in this study is shown in Table 1. The absorbent is one of the organic solvents and is relatively cheap. The ionic liquid of [HMIM][Tf2N] as the absorbent is also used for validation and comparison.

**2.2. Measurement of absorption equilibrium solubilities**

Figure 2 shows the apparatus to measure absorption equilibrium solubilities [1].

The absorbent is set in the equilibrium cell and the refrigerant is set in the reservoir. Both is connected via valve V3.

The refrigerant in the reservoir is added into the equilibrium cell by the procedure that the valve V3 is opened for a certain time and closed. Then the equilibrium pressure P1 and P2 are measured. This procedure is repeated.

The increase of absorption equilibrium solubilities is the quantity of refrigerant moved from the reservoir to the equilibrium cell minus the increase of the quantity of refrigerant in the equilibrium cell.

The quantity of refrigerant moved from the reservoir to the equilibrium cell is estimated using the volume of area in which the refrigerant is present in the reservoir (blue part of Fig. 2, 153mL) and the change of the equilibrium pressure P1 after the addition of the refrigerant to the equilibrium cell.

The increase of the quantity of refrigerant in the equilibrium cell is estimated using the volume of area in which the refrigerant is present (green part of Fig. 2, 148mL minus the volume of the absorbent) in the equilibrium cell and the change of the equilibrium pressure P2 after the addition of the refrigerant to the equilibrium cell. The volume of the absorbent is set to be about 22mL.
The measurement temperature is from 35°C to 80°C. T1 and T2 are K sheath type thermocouples (1.6mm), and P1 and P2 are the pressure sensors (GP-M025, KEYENCE).

Figure 2. Outline of apparatus for equilibrium absorption solubilities.

Figure 3 shows the experimental results of the relation between the refrigerant concentration and the pressure at different temperatures. The left of Fig. 3 indicates the result in case of [HMIM][Tf2N] and the right of Fig. 3 indicates the result in case of Tetraethylene Glycol Dimethyl Ether. The refrigerant concentration is the mass ratio to the sum of the refrigerant and the absorbent. The dotted line in the right of Fig. 3 is fitted to the experimental data by quadratic function.

The refrigerant concentration in case of Tetraethylene Glycol Dimethyl Ether is much higher than that in case of [HMIM][Tf2N] at the same temperature.

In order to validate the measured absorption equilibrium solubilities, the data of ref [1] in case of R1234yf/[HMIM][Tf2N] is used.

The temperature conditions for the validation are follows.
- Evaporation temperature $T_e$ is 10°C
- Condensation temperature $T_c$ is 35°C
- Absorption temperature $T_a$ is 35°C
- Generation temperature $T_g$ is 80°C

Table 2 shows the refrigerant concentration of the strong solution $x_s$ and that of the weak solution $x_w$ and the circulation ratio in the condition above including in case of R1234yf/Tetraethylene Glycol Dimethyl Ether. The circulation ratio is defined to be the mass flow ratio of the strong solution to that of the absorbed refrigerant and can be also calculated to be $(100\% - x_w) / (x_s - x_w)$. The refrigerant pressure is estimated using Refprop.
In case of R1234yf, the absorption (=evaporation) pressure is 438kPaA, and the generation (=condensation) pressure is 895kPaA. The pressure loss is not considered. It is confirmed that the refrigerant concentration of the strong and weak solutions and the circulation ratio of ref [1] in case of R1234yf/[HMIM] [Tf$_2$N] is almost same as this work. Further, the refrigerant concentration difference between the strong and weak solutions in case of R1234yf/Tetraethylene Glycol Dimethyl Ether is increased, and the circulation ratio is significantly improved.

Table 2. Refrigerant concentration of the strong and weak solutions and the circulation ratio at $T_e$=10℃, $T_s$=35℃, $T_a$=35℃, $T_g$=80℃.

2.3. PTx lines and enthalpy-concentration diagrams

The Non-Random Two Liquid (NRTL) equation is applied to the experimental results of the relation between the refrigerant concentration and the pressure at different temperatures shown in the right of Fig. 3 for R1234yf/Tetraethylene Glycol Dimethyl Ether. The parameter $\alpha$ of the NRTL equation is set to be constant ($\alpha=0.2$) in this work [3]. It is confirmed that the deviations of the calculated refrigerant concentration using the NRTL equation from the experimental refrigerant concentration for R1234yf/Tetraethylene Glycol Dimethyl Ether are very small.

The left of Fig.4 shows PTx lines, and the right of Fig.4 shows the enthalpy-concentration diagrams in case of R1234yf/Tetraethylene Glycol Dimethyl Ether. The enthalpy of the solution which absorbed the refrigerant is calculated based on ref [4]. The enthalpy per unit solution mass is plotted against the refrigerant concentration which is the mass ratio of the refrigerant to the sum of the refrigerant and the absorbent. The enthalpy of the saturated liquid of the refrigerant at 0℃ is 200kJ/kg, and the enthalpy of the absorbent at 0℃ is 200kJ/kg.

Fig. 4. PTx lines (left) and enthalpy-concentration diagrams (right) in case of R1234yf/Tetraethylene Glycol Dimethyl Ether

3. Process simulation

3.1. Flow and conditions for process simulation

The process simulation in case of R1234yf/Tetraethylene Glycol Dimethyl Ether is conducted for the double expansion flow indicated in Fig. 5.
The refrigerant at the outlet of the evaporator (1) is compressed to the intermediate pressure (2) by the low-stage compressor and is mixed (8) with the saturated vapor refrigerant from the separator (7). The strong solution (10) which absorbs the refrigerant (8) at the absorber is compressed (11) by the solution pump and is heated (12) at the solution heat exchanger and is separated into the refrigerant (9) and the weak solution (13) at the generator. The separated refrigerant (9) is condensed (3) at the condenser and is decompressed (4) by the expansion valve EV2 and is separated into the saturated vapor refrigerant (7) and the saturated liquid refrigerant (5) at the separator. The saturated liquid refrigerant (5) is decompressed (6) by the expansion valve EV1 and is directed to the evaporator. The weak solution (13) is cooled (14) at the solution heat exchanger and is decompressed (15) by the expansion valve EV3 and is directed to the absorber.

The high-stage compressor is provided for operation when the quantity of waste heat is relatively small.

The simulation conditions are follows.
- Compression efficiency is 75%
- Pump efficiency is 50%
- Superheat at the outlet of the evaporator is 5K
- Subcool at the outlet of the condenser is 0K
- Temperature efficiency of the solution heat exchanger is 85% (based on weak solution)
- Pressure and heat loss is none.
- Evaporation temperature $T_e$ is 5℃
- Condensation temperature $T_c$ is 30℃
- Absorption temperature $T_a$ is 30℃

![Fig. 5. Flow of the process simulation (double expansion).](image)

### 3.2. Results of process simulation

Table 3 shows the example of simulation results of the state value at each position and the heat quantity and the power when the high-side compressor is not operated, the intermediate temperature $T_m$ is 12℃, the generation temperature $T_g$ is 80℃ and the quantity of evaporation $Q_e$ is 100kW.

The intermediate temperature $T_m$ is defined to be the saturated temperature of the refrigerant at the outlet of the low-stage compressor.

Table 3. Simulation results of the state value at each position (upper) and the heat quantity and the power (lower) at $T_e=5℃$, $T_c=30℃$, $T_g=80℃$, $T_a=12℃$, $Q_e=100kW$ without high-stage compressor.

<table>

<td>17.9</td>
<td>377</td>
<td>0.643</td>
<td>100</td>
</tr>
</tbody>
</table>
Cooling COP_{c} based on the power in this hybrid cycle is 17.0 (=100kW / (3.5kW+2.3kW)). On the other hand, although the details are omitted, the compression power in the single compression cycle under the same condition is 14.0kW, so cooling COP_{c} in the single compression cycle is 7.2 (=100kW / 14.0kW). Therefore, cooling COP_{c} based on the power in the hybrid cycle corresponds to about 238% of that in the single compression cycle. The required quantity of generation heat corresponds to about 2.1 times of that the evaporation heat. The circulation ratio in the absorption process is about 4.7 (=3.592kg/s / 0.765kg/s).

Cooling COP_{c} based on the power (left) and the quantity of generation heat $Q_{g}$ (right) are shown in Fig. 6 when the intermediate temperature $T_{m}$ and the generation temperature $T_{g}$ are changed in the condition above. Cooling COP_{c} is expressed as a ratio to that of single compression cycle in the same condition, and the quantity of generation heat $Q_{g}$ is expressed as a ratio to that of evaporation heat $Q_{e}$. The result in the condition of Table 3 (the intermediate temperature $T_{m}$ is 12℃ and the generation temperature $T_{g}$ is 80℃) is indicated by “□” in Fig. 6.

It can be seen that COP_{c} has a local maximum value against the intermediate temperature $T_{m}$ (indicated by “〇”), and the quantity of generation heat $Q_{g}$ increase as the intermediate temperature $T_{m}$ decreases. It is considered that although the compression power decreases with the decrease in the intermediate temperature $T_{m}$, the power of the solution pump and the quantity of generation heat $Q_{g}$ increase due to the increase in the circulation ratio.
Cooling COP\textsubscript{c} based on the power against the quantity of generation heat \(Q_g\) is shown in Fig. 7 in the condition above. It can be seen that COP\textsubscript{c} has a local maximum value against the quantity of generation heat \(Q_g\) (indicated by “〇”).

When the generation temperature \(T_g\) decreases, the maximum value of COP\textsubscript{c} decreases. However, it can be seen that the required quantity of generation heat \(Q_g\) at that time is also reduced.

4. Conclusions

After measuring the equilibrium absorption concentration, PTx lines and enthalpy-concentration diagrams were created, and process simulation was performed in the hybrid refrigeration cycle which uses R1234yf as the low-GWP refrigerant and Tetraethylene Glycol Dimethyl Ether (organic solvent) as the absorbent. Below are the conclusions:

- The circulation ratio of the absorption process using Tetraethylene Glycol Dimethyl Ether as the absorbent is significantly lower than that using [HMIM][Tf\textsubscript{2}N] (ionic liquid) in case of R1234yf as the refrigerant.
- In the simulation condition of this work, there is a local maximum value of cooling COP\textsubscript{c} based on the power of the compressor and the solution pump against the quantity of generation heat. It was confirmed that there are the conditions that the estimated cooling COP\textsubscript{c} based on the power in the hybrid refrigeration cycle can be more than twice as high as that in the single compression refrigeration cycle.

The Performance Playbook: A policy strategy for scaling heat pump adoption with happy consumers and utilities

Andy Frank
Nate Kinsey

Sealed, 22 W 38th Street Floor 10, New York, NY 10018
andy.frank@sealed.com

Abstract

Across the country, states and utilities are implementing programs to accelerate the market adoption of heat pumps to meet energy and climate goals. Through case studies of leading heat pump rebate and incentive programs, including California’s Technology and Equipment for Clean Heating initiative, the City of Denver’s Climate Action Rebates, and New York State’s Clean Heat program, Sealed explores each program’s unique market animation strategies and their impact on consumer adoption of heat pumps. These programs attempt to utilize “tried and true” market animation strategies that largely rely on financial incentives for consumers, but they have all caused a market “sugar crash” when program funding is exhausted. Market strategies based solely on large consumer rebates make achieving the adoption of heat pumps difficult, if not impossible, at the speed and scale required to reduce greenhouse gas emissions from commercial and residential buildings.

But while program sugar crashes are a well known phenomenon, little work has been done to quantify the effect and compare the impact across geographies and program designs. This paper takes a first step to track the speed and scale of sugar crash program spending, and offers solutions to the problem.

Specifically, a “Performance Playbook” is proposed that seeks to address this sugar crash problem. Only market-aligned strategies that maximize scarce ratepayer funds can accelerate the consumer adoption of heat pumps and provide utilities with valuable grid services. At its core, the Performance Playbook is built upon the principles that heat pump incentive programs should be:

● Easily accessible for both consumers and market actors,
● Flexible to adapt to evolving market conditions and long-term policy goals, and
● Performance-based to ensure market actors complete high-quality installations.

Keywords: consumer facing rebates, market based incentives, sugar crash, sugar rush.

New York State’s Clean Heat Program

Approved by the New York Public Service Commission (NY PSC) in its 2018 Order Adopting Accelerated Energy Efficiency Targets, the New York State Clean Heat program (Clean Heat Program) is the primary rebate program for accelerating the adoption of heat pumps in New York. The program was originally approved in 2018 with a total budget of $250 million and a statewide energy savings goal of 5 million gross MMBtus. On April 1, 2020, the Clean Heat Program began accepting rebate applications with a revised

1
statewide budget of $454 million and a heat pump energy savings goal of 3.5 million gross MMBtus.1

The Clean Heat program is administered on a statewide basis by New York’s investor-owned utilities and in coordination with the New York State Energy Research and Development Agency (NYSERDA). Collectively this group is referred to as the “Joint Efficiency Providers” and strives to create a consistent experience and the market conditions to accelerate the adoption of heat pumps in New York.

Table 1 shows the adopted budgets and MMBtu savings goals for each of New York’s investor-owned utilities.

Market Animation Strategy and Impact

The initial Order creating the Clean Heat program did not prescribe strategies or tactics the Joint Efficiency Providers should use to animate the market. The Order also did not require a percentage or fixed amount of the program budget to be set aside for certain building types (i.e., small residential, multifamily, or commercial buildings). As such, the Joint Efficiency Providers elected to animate New York’s entire building market through a program design that offered a customer-facing rebate structured as 1) a fixed dollar amount per heat pump unit, 2) per heat pump system capacity, or 3) per annual energy savings generated by a heat

---

2 Table 1 is a recreation of Appendix C Table C1: 2020-2025 Heat Pump Budgets and Targets (Gross MMBtu) from the January 2020 Order Authorizing Utility Energy Efficiency and Building Electrification Portfolios through 2025. See: https://documents.dps.ny.gov/public/Common/ViewDoc.aspx?DocRefId={06B0FDEC-62EC-4A97-A7D7-7082F71B68B8}.
pump project. At the program’s launch in April 2020, the Joint Efficiency Providers offered 9 distinct rebate categories.

Over the life of the Clean Heat Program, the Joint Efficiency Providers have increased rebate values, decreased rebate values, and created entirely new rebate categories to influence heat pump installations in their respective service territories. As of November 23, 2022, the Clean Heat Program has 12 different rebate categories that provide financial rebates for air-source heat pumps, ground-source heat pumps, and heat-pump water heaters to customers, contractors, distributors, and, in some categories, all three market actors.

As of November 23, 2022, over 26,000 buildings have participated in the Clean Heat Program. On December 19, 2022, the Department of Public Service staff supporting the NY PSC filed a comprehensive Energy Efficiency and Building Electrification Report. This report summarizes the performance of all of New York’s efficiency programs, including the Clean Heat Program, and asks stakeholders for comment on the future direction of these programs.

California’s Technology and Equipment for Clean Heating Program

In response to the passage in 2018 of California Senate Bill 1477: Low-emissions buildings and sources of heat energy, the California Public Utilities Commission (CPUC) created the Technology and Equipment for Clean Heating (TECH) initiative to serve as the state’s main incentive program for accelerating the market adoption of heat pumps. Originally approved with a total budget of $120 million, the TECH initiative was bid out to a third party non-utility program administrator. The winning bid was led by the Energy Solutions firm and a group of 11 supporting companies that together are responsible for:

1. Offering midstream and upstream incentives to animate the market,
2. Administering regional pilots and quick-start grants designed to overcome identified market barriers to heat pump adoption,
3. Providing low-interest financing for projects in environmental justice communities,
4. Informing future clean space and water heating policies in California through meter-based data driven analysis.

Of the $120 million approved by the CPUC for the TECH initiative, approximately $37.5 million was reserved for single-family heat pump and heat-pump water heater incentives, and approximately $13.3 million was reserved for multi-family heat pump and heat-pump water heater incentives.

Market Animation Strategy and Impact

By statute, the TECH initiative can provide incentives only through midstream or upstream techniques to encourage customer adoption. The TECH team identified contractors as key stakeholders in the heat pump supply chain and elected to issue cash incentives directly to those contractors. The TECH initiative doesn’t have requirements for how much or how little of the TECH incentive contractors must pass through to the end customer.

The TECH initiative’s focus on the residential building sector allowed the TECH team to design a simpler and more sector-specific set of incentives. Single-family incentives launched on December 7, 2021, utilized a

1 Specific utilities also provided “kicker” rebates for heat pump installations completed in “High Priority Electrification Zip Codes” identified having natural gas distribution system capacity constraints. See: https://cleanheat.ny.gov/assets/pdf/national-grid-high-priority-electrification-zip-codes.pdf
2 Decision 20-03-027 approved the TECH program. See: https://docs.cpuc.ca.gov/PublishedDocs/Published/G000/M331/K772/331772660.PDF
3 The Tech California Team consists of the following firms: Energy Solutions, VEIC, Frontier Energy, Association for Energy Affordability, Building Decarbonization Coalition, Recurve, the Ortiz Group, Ardenna Energy, Electrify My Home, National Comfort Institute, Tre’ Laine, and Energy Outlet. For more details on each firm and links to the company websites, see: https://techcleanca.com/about/
4 Initial funding for the TECH initiative was provided natural gas utility cap and trade proceeds. This funding source restricted the ability of TECH to offer rebates only to customers in natural gas territories.
5 Senate bill 1477 low-emissions buildings and source of heat energy. (2017-2018) only allows the TECH initiative to provide “upstream and midstream incentives to install low-emission space and water heating equipment in existing and new buildings, with technologies identified pursuant to subdivision.” See: https://leginfo.legislature.ca.gov/faces/billNavClient.xhtml?bill_id=201720180SB1477

3
two-tier and a fixed-dollar amount, per unit, incentive for air-source heat pumps and heat-pump water heaters.\(^8\) Tier 1, or the baseline incentives, were available to all participants. Tier 2, or enhanced incentives, were higher incentives only available in geographies where other energy efficiency heat pump program offerings were available. The TECH initiative was able to “stack,” or “braid,” their incentives with other heat pump incentives because the program wasn’t bound by other regulatory compliance metrics, such as energy efficiency savings goals.

On May 12, 2022, the TECH initiative announced that funding for its heat pump and heat-pump water heater incentives had reached capacity and were no longer processing applications.\(^9\) As of November 23, 2022, the TECH program has incentivized the installation of 9,555 air-source heat pumps and 1,270 heat-pump water heaters. The average incentive provided for these installations was $3,422 for air-source heat pumps and $3,555 for heat-pump water heaters.\(^10\)

**Denver’s Climate Action Rebates**

In November 2020, Denver voted in favor of Ballot Initiative 2A, approving the increase of the city’s and county’s sales tax rate by 0.25% starting in 2021. Additionally, the initiative created a new city budget fund called the Climate Protection Special Revenue Fund (Climate Action Fund).\(^11\) At the time of passage, the Climate Action Fund was estimated to be valued at approximately $40 million annually and could provide financial and technical support to a range of clean energy investments.

In November 2021, in response to the creation of the Climate Action Fund, and to provide direction on how the funds should be invested, the Office of Climate Action, Sustainability, and Resiliency filed the Climate Protection Fund Five-Year Plan. The plan identified the investments and strategies the office intends to make to achieve the city’s goal of reducing greenhouse gas emissions by 65% by 2030.\(^12\) One of these investments and strategies included residential energy rebates designed to accelerate the adoption of clean energy technologies, including “highly efficient, all-electric energy equipment such as space/water heat pumps, electric vehicle charging, [and] solar and energy storage.”\(^13\)

On Monday March 14, 2022, Denver’s City Council approved Resolution 22-0227, and created a new, three-year $9 million residential energy rebate program, called the Climate Action Rebate program.\(^14\) Unlike other heat pump rebate programs, the Climate Action Rebate program sought to incentivize a range of residential electrification technologies, including electric modes of transportation, rooftop solar, battery-energy storage, and other climate-action related technologies as determined by the program administrator, Aptim Environmental and Infrastructure. The Resolution covered the period from April 1, 2022, to March 1, 2025, and had the goal of reaching between 1,500 and 2,000 households annually.

**Market Animation Strategy and Impact**

As described by Grace Rink, the Chief Climate Officer for the City and County of Denver, and Executive Director of its Office of Climate Action, Sustainability, and Resiliency, the Climate Action Rebates sought to animate the market for electrification technologies and drive down future installation costs.\(^15\) The program was also intentionally designed to amplify and stack with air-source heat pump and heat-pump water heater rebates available from Xcel Energy (Xcel), the City and County of Denver’s investor-owned electricity utility. This was achieved by requiring homeowners to utilize Xcel’s trade ally network to complete their installations.

On June 24, 2022, the city announced that funding for its heat pump and heat-pump water heater rebates had reached capacity and was no longer processing applications. During the 63 days between program launch and program pause, 350 households took advantage of the Climate Action Rebates for heat pumps.  

**Market Sugar Rush and Sugar Crash**

The Clean Heat Program, the TECH initiative, and the Climate Action Rebates all deployed different strategies and tactics to animate the heat pump market. In the case of the Clean Heat Program and the TECH initiative, these efforts were able to animate the market on a statewide basis and, in the process, reached thousands of homes. In the case of the Climate Action Rebates, the program was able to animate the market on a city level and, in the process, reached hundreds of homes. These efforts should be celebrated, as every heat pump installation represents progress toward a more stable climate. However, in the process of animating these markets, each program caused a market effect that Sealed refers to as a market sugar rush, followed by a sugar crash.

Also known as boom-bust cycles, sugar rushes and sugar crashes are a symptom of rebate or incentive programs that have a combination of short-term goals, short-term budgets, and financial incentives that are too generous. Together these program design elements can inject greed as well as fear, uncertainty, and doubt, commonly referred to as “FUD,” into the market.

Con Edison’s Clean Heat Program is the largest example of a sugar rush and crash. At the program’s launch, in April 2020, the rebate offered to customers was simple and generous: Customers who installed a 3-ton heat pump, a standard size for most homes, received a $7,200 rebate. However, due to low initial participation, Con Edison dramatically increased the program’s rebate values starting August 1, 2021. For that same 3-ton heat pump, homeowners now received an $18,000 rebate, but only if they decommissioned their existing fossil-fuel heating system. Installations skyrocketed — with monthly installations almost doubling — but this 150% increase in rebate value turned out to be too generous for the market.

Due to an overwhelming market response, Con Edison made a pivotal announcement at the end of 2021: Starting March 1, 2022, rebates would be reduced by approximately 50%, decreasing the value of a 3-ton heat pump to just $9,720. This pivot by Con Edison to manage its short-term program budget infused the program with uncertainty and fear, commonly referred to as “FUD,” into the market.

---

16 The program also provided rebates for e-bikes, electric vehicle (EV) charging home wiring, rooftop solar, battery energy storage, and electric service upgrades to enable another measure. See: https://www.eebco.org/resources/Documents/POLICY%20ACTION%20COMMITTEE/HVACHIPS%20ACTION%20GROUP/Flier%20Denver%20Climate%20Action%20Rebates%20Summary%20Overview_4.15.22.pdf
17 See: https://www.genesys.net/articles/denver-passed-a-sales-tax-for-climate-is-it-working/
18 Con Edison and other stakeholders initially believed the de-commissioning requirement would slow market demand for the largest tier of heat pump incentives that included decommissioning.
market with additional FUD, resulting in another rush in rebate applications from consumers trying to beat the new deadline, followed by another market crash in March and April.

Because of the huge demand caused by the pivot to lower rebates, on May 9, 2022, Con Edison announced the Clean Heat program would no longer accept rebate applications starting May 14, 2022. This announcement caused another FUD-driven sugar rush, as customers and contractors hurried to meet the May 13, 2022, deadline. Chart 1 documents the sugar rush and sugar crash by quarter.

On July 18, 2022, Con Edison announced they had received rebate applications worth $642 million in 2022, bringing total applications to the program since its launch to $755 million — $528 million more than originally planned. On August 11, 2022, the NY PSC approved Con Edison’s petition to transfer unspent energy efficiency funding to cover the cost overrun. The NY PSC also approved Con Edison’s request for a new $10 million monthly Continuity Funding Mechanism to restart the Clean Heat Program in their service territory, with the program re-starting on January 17, 2023.

The Performance Playbook

To address these market dynamics and accelerate consumer adoption of heat pumps in alignment with utility price signals, Sealed has developed a three-part market transformation strategy called the Performance Playbook. The Performance Playbook pairs proven market-animation strategies, such as consumer-facing rebates, with flexible market incentives for market actors, along with performance-based incentives to sustainably accelerate market growth while avoiding sugar highs and sugar crashes. Each component is explored below.

Consumer-Facing Rebates and Rebate Blocks

First, heat pump programs that provide consumer-facing rebates, like New York’s Clean Heat Program and Denver’s Climate Action Rebate program, should be restructured to predictably decrease in value as market adoption increases. In many leading heat pump markets, consumers have become accustomed to the rush of receiving a rebate for installing a heat pump, but what causes a subsequent crash is the fear of missing the opportunity to receive the rebate. Program designs that set clearer and more sustainable expectations of how much money customers will receive negate this fear.

Incentive blocks, or phase-downs, have been utilized by multiple rooftop-solar programs, including New York’s NY-Sun program and the California Solar Initiative, to reduce incentive amounts over time in a transparent way. These programs were by no means perfect, but they helped grow their states’ solar markets in a predictable fashion by providing long-term incentive certainty. Ideally, these declining incentive blocks
should be executed over multi-year program budgets to minimize year to year fluctuations in program budgets.

Chart 2 provides an illustrative example of decreasing rebate blocks, starting with a $3,000 heat pump incentive and decreasing the incentive value by $500 over time. Each incentive block should represent a market milestone, such as 10,000 units installed.

Market-Based Incentives

Second, smaller and more stable consumer-facing rebates should be paired with market-based incentives that numerous market actors, or aggregators, can receive. Studies have found that such market-based midstream and upstream incentive programs drive heat pump adoption better than stand-alone consumer-facing rebates.

In addition, the traditional rebate-heavy approach often suffers from being complicated and expensive. One study of more than 600 utilities found that just 60% of the money underpinning such energy efficiency programs was allocated to incentives. The rest? Spent on administrative and marketing costs. While we do not know the administrative allocation of the programs cited in this paper, it is clear that administrative costs are often higher than necessary or sustainable.

Under the Performance Playbook, aggregators receive incentives that can be used in a variety of ways. Upfront rebates can be used to offset the cost of energy efficiency projects. Incentives can also be used to lower financing costs, minimize sticker price or fund project “extras,” like smart thermostats. In other words, market-based incentives provide flexibility, as aggregators compete to discover innovative ways to drive heat pump adoption and performance at the lowest possible cost.

These market-based incentives, like the ones available through California’s Market Access Program or the Inflation Reduction Act’s HOMES program, motivate market actors to invest in market transformation activities, such as customer marketing, software, and infrastructure, necessary to have a sustainable market. And since these incentives are delivered midstream, they can be lowered if market demand is higher than initially expected.

Graph 1 summarizes the key differences between a traditional approach and one based on the Performance
Performance-Based Incentives Ensure Consumer, Ratepayer, and Taxpayer Protection

Third, any incentives paid out to drive the installation of heat pumps should be based on how those energy efficiency projects ultimately perform. This is the measured savings approach that is one pathway defined in the Inflation Reduction Act’s HOMES program. The risks of energy efficiency projects are currently shared by consumers, ratepayers, and taxpayers alike, whereas under the Performance Playbook these risks lie with aggregators.

With the Performance Playbook, therefore, incentives are valued based on measured energy savings in order to drive consumer adoption. One survey of New York homeowners discovered that while incentives of 50% of project costs drove significant uptake in heat pump installations, the bigger impact came from performance-based financing. In other words, consumers were more willing to pursue energy efficiency projects if market actors, like aggregators, could take on the project performance risk, as Graph 2 shows.
Conclusion

The rebate and incentives provided for heat pump technologies is exploding, with the August 2022 passage of the Inflation Reduction Act injecting billions of additional dollars into the market. Policymakers across the country will have to grapple with how best to design programs to accelerate heat pump adoption without crashing the market.

Now is the time to learn from previous programs, set realistic incentive amounts and, most importantly, design programs that can last and achieve true market transformation. The Performance Playbook can do this by leveraging taxpayer and ratepayer investments to accelerate the market rather than crash it. By focusing on flexible, performance-based incentives that have long-term budget certainty, precious public resources can be used to unlock multiples of private capital.

But this will only happen if policymakers, utilities, and other stakeholders take a hard look at past program experience, and better understand the relationship between incentive levels, program design, and market demand.
Exploration of Heat-Driven Ejector High-Temperature Heat Pumps

Pengtao Wang, Stephen Kowalski, Cheng-Min Yang, Jian Sun, Zhiming Gao, Kashif Nawaz*

Multifunctional Equipment Integration Group, Building Technology Research and Integration Center, Oak Ridge National Laboratory, Oak Ridge, TN 37830, USA

Abstract

Heat-driven ejector heat pumps use a supersonic ejector as a thermo-compressor to replace the mechanical compressor. Supersonic ejectors have many advantages in high-temperature heat pump (HTHP) applications, including high operating temperature tolerance, no need for lubrication, low maintenance, and low cost. The coefficient of performance of ejector HTHPs could be improved by selecting binary fluids with unique thermodynamic properties. Although supersonic ejectors have been widely used in refrigeration systems, their application in spaces and water heating is limited. This study explores the theoretical potential of ejector HTHPs with a sink temperature of 100°C–130°C and a lift temperature of 10°C–30°C. Ejector HTHPs were evaluated with single-fluid ejectors (SFEs) and binary-fluid ejectors (BFEs). A comprehensive, geometry-free theoretical model of BFEs was developed to predict the theoretical maximum entrainment ratios. HFE7500 and R718 (water) were selected as working fluids for SFEs and BFEs. SFEs operating with R718 provided a higher coefficient of performance of ejector HTHPs than SFEs operating with HFE7500 and BFEs. This study preliminarily demonstrates the technical potential of ejector HTHP applications in recovering moderate-temperature heat sources.

Keywords: Ejector, High temperature heat pump, binary fluid, COP;

1. Introduction

High-temperature heat pumps (HTHPs) have great potential to improve energy efficiency and reduce CO₂ emissions by replacing gas-fired boilers for industrial process heating. Many HTHPs under development and case demonstrations operate with electricity-driven vapor compression cycles, as reported by International Energy Agency (IEA) Annex 58. A basic configuration of HTHPs working with a vapor compression cycle is shown in Fig. 1(a), in which a mechanical compressor is used to lift the pressure of the refrigerant vapor (Process 1→2). The compressor is the main component in electric-driven HTHPs, accounting for 48.2%–
57.3% of the total cost of 100 kW HTHPs using R245fa [1]. Corresponding to a high sink temperature ($T_{\text{sink}} > 100^\circ\text{C}$) in HTHPs, the high pressure and temperature of refrigerants challenge state-of-the-art compressor technologies in the following ways:

- **Risk of wet compression:** Emerging refrigerants with a low global warming potential (GWP), such as R1336mzz(Z), have a saturated vapor curve with a positive slope ($\frac{dT}{ds}$), requiring internal heat exchangers to provide substantial superheating of suction vapor [2].
- **Overheating of compressors:** Auxiliary cooling technology and components are used in HTHPs to effectively control the temperature of compressors, such as the vapor injection technique with an economizer [3].
- **Availability of lubricant oils:** High temperature and pressure challenge the thermal stability of lubricant oil and its material compatibility with refrigerants and sealing materials [4].
- **Limited drop-in operation with alternative refrigerants:** Mechanical compressors have complex designs, infrastructure, and process controls [5], making it difficult to operate with various refrigerants.

These challenges associated with electric-driven HTHPs could be alleviated by using heat-driven heat pumps [6]. Heat-driven heat pumps use thermal chemical and physical processes, such as adsorption or absorption HTHPs and transformers; thermal engines, such as Stirling engines and Vuilleumier engines; thermal acoustic coupling effects [7]; and thermo-compressors. The ejector-based HTHP is a typical heat-driven heat pump that uses a supersonic ejector as a thermo-compressor, which replaces the mechanical compressor in a conventional vapor compression cycle, as shown in Fig. 1(b). Primary fluid (PF), at high temperature and pressure (state point 2), accelerates into a supersonic flow and creates a vacuum in the suction chamber of the ejector, which entrains the secondary fluid (SF), at low temperature and pressure (state point 6), into the ejector. PF and SF mix, and the pressure of mixed PF-SF is sequentially lifted to a moderate level (state point 3) through a normal shock wave and a diffusing process. Supersonic ejectors are desirable in HTHPs because of their simple structure, high reliability, low cost, and low maintenance (without moving parts) [8-10]. Furthermore, the ejector could operate with a wide range of refrigerants via drop-in replacement [11], and it is scalable to large systems and multi-stage systems at high temperatures. For example, a steam ejector used in a thermal power plant, driven with a PF at 4.33 MPa and 350°C, could upgrade the low-pressure SF from 1.152 MPa and 400°C to 1.3 MPa and 366°C [12].

Supersonic ejectors in heat-driven refrigeration applications have been extensively studied, and they are attractive for using available waste heat [13] and solar thermal energy [14]. However, few studies have examined ejector-based heat pumps. The technical barriers in ejector-based heat pumps are a low heating cycle coefficient of performance (COP), a small pressure lift ratio, and poor performance under off-design conditions. Theoretically, a low heating cycle COP of ejector heat pumps could be addressed by replacing a single fluid with a binary-fluid pair (i.e., a PF and SF with unique thermal properties) [15]. The heating cycle COP of heat pumps with a binary-fluid ejector (BFE) is approximate to [16, 17]
\begin{align*}
CO_P_{HP} = 1 + \omega \frac{\Delta h_{SF}}{\Delta h_{PF}} & \approx 1 + \omega \frac{h_{iv, SF}}{\Delta h_{iv, PF} + h_{iv, PF}} \quad (1)
\end{align*}

where \( h_{iv, PF} \) and \( h_{iv, SF} \) are the latent heat of evaporation of the PF and the SF, respectively. \( \Delta h_{sh, PF} \) is the increased sensible heat of the PF in the high-temperature evaporator (HTE). The entrainment ratio, \( \omega \), is defined as the ratio of mass flow rates of the SF and PF, denoted by \( \dot{m}_{SF} \) and \( \dot{m}_{PF} \).

\[
\omega = \frac{\dot{m}_{SF}}{\dot{m}_{PF}} \quad (2)
\]

Equation (1) shows that choosing an SF with a larger \( h_{iv} \) than PF, and a PF-SF pair yielding a large \( \omega \) in BFEs, could significantly increase \( CO_P_{HP} \) [18]. Previous theoretical research demonstrated that, for an ejector heat pump water heater with \( \Delta T_{sink} = 65^\circ C \), using a binary-fluid pair of HFE7500 and water, \( \frac{h_{iv, SF}}{h_{iv, PF}} = 25.1 \), and neglecting \( \Delta h_{PF} \), the heating cycle COP could reach 2.0 with a low entrainment ratio of 0.1 [16].

This study explored the technical potential of supersonic ejectors for heat-driven HTHPs operated with \( T_{sink} = 100^\circ C \sim 130^\circ C \) and \( \Delta T_{lift} \approx 10^\circ C \sim 30^\circ C \). The single-fluid ejector (SFE) and BFE were theoretically evaluated for the performance of HTHPs. The entrainment ratios of SFEs and BFEs were theoretically predicted with a comprehensive, geometry-free model of an ejector. HFE7500 and R718 (water) are selected as the working fluids for SFE or BFE. The performance of ejectors and ejector HTHPs are investigated for various working conditions.

2. Thermodynamic Model of Heat-driven Ejector HTHPs

A heat-driven ejector HTHP essentially consists of a HTE, a low-temperature evaporator (LTE), an ejector (EJT), a condenser (COND), a separator (SEP), an expansion valve, and a circulation pump, as shown in Fig. 2(a). In Fig. 2, “1, 2, 3, . . .” and “i, ii, iii, . . .” denote the state points in the system-level loop of the HTHP and the component-level process within the EJT, respectively. The working fluid loops are as follows:

1→2, the liquid PF evaporates in the HTE;

i(2)→iii, the high-pressure PF steam accelerates into a supersonic flow and creates a vacuum in the suction chamber of the EJT;

iii→vi→v, PF and SF mix in the constant section of the mixing chamber of the EJT;

vi→vii, the supersonic flow of the mixed PF-SF flows through a normal shock wave;

vii→viii, the subsonic flow of the mixed PF-SF diffuses in the diffuser section of the EJT;

3(viii)→4, the mixed PF-SF vapor condenses in the COND;

4→5 and 5→6, the liquid PF and SF are separated in the SEP;

5→1, the liquid PF is pumped to the HTE;

6→7, the liquid SF throttles in the expansion valve;

7→8, the SF evaporates in the LTE.

iv(8)→v, the SF vapor accelerates into a sonic flow within the EJT.

The EJT in the investigated ejector HTHP could be an SFE or BFE, depending on the selected PF and SF. For the BFE, the separation of PF-SF in the SEP could be a gravity-driven process for an immiscible fluid pair with a large difference in density, or a thermal-driven fractional condensation process for a miscible fluid pair with a large difference in normal boiling point [19]. In this study, a gravity-driven separator was employed for the binary-fluid pair of HFE7500 and R718, as discussed in the following section. If the same working fluid is selected for the PF and SF, the BFE is reduced to the SFE, and the SEP is not needed.
2.1. Thermodynamic Model of an Ejector HTHP

A thermodynamic model of a two-stage BFE HPWH was developed by applying the mass and energy conservation for each component, as summarized in Table 1 [16, 20, 21]. The operating parameters specified for the ejector-drive HTHPs include the sink temperature, \( T_{\text{sink}} \), the source temperature, \( T_{\text{source}} \), and the driven temperature, \( T_{\text{LTE}} \). \( T_{\text{sink}} \) is the temperature of heat delivered by HTHPs, and \( T_{\text{sink}} = T_{\text{COND}} - T_{\text{source}} \) is the temperature of waste heat available for HTHPs, and \( T_{\text{source}} = T_{\text{LTE}} \). The lift temperature of HTHP, \( \Delta T_{\text{lift}} \), is defined as

\[
\Delta T_{\text{lift}} = T_{\text{sink}} - T_{\text{source}} = T_{\text{COND}} - T_{\text{LTE}}
\] (3)

The system-level performance of an ejector HPWH was evaluated by its heating cycle COP, \( \text{COP}_{\text{HP}} \), given as

\[
\text{COP}_{\text{HP}} = \frac{Q_{\text{COND}}}{Q_{\text{HTE}}} \approx 1 + \frac{Q_{\text{LTE}}}{Q_{\text{HTE}}}
\] (4)

where \( Q_{\text{COND}} \) is the thermal capacity of the ejector HTHP, which equals the released heat of the mixed PF-SF discharged from the ejector. \( Q_{\text{HTE}} \) and \( Q_{\text{LTE}} \) are the heat input in the HTE and the LTE, respectively.

For the investigated ejector HTHP with a specified thermal capacity, the mass flow rates of the PF and SF were predicted by a theoretical model of the BFE. The comprehensive, geometry-free model predicted the
optimized performance of ejectors under specified operating parameters of HTHPs. The theoretical model was developed based on the gas-dynamic equations and the conservation equations [22, 23]. Detailed information of the theoretical model of the BFE was reported in previous publications [20, 21]. The theoretical model of the BFE was solved with the real properties of working fluids using the Engineering Equation Solver (EES, F-Chart software). The model predicted the theoretical maximum value of $\omega$ for an ejector operated under on-design conditions [21]. It is assumed that

- The isentropic efficiencies of ejector components in the theoretical model include 0.92 for the primary nozzle, 0.86 for the secondary nozzle, 0.95 for the mixing chamber, and 0.81 for the diffuser [15];
- The PF and SF entering the ejector are saturated vapor at $T_{HTE}$ and $T_{LTE}$, respectively; and
- The critical backpressure of the injector is the saturated vapor pressure of the mixed PF-SF (in a two-phase condition) at $T_{COND}$.

3. Working Fluids for Heat-driven Ejector HTHPs

The performance of an ejector is closely related to the ejector’s backpressure, which equals the saturated vapor pressure of the working fluid in the COND. For an ejector with a fixed geometry, its optimum performance could be achieved under on-design conditions, which require the backpressure to be no larger than the ejector’s critical backpressure. For the heat-driven ejector HTHPs in this study, high normal boiling points corresponding to low saturated vapor pressure at $T_{sink}$ were prioritized in selecting the working fluids. Additional considerations in selecting binary-fluid pairs included the following:

- The PF has a much larger molecular weight (MW) than the SF for a high entrainment ratio of BFEs;
- The SF has a much larger latent heat of evaporation for a high COP of HTHPs; and
- The PF and SF are immiscible and have significant different density for gravity-driven separation; or the PF and SF have a significant difference in normal boiling point (NBP) for thermal separation.

HFE7500 and R718 were selected as the working fluids, as described in Table 2. HFE7000 is a hydrofluorocarbons (HFE) with a relatively low GWP and zero ozone depletion potential. HFEs are nonflammable fluids with low toxicity, are chemically inert, and have high-temperature stability [24]. HFEs are considered to be third-generation refrigerants to replace chlorofluorocarbons, hydrochlorofluorocarbons, and hydrofluorocarbons [25].

R718 is a natural refrigerant that has been extensively used in ejector-based refrigeration systems. The challenges of using R718 in HTHPs are high compression ratio, large adiabatic coefficient, and low vapor density. Therefore, large-scale multi-stage compressors with intermediate cooling are required in conventional HTHPs. R718 is an ideal working fluid for ejector HTHPs because of the large latent heat of evaporation, high critical temperature, and relatively low vapor pressure at $T_{sink}$.

4. Performance of Heat-driven Ejector HTHPs

The investigated ejector HTHP was operated with $T_{sink} = 100°C–130°C$ and $\Delta T_{sink} = 10°C–30°C$. The temperature difference for heat transfer in the COND and the LTE was neglected. The inlet of the SF and the discharged PF-SF mixture for the ejector were saturated vapor at $T_{LTE}$ and $T_{COND}$, respectively. The inlet of the PF is saturated vapor at the operating temperature of $T_{HTE}$, which is a variable parameter in a range of 190°C–260°C. The maximum pressure of HTE, $P_{HTE,max}$, is 4.7 MPa for R718 and 1.5 MPa for HFE7500. The theoretical model of the ejector predicted the entrainment ratio, $\omega$, with the inlet and outlet conditions of the working fluids. The performance of the ejector HTHP was evaluated with a unit mass flow rate of PF (1 kg/s), which corresponds to an SF mass flow rate of $\omega$ kg/s.
4.1. BFEs and BFE HTHPs

The BFE operated with HFE7500 as the PF and R718 as the SF. Figure 3 shows the component-level performance of BFEs, ωBFE, and the system-level performance of BFE HTHPs, COPHP, under various THTE and ΔTlift. For a specified ΔTlift, ωBFE increased as THTE increased until ωBFE reached its maximum value, ωBFE,max; after that, further increasing THTE significantly reduced ωBFE. The existing optimum temperature of HTE, THTE,opt, for ωBFE,max was consistent with previous experimental and theoretical results of SFEs in heat-driven refrigeration systems [26] and ejector heat pump water heaters [20, 27]. THTE,opt is related to the critical points of the PF, Tcr, as the thermal physical property of the PF significantly deteriorates near its critical point. For HFE7500 with Tcr = 261.0°C, THTE,opt = 240°C. For a specified Tsink, ΔTlift had no obvious effects on THTE,opt because ΔTlift was only related to the inlet condition of the SF. The trends of COPHP vs. THTE and ΔTlift were similar to those of ωBFE, indicating that ωBFE dominated the performance of ejector HTHPs. For Tsink = 120°C, as ΔTlift increased from 10°C to 30°C, ωBFE,max decreased from 0.12 to 0.05, and COPHP,max decreased from 2.14 to 1.43.

Figure 4 shows ωBFE,max and COPHP,max vs. ΔTlift with various Tsink. Generally, higher ΔTlift and/or Tsink result in lower ωBFE,max and COPHP,max, and the influences of Tsink weaken at higher ΔTlift. The largest values of ωBFE,max and COPHP,max were 0.16 and 2.48, achieved at ΔTlift = 10°C and Tsink = 110°C. The smallest values of ωBFE,max and COPHP,max were 0.04 and 1.39, achieved at ΔTlift = 30°C and Tsink = 130°C. Regarding the thermo-compressor, the ejector increased the low pressure of the SF vapor (i.e., pSF at pSF) to moderate pressure (i.e., pmaxSF at Tsink). For a specified Tsink, a higher ΔTmax provided a lower vapor pressure of the SF entering the BFE. For a specified ΔTlift, a higher Tsink required a higher vapor pressure of the SF discharged from the BFE. Therefore, higher ΔTlift and/or Tsink consumed more power provided by the kinetic energy of the PF, resulting in lower energy efficiencies of BFEs and HTHPs.

![Figure 4](image4.png)

Fig. 4. The maximum performance of BFEs and BFE HTHPs. (a) Maximum entrainment ratio and (b) maximum COP.
4.2. SFEs and SFE HTHPs

The $T_{\text{HTE,opt}}$ for the maximum performance of SFEs and SFE HTHPs was 230°C for HFE7500 and 260°C for R718. Figures 5 and 6 show the performance of SFEs and SFE HTHPs operating with HFE7500 and R718, respectively. Similar to BFEs, higher $\Delta T_{\text{lift}}$ and/or $T_{\text{sink}}$ result in lower $\omega_{\text{SFE,max}}$ and $COP_{\text{HP,max}}$. However, the influences of $T_{\text{sink}}$ on $\omega_{\text{SFE,max}}$ and $COP_{\text{HP,max}}$ were less sensitive than those of BFEs, particularly for HFE7500 at higher $\Delta T_{\text{lift}}$, and for R718. SFEs with HFE7500 had higher $\omega_{\text{SFE,max}}$ than SFEs with R718 because of the much higher molecular weight of HFE7500 than R718 [28]. However, HFE7500 provided lower $COP_{\text{HP,max}}$ than R718. For HFE7500, the largest value of $\omega_{\text{SFE,max}}$ was 2.86, and the largest value of $COP_{\text{HP,max}}$ was 2.14, achieved at $\Delta T_{\text{lift}} = 10^\circ C$ and $T_{\text{sink}} = 130^\circ C$. For R718, the largest value of $\omega_{\text{SFE,max}}$ was 1.771, and the largest values of $COP_{\text{HP,max}}$ was 2.67, also achieved at $\Delta T_{\text{lift}} = 10^\circ C$ and $T_{\text{sink}} = 130^\circ C$.

![Fig. 6. The maximum performance of SFEs and SFE HTHPs with R718. (a) Maximum entrainment ratio and (b) maximum COP.](image2)

4.3. Comparison of BFEs and SFEs

Figure 7 compares the performance of ejectors and ejector HTHPs with single and binary fluids. Generally, $\omega_{\text{max}}$ of the BFEs was much lower than that of SFEs, but $COP_{\text{HP,max}}$ of BFE HTHPs was comparable to that of SFE HTHPs. For SFEs, HFE7500 has larger $\omega_{\text{SFE,max}}$ but smaller $COP_{\text{HP,max}}$ than R718. The discrepancy in $\omega_{\text{SFE,max}}$ and $COP_{\text{HP,max}}$ is due to the difference in changed specific enthalpy of the PF in the HTE, $\Delta h_{\text{PF}}$, and the SF in the LTE, $\Delta h_{\text{SF}}$. The binary fluids have a much larger $\Delta h_{\text{SF}}/\Delta h_{\text{PF}}$ but a much smaller $\omega_{\text{SFE,max}}$, as described in Table 3. According to Eq. (1), $COP_{\text{HP,max}}$ is linearly related to the product of $\omega_{\text{SFE,max}}$ and $\Delta h_{\text{SF}}/\Delta h_{\text{PF}}$. Therefore, BFE HTHPs and SFE HTHPs had comparable values of $COP_{\text{HP,max}}$. SFEs with R718 provided the best performance of HTHPs at a low $\Delta T_{\text{lift}}$, whereas BFEs with HFE7500/R718 only provided a slightly better performance of HTHPs at $\Delta T_{\text{lift}} > 25^\circ C$. This indicates that selecting HFE7500/R718 as a binary-fluid pair for BFE HTHPs cannot fully extract the technical potential of BFE HTHPs. Considering the system
simplification of ejector HTHPs, SFEs with R718 are recommended for heat-driven ejector HTHPs. In addition, operating a SFE HTHP with R718 in an open-loop system may improve $\omega_{\text{SFE,max}}$.

For SFE HTHPs with R718 operated at $T_{\text{sink}} = 120^\circ\text{C}$ and $\Delta T_{\text{lift}} = 10^\circ\text{C} - 30^\circ\text{C}$, Carnot efficiencies (i.e., the second law efficiencies) ranged from 6.7% to 10.4%, which are much lower than those of conventional HTHPs—typically 40%–60% from experimental measurements [29].

5. Conclusions

This study explored the technical potential of heat-driven ejector HTHPs. SFEs and BFEs were theoretically evaluated regarding the performance of ejector HTHPs. The entrainment ratios of ejectors were predicted with a geometry-free model. A thermodynamic model of an ejector HTHP was developed with mass and energy conservation equations. HFE7500 and R718 were selected as the working fluids for SFEs and BFEs. The performance of ejector HTHPs was investigated under the operation of $T_{\text{sink}} = 100^\circ\text{C} - 130^\circ\text{C}$ and $\Delta T_{\text{lift}} = 10^\circ\text{C} - 30^\circ\text{C}$. The conclusions from this primary study are as follows:

- SFEs had better component-level performance than BFEs in terms of the entrainment ratio, and BFEs had a much smaller entrainment ratio than SFEs.
- HTHPs with BFEs and SFEs had comparable heating cycle performance.
- The binary-fluid pair of HFE7500 and R718 cannot fully extract the technical potential of BFEs. An SFE with R718 could be a candidate for heat-driven ejector HTHPs.
- The Carnot efficiency of heat-driven ejector HTHPs was much lower than the state-of-the-art electric-driven HTHPs.

Future research will focus on

- Seeking binary-fluid pairs for BFEs to provide a large entrainment ratio and a large difference in the increased enthalpy in the HTE and LTE; and
- Identifying the deployment of steam ejector HTHPs in open-loop applications.

Abstract

With the proposal of the national "double carbon" strategic goal, air source heat pump (ASHP), as a high-efficiency and energy-saving product, will be more and more widely used. Frosting is one of the main factors to reduce the heating capacity of ASHP in winter. The main technical solution for the problem is delaying frosting and high efficient defrosting. The research of domestic and foreign scholars on restraining frosting technologies and defrosting methods for ASHP are summarized. The researches show that changing the inlet air parameters and the structure of evaporators can realize restraining frosting without or only consuming less energy; electric heating defrosting needs consuming additional electrical energy; for small scale refrigeration and heat pump equipment, reverse-cycle defrosting and hot gas by-pass defrosting are most commonly used; a new defrosting method with small energy loss, continuous heating and non-stop defrosting needs to be developed in the future.

Keywords: ASHP; restraining frosting; defrosting; heating performance;

1. Introduction

In recent years, with the implementation of the “coal-to-electricity” project in China, air source heat pump (ASHP) has been widely used in northern China. However, when the ASHP is running in winter, especially when the outdoor air humidity is high, when the outdoor temperature is lower than 0°C, Frost will grow on the fins of the evaporator. Frosting will not only increase the heat transfer resistance, but also increase the wind resistance, reduce the heat transfer efficiency and the performance of the unit, and even in case of severe frost, the unit will be shut down. Therefore, the frost layer on the fins of the outdoor heat exchanger must be removed periodically. Seeking a suitable defrosting method has been a hot topic of domestic and foreign scholars. This paper summarizes the research on frost suppression and defrosting technology of ASHP by domestic and foreign scholars. The existing problems of frost suppression and defrosting technology are analyzed. The defrosting technology of large and medium-sized ASHP has been prospected.

2. Study on restraining frosting for ASHP

The evaporator frosting is greatly affected by the surrounding environment. Air parameters, surface characteristics, cold surface temperature, and fin structure have significant effect on frosting process and frost layer characteristics [1]. At present, the main methods to inhibit frost growth are to reduce the relative humidity of air around the evaporator, increase air temperature and speed.

\textsuperscript{a} NIU Jianhui. Tel.: +86+313+418+7742; fax: +86+313+418+7742. E-mail address: zjknjh@163.com.
2.1. Reducing the relative humidity of the air

Xia et al. [2] found that after 50 min of heat exchanger operation, the frost deposition was 1.34 times higher at 80% RH than at 70%. The former evaporator heat exchange decreased by 23.1% and the latter by 17.2%. This indicates that the higher the inlet air humidity, the higher the thickness of frost formation, the greater the frost deposition, and the greater the impact on the evaporator performance. For the ASHP, using the solid or liquid desiccant is mainly used to reduce the air humidity around the evaporator. Wang et al. [3] proposed a novel frost-free heat pump water heater system incorporating an energy storage device and an auxiliary heat exchanger covered by a solid desiccant. Experimental results showed that the relative humidity increased from 75% to 85% at a temperature of 0 °C, and the average COP of the system decreased by 6.7%. A novel frost-free air source heat pump (ASHP) combined with membrane-based liquid desiccant dehumidification and humidification is proposed and investigated by Su et al. [4]. Results demonstrate that the COP_{ref} and the COP_{tot} of the novel system are at least 37.7% and 64.3% higher than that of the COP_{reverse} of conventional reverse-cycle defrosting ASHP system in the variation ranges of the analyzed parameters, respectively.

2.2. Raising the temperature of the air

Increasing the inlet air temperature of evaporator can restrain frost growth effectively. Chen [5] proposed of setting a plate collector at the inlet of the outdoor heat exchanger, using solar preheating inlet air can effectively improve the evaporative temperature, so as to improve the system coefficient of performance (COP). Liu et al. [6] pointed out that in order to ensure energy saving and improve the efficiency of heat pump, the wet air can be heated by heat recovery technology. Kwak et al. [7] set the electric heater at the outdoor heat exchanger air inlet and turned on the electric heater to increase the outdoor heat exchanger inlet air temperature when the outdoor environment reached the frost condition, and the experiment concluded that the heat supply increased by 38.0% and the COP increased by 57.0% compared with the conventional heat pump, and the heat supply could be continuous and stable throughout the defrost period.

2.3. Increasing the speed of inlet air

Increasing air velocity can suppress frosting. Gu et al. [8] studied to compare the evaporation temperature of coils at windward velocity of 3m/s and 1.2m/s and found that the decrease in wind speed led to a rapid decrease in evaporation temperature, which resulted in faster frosting of the coils. Guo et al. [9] studied the influence of wind speed on frost layer growth. The results showed that the frost layer growth rate of outdoor heat exchanger increased with the decrease in air speed. Sheng et al. [10] concluded that increasing the flow rate may delay the formation of the early frost layer. When some frost layers appear, increasing the flow rate will lead to an increase in the density of the frost layer and promote the frost formation process.

2.4. Changing the structure of evaporator

Domestic and foreign scholars mainly studied increasing the evaporator area, changing the structure and spacing of fins, and the number of tube rows along the airflow direction to restrain frosting on the evaporator surface. Huang et al. [11] used three outdoor units with different fins to compare the performance of ASHP, and found that flat fins had the best thermal properties. A defrost-free heat exchanger that has fin surfaces with fine irregularities was proposed by Yajima et al [12]. It could be confirmed that the heat pump, fitted with the defrost free heat exchanger where the fine irregularities were formed only on the fin-ends. The use of the defrost-free heat exchanger has made it possible to achieve a higher COP. Cheng et al. [13] simulated the air-side heat exchanger of air-source heat pump chiller and hot water unit with different fin spacing, tube diameter and tube spacing. The study shows that the fin spacing: 2 mm for light frost zone, 2.5 mm for general frost zone, and 3.5 mm for heavy frost zone is the optimal value; tube diameter 8 mm is better than 10 mm and 12 mm; tube spacing 27.4 mm is better than 25.4 mm.

2.5. Changing evaporator surface characteristics

Some scholars in China and abroad have studied the inhibition of frosting by surface treatment technology (hydrophobic coating or hydrophilic coating). He et al. [14] prepared a superhydrophobic aluminum-based fin
with a contact angle of 158.3°, and the experimental study results showed that the superhydrophobic surface exhibited good frost inhibition and rapid frost melting properties.

Shan [15] conducted a theoretical and simulation study on fins with a superhydrophobic composite coating of epoxy resin + 2 wt% graphene and found that the coated fins could provide frost suppression, shorten defrosting time, and improve heat transfer efficiency.

2.6. Changing the temperature of cold surfaces

The effect of cold surface temperature and air humidity on frosting is more obvious than air temperature, flow rate and heat exchanger structure [16]. Wang et al [17] found that when air temperature is 10.5°C, relative humidity is 80%, wind speed is 3m/s, cold surface temperature is -3.5°C~19.7°C, the temperature of cold surface has a significant influence on frosting rate, defrosting frequency and frosting height.

3. Study on defrosting technology for ASHP

Common defrosting methods include reverse cycle defrosting (RCD), hot-gas bypass defrosting (HGBD), and electric heating defrosting (EHD). In recent years, researchers have proposed a variety of new ASHP defrosting methods for reverse RCD and HGBD technology, and studied the defrosting effect, system performance and indoor comfort. In addition, in recent years, scholars have proposed energy storage defrosting (ESD), liquid defrosting (LD) and so on.

3.1. Study on Reverse Cycle Defrosting

3.1.1. Conventional reverse cycle defrosting

RCD is an effective defrosting method widely used at present. RCD is mainly used in small household air conditioning, heat pump and refrigeration equipment.

A large number of theoretical and experimental studies on RCD methods have been carried out in China and abroad. Song et al. [18] proposed that the distribution of chillers in the circuit has an effect on the reverse cycle defrost performance, and that the defrost efficiency of vertically installed multi-circuit heat pump units was improved by 7.4% compared to the uneven distribution of refrigerant in each circuit. Reverse cycle defrosting will cause the room temperature to decrease by about 2~5°C, and it will take about 10min for the system to return to normal heating state after defrosting [19].

It can be seen that the conventional RCD inevitably needs to absorb heat from the room. It causes a large fluctuation of indoor temperature and causes discomfort to human body. In addition, when the four-way valve is switched. In addition, when the four-way valve is switched, it has a great pressure impact on the compressor and pipeline.

Hu et al. [20] developed a novel reverse cycle hot gas defrost method for air source heat pumps. The experimental results suggested that the use of the novel reverse-cycle hot gas defrosting method for the experimental ASHP unit was able to help shorten the defrosting time by 3 min or 38%, and minimize the risk of shutting down the ASHP unit due to low suction pressure through increasing the compressor’s suction pressure by about 200 kPa, when compared to the use of the traditional standard reverse-cycle hot gas defrosting method.

3.1.2. Reverse cycle defrosting with new heat dissipation terminal

In order to reduce the influence of RCD on indoor thermal comfort and improve the heating performance of the heat pump system, some scholars proposed an ASHP system with radiation heat dissipation terminal [21-24].

Xu et al. [25] effectively coupled the condenser of the heat pump system with the radiation heat pipe. The refrigerant medium is filled inside as the heat dissipation medium. Experimental studies showed that the heating apparatus of heat pump-driven heat pipe has a fast start-up speed. After defrosting, the surface temperature of radiator recovered quickly and distributed evenly. Qu et al. [26] proposed a thermal storage based reverse cycle defrost method, stating that the optimal defrost strategy is to keep the low-level cycle compressor frequency at 90 Hz and the high-level cycle expansion valve opening at 80%. This method can reduce the energy consumption of air source heat pump defrosting. The principle is shown in Fig.1.
3.2. Study on hot-gas bypass defrosting

3.2.1. Conventional hot-gas bypass defrosting

The HGBD is to set a bypass pipeline between the compressor discharge pipe and the evaporator inlet pipe. When defrosting, the solenoid valve on the bypass pipeline is opened, and the compressor discharge vapor was directly discharged into the frosting evaporator.

Lai et al. [27] concluded that the most influential factors of bypass defrost efficiency are the bypass volume, the point of entry into the defrost, and the defrost frequency, and the optimal time entry point for defrost can be determined by the frost inflection point. Xi et al. [28] proposed a new intelligent control strategy based on the maximum heating capacity of the hot gas bypass defrost system and designed a suitable defrost start-stop point. The results showed that the heating capacity of the hot gas bypass defrost was increased by 10.17 % and the overall energy efficiency was improved by 4.06 %. Huang et al. [29] pointed out that the time of HGBD is 2.89 times of RCD. The superheat in suction of compressor is always around 0 ℃ during defrosting. The discharge temperature and superheat of the compressor continuously reduce, and the safe operation of the compressor is threatened. For heat pumps and water heaters with trans critical CO₂, the power consumption of RCD is lower than that of HGBD, and the average heating COP is higher [30-32].

3.2.2. Hot-gas bypass defrosting with continuous heating

In view of the problem that the system heating is insufficient or even stopping heating during defrosting, some scholars upgraded the defrosting method of hot-gas bypass with double/multiple circuits hot-gas bypass defrosting to achieve continuous heating.

Si et al. [33] proposed a double-loop bypass defrosting technology, in which the indoor unit keeps continuous heating operation under experimental conditions, and as the outdoor temperature decreases, the amount of frosting decreases, the heating operation time is extended, and the proportion of heating time in the whole defrosting/heating cycle keeps increasing. Liu et al. [34] proposed an ASHP system with continuous heating in defrosting. The system has at least two outdoor heat exchangers, one is defrosting, the other one continues to absorb heat from the outdoor air. Part of the heat is used for heating and the other is used for defrosting the outdoor heat exchanger to achieve defrosting while continuing to heat. The system principle is shown in Fig.2 and it is still part of the discharge defrosting of the bypass compressor.
Fu et al. [35] proposed a new grouping throttle defrosting method based on the HGBD method. The principle is shown in Fig. 3. The outdoor heat exchanger is divided into two rows, the parallel capillary and solenoid valve are connected in the middle. In defrosting the front and rear heat exchange tubes are used as condenser and evaporator respectively, and the four-way valve is used to defrost them respectively. Under the working condition of outdoor temperature of 2℃ and relative humidity of 80%, the defrosting time of reverse cycle is about 440s, and the defrosting time of this system is about 430s, which is slightly shorter than the defrosting time of reverse cycle method.

3.3. Study on electric heating defrosting

EHD usually installs an electric heater in the evaporator shell, or installs a heater element on the evaporator fin to defrost. Wang et al. [36] proposed an air-source heat pump system with auxiliary heating from an external heat source, with an additional electric heater between the expansion valve and the condenser. The principle is shown in Fig. 4. The system can extend the operating time of the air-source heat pump for heating under low temperature and high humidity conditions and achieve continuous heating during defrost, but the COP under each condition will be reduced, resulting in increased power consumption.
3.4. Study on energy storage defrosting

The ESD method can fundamentally solve the problem of energy shortage of the traditional defrosting method [41], and improve the running stability of the ASHP to a certain extent. Liu et al. [42] designed a phase change heat storage exchanger through an air source heat pump defrost system with compressor housing heat storage combined with hot gas bypass circulation, and the experimental results showed that the defrosting time and energy consumption were reduced by 10s (9%) and 12.1kJ (21.7%), respectively, compared to reverse cycle defrosting. Zhao et al. [43] used paraffin wax as the heat storage medium and adopted the idea of "waste heat storage and waste heat defrost" to achieve the "frost-free effect", and the system suction and discharge pressure and compression ratio changed smoothly compared with RCD. Chen et al. [44] used the heat storage module with electric heating layer matrix structure to realize VRV system defrosting with heating without shutdown. Zhu et al. [45] proposed a new air source heat pump thermal storage heating system using peak and valley electricity and variable flow operation to achieve economical operation. Through simulation calculation and analysis, the results showed that the operating cost of the system in the heating season can be reduced by more than 50% compared with the annual cost of central heating. Zhao et al. [46] proposed an energy storage air source heat pump system for rapid heating and defrosting, as shown in Fig. 5. Tests were conducted under experimental conditions, and the results showed that the defrosting time of the new system was 68% shorter and the defrosting energy consumption was 51.4% less than that of the conventional system.
3.5. Study on liquid defrosting

The LD was first used in the cold storage refrigeration system [47]. This system includes two parallel evaporators. Through valve switching, the subcooling liquid after refrigerant defrosting can be evaporated and cooled in another evaporator. Although the system can realize defrosting without stopping cold storage refrigeration, defrosting will also lead to temperature rising for the cold storage.

Niu et al. [48] proposed a heat pump system with multi-outdoor units in parallel defrosting in turn, which principle is shown in Fig. 6, and carried out detailed theoretical and experimental research. The results showed that the system performance achieve best when 4 outdoor units are used for defrosting, and the heating capacity of the system can still reach 60% of that without frost. This method can achieve defrosting with heating at the same time, but for the multiple evaporators, the distribution of refrigerant flow becomes a key factor affecting the operation stability of the system during defrosting.

![Fig. 6. Principle of sub-cooling defrosting with multi-outdoor units [48].](image)

3.6. Other defrosting methods

Lin et al. [49] put forward hot water defrosting. The defrosting device that can produce hot water is placed on the condenser of the outdoor unit. Through this device, the defrosting is carried out, and the systematic frosting and heating of the air conditioning are carried out at the same time. The defrosting device is an independent additional system with high reliability.

A new defrosting strategy through injecting medium-pressure vapor refrigerant into compressor during defrosting process was proposed by Wei et al. [50]. For the ASHP in the experiment, with the injected electronic expansion valve opening less than 50%, the experimental unit can run safely and defrosting performance improve gradually with the opening increase.

Cai [51] found through simulation studies that the morphology of the frost layer changed significantly after the electric field intensity was applied to the environment, and the individual areas of frost aggregation gradually showed elongated morphological changes, and the frost layer was significantly suppressed.

Tan et al. [52] found through experiments that ultrasonic waves can remove the frost in a certain area of the evaporator surface, and the energy consumption is less than 50% of the energy consumption of the reverse defrost, and the defrosting efficiency is 7~29 times higher than the reverse defrost.

4. Conclusions

In view of the problem of frosting/defrosting in the ASHP system, the research on restraining frosting and defrosting technology is analyzed and reviewed, the conclusions are as follows:

1) Changing air parameters, evaporator structure and surface conditions can play an important role in restraining frosting. However, it can only delay frosting to a certain extent, once the evaporator getting frosting, a certain defrosting method must be used to remove the frost layer.

2) Reverse cycle defrosting and hot-gas bypass defrosting are the most common methods. At present, the research is more focused on the combination of new heat dissipation terminals to improve indoor comfort for reverse cycle defrosting. Based on hot-gas bypass defrosting, multiple evaporators are used to realize non-
stopping heating operation. Due to part of discharge vapor of the compressor is used for defrosting, the system heating capacity decreases and the heating performance deteriorates.

3) Electric heating defrosting is widely used in refrigerators at the cost of extra electric energy. Energy storage defrosting is in the experimental and simulation stage, and has not been applied widely yet. The application of the liquid defrosting method in the defrosting of the evaporator of the cold storage will lead to a temperature increase in the cold chamber. Four outdoor units are used in the ASHP to obtain the optimal defrosting performance.

4) Restraining Frost Formation has attracted much attention due to no energy consumption or low energy consumption. If frost can be restrained or delayed from the source, it will further promote the development of ASHP. At present, the commonly used defrosting methods are mainly used for small-sized ASHP. For large or medium-sized ASHP, due to the excessive thermal inertia of the system, the heat loss of cold and hot fluid mixing cannot be ignored. In the future, it is necessary to develop a defrosting method with small energy loss, continuous heating and uninterrupted defrosting.

Impact Analysis of Transitioning to Heat Pump Rooftop Units for the U.S. Commercial Building Stock

Chris CaraDonna†, Andrew Parker, and Ryan Meyer
National Renewable Energy Laboratory, Golden, Colorado, United States

Abstract

Twenty percent (25%) of the energy consumed by the U.S. commercial building sector is from on-site combustion of fossil fuels for space heating. Part of decarbonizing U.S. energy systems to meet climate initiatives will require electrification of space heating equipment, often by transitioning to heat pumps. Rooftop units (RTU) are the most prominent commercial building HVAC system type and should therefore be prioritized for electrification solutions. However, there is limited understanding of the impact on emissions when considering regional electricity generation methods, as well as the impact of ambient temperature on capacity and efficiency, defrost operation, realistic sizing methodologies, and supplementary heating on overall heat pump performance. This study explores the effects of transitioning all installed, existing RTUs to high-performance heat pump RTUs for the U.S. commercial building stock. The analysis is performed using ComStock™, the U.S. Department of Energy’s calibrated model of the U.S. commercial building stock. Results show 10% and 9% reductions in stock aggregate energy consumption and greenhouse gas emissions, respectively. This analysis will help inform the transition to heat pump RTUs for the U.S. commercial building stock.

1. Introduction

1.1. Decarbonizing the U.S. commercial building stock

Several simultaneous market transformations must occur to decarbonize the U.S. energy systems. These include renewable power supply and storage options, widespread adoption of energy efficiency and electric demand flexibility, as well as ending the burning of on-site fossil fuels such as natural gas, propane, fuel oil and others. Buildings burn fossil fuels on-site primarily for space heating, water heating, equipment loads and cooking. The combined on-site natural gas combustion of the residential and commercial sectors is estimated to contribute to 9% of all U.S. carbon dioxide (CO2) emissions annually [1].

Natural gas is the primary space heating and water heating fuel source for half of all commercial buildings in the U.S. by number, representing almost 70% of commercial building floor space, with more than half of the natural gas consumed for space heating [2]. In addition to natural gas, almost 10% of commercial buildings report using fuel oils and propane for primary space heating purposes [2]. This leaves only 25% of all commercial buildings currently relying on electricity as their only source for space heating needs [2].

† christopher.caradonna@nrel.gov
1.2. Heat pump rooftop units as a decarbonization pathway

Many technologies are used to provide space heating in commercial building HVAC systems. Packaged rooftop units (RTUs) are currently used to heat 37% of commercial buildings in the U.S. (representing 50% of the total commercial floor space) [2]. Heat pumps currently provide space heating for only approximately 11% of commercial buildings (representing 15% of the total floor area) [2].

Heat pumps offer a high-performance electric option for commercial building space heating. Their use of electricity for heating enables pathways toward decarbonization with heat pumps delivering space heating 2-4 times more efficiently than electric resistance options. Based on the 2018 Commercial Buildings Energy Consumption Survey (CBECS) data, it is estimated that fewer than 15% of commercial buildings utilize heat pumps for space heating equipment, and when they are in use they are more commonly found in the warmer southern region of the U.S. [2].

Heat pump technologies are available on the market today to replace existing gas-fired or electric resistance RTU systems. Most manufacturers offer heat pump rooftop units (HP-RTU) with compressors capable of providing 105 kW or less of cooling capacity (30 tons). There is remarkable opportunity for growth and widespread adoption of this technology, and expansion of the field will have an extensive impact on electrification efforts.

1.3. ComStock energy modeling

ComStock™ is a physics-based model of the U.S. commercial building stock built from an ensemble of 350,000 OpenStudio® whole-building energy models using the EnergyPlus® simulation engine. As used in this analysis, ComStock represents 66% of the U.S. commercial building stock by floor area. Unlike analyses that use a small number of “typical” building energy models to represent the stock, ComStock includes a diverse range of building and HVAC system configurations, construction vintages, hours of operation, etc. The relative prevalence of these building characteristics is informed by a wide range of data sources, including commonly used datasets such as CBECS [3], proprietary data sources such as CoStar [4], and difficult-to-acquire data sources such as whole-building hourly electricity consumption data from a large sample of buildings. The diversity of building characteristics helps create more robust conclusions because the models reflect the diversity found in reality. ComStock has gone through extensive calibration and validation, particularly on the electricity consumption side, as documented in detail in [5].

For this paper, two of the most important ComStock inputs are the prevalence of HVAC system types and heating fuels. Both model inputs are derived from the CBECS 2012 microdata, in particular the HVAC-related questions [3]. Rather than assuming a uniform distribution of the prevalence of natural gas or electric heating across each census division, data from the residential American Communities Survey (ACS) [6] was used to supplement the CBECS data. The CBECS totals for each census division were maintained, while counties with more residential natural gas heating according to ACS were scaled to have a higher percentage of the commercial natural gas heating, and vice-versa. For a more detailed description of the ComStock model, including the data sources and assumptions referred to above, see the “ComStock Documentation” National Renewable Energy Laboratory (NREL) report expected to be published in March 2023.

2. Methodology

2.1. Analyzing measures with ComStock

ComStock uses a representative set of 350,000 unique OpenStudio energy models to represent the energy usage and behavior of the U.S. commercial building stock [7]. ComStock’s bottom-up engineering model approach is especially well-suited for studying the impact of proposed changes to the existing building stock [8], [9]. For this workflow, the baseline set of ComStock OpenStudio models is modified to represent the proposed change to be studied. For example, if increasing the efficiency of cooling equipment in all commercial buildings by 10% was proposed, then the baseline (representing the building stock circa ~2018) set of OpenStudio energy models would be modified to have 10% higher cooling efficiency. The results of this modified run can then be compared back to the original ComStock baseline results to understand the various changes that occurred due to the modification.

In this study, the ComStock baseline is modified to represent replacing all RTUs in the existing building stock, either gas-fired or electric resistance, with high-performance HP-RTUs. This change affects HVAC equipment serving ~45% of the floor area in the ComStock baseline; the floor area representation of all HVAC
system types in ComStock is shown in Fig. 1 [7]. High-performance HP-RTUs are defined to include the following features:

- Single-zone variable air volume (VAV) fan operation
- High-efficiency variable-speed compressor(s) for heating and cooling (>17 IEER)
- High-efficiency variable-speed fans
- Cold climate suitable with low temperature capabilities (minimum compressor operating temperature ≤ -17.8°C) and compressor defrost operation

![Fig 1. ComStock HVAC system type prevalence by stock floor area.](image)

Note that PSZ-AC stands for packaged single-zone air conditioner, PTHP stands for packaged terminal heat pump, PVAV stands for packaged variable air volume, DOAS stands for dedicated outdoor air unit, and PFP stands for parallel fan-power.

2.2. Baseline building stock RTU modeling

The state of the existing RTUs in ComStock is based on a combination of when the buildings were built and how the equipment has been updated over time, described in detail in the “ComStock Documentation” NREL report expected to be published in March 2023. Equipment performance is assumed to meet the energy code requirements in force at the time and place of installation. For this reason, most of the existing RTUs are modeled as constant air volume with single speed compressors. This is influential to the results in this analysis since energy savings will be calculated based on the energy performance of the ComStock baseline models versus an updated version of the ComStock baseline that uses the proposed HP-RTUs.

The in force energy code for the ComStock baseline is shown as a percentage of applicable floor area in Fig 2. Applicable floor area for this analysis includes ComStock buildings with "PSZ-AC with gas coil" and "PSZ-AC with electric coil" HVAC system types. Most ComStock baseline RTUs follow energy code requirements from the early 2000s. Other energy efficiency features such as demand control ventilation, energy recovery, and economizer control are only applied to baseline ComStock RTUs if required by the in force energy code for the particular model. The ComStock workflow checks the necessary characteristics of each RTU to determine if the feature is required. Similarly, heating, cooling, and fan efficiencies are set based on the in force code year. For models with the "PSZ-AC with electric coil" HVAC system type, the ComStock baseline will use electric resistance coils with a coefficient of performance (COP) of 1. For models with the "PSZ-AC with gas coil" HVAC system type, the ComStock baseline will use a gas furnace efficiency of generally around 80%.
2.3. Heat pump RTU modeling

The HP-RTUs are modeled using the EnergyPlus “AirloopHVAC:UnitarySystem” object [10], [11]. An OpenStudio measure is used in conjunction with the ComStock workflow to modify/remove any applicable RTUs in the ComStock baseline models (“PSZ-AC with gas coil” and “PSZ-AC with electric coil” in Fig. 1) and articulate the appropriate HP-RTU objects and settings. Non-applicable systems are not affected, nor are core operational parameters of systems such as schedules, thermostat setpoints, unoccupied operation behavior, and design outdoor airflow rates. Furthermore, energy-saving features found in applicable baseline RTUs such as airside heat/energy recovery, economizers, or demand control ventilation are preserved as-is for the new HP-RTU systems. This provides even comparability, noting that these features are feasible and available in HP-RTU systems. The modeling details of the HP-RTU system are described further in the following subsections.

2.3.1. Single-zone VAV operation

The modeled HP-RTUs utilize a single-zone VAV operation, which varies the supply airflow and discharge air temperature to efficiently maintain zone thermostat setpoints. During heating operation, as loads increase, first the supply air temperature is gradually raised until it hits a maximum threshold, and then supply airflow is increased until loads are met. During cooling operation, as loads increase, supply air temperature is gradually lowered until it meets a minimum threshold, and the supply airflow is increased until loads are met (Fig. 3) [12]. This is generally expected to provide fan energy savings during periods of reduced loads. The minimum supply airflow ratio modeled is 40%, which is common for single-zone RTUs [13]. The exception to the 40% minimum is when higher outdoor airflow rates are required to maintain ASHRAE Standard-62.1 minimum outdoor airflow rates: in these cases, the minimum flow rate to satisfy design outdoor air ventilation rates are modeled [14].
2.3.2. Cooling performance

The variable-speed direct expansion (DX) cooling system in the proposed HP-RTUs is modeled using the EnergyPlus “Coil:Cooling:DXMultiSpeed” object using four speeds of cooling [10], [11]. The highest speed (speed 4) represents the cooling performance at rated conditions with the compressor fully loaded. The efficiency values used for this study are based on a 10-ton variable-speed RTU with a full-load COP of 3.6 at rated conditions with Integrated Energy Efficiency Ratio (IEER) above 17 [15]. Because the EnergyPlus COP input is compressor-only, and therefore removes supply fan energy, the modeling input is adjusted to 4.11 COP using the methodology from the Pacific Northwest National Laboratory’s (PNNL’s) Daikin Rebel study [15].

The other speed levels (speeds 1 through 3) represent lower compressor speeds, which would occur when the required load to be met is less than the full capacity of the unit. Each speed corresponds to a fraction of the rated capacity, a rated COP, and a rated airflow. Lower compressor speeds generally show higher COP values, which allows for higher efficiencies during these periods of partial loading. For instance, a PNNL lab testing and modeling study showed 20-50% annual cooling energy savings for variable speed RTUs over conventional RTU cooling systems [15]. The capacity fractions and COPs for the different compressor speeds were determined using NREL lab testing data for three variable-speed central ducted AC systems. Because the testing is based on residential central AC units rather than commercial RTUs, the values derived from the testing are normalized to the rated COP of 4.11 to better represent a commercially available HP-RTU for this study (Table 1) [15]. Variable speed HP-RTUs are capable of modulating to the specified fractions, but they may not do so in the same manner as the residential units the performance parameters are based on [13].

Five performance curve modifiers are used for modeling the DX multispeed cooling objects. The performance curves were derived from separate work that used NREL lab testing data of three variable speed central ducted AC systems where values representative of the three systems are used. For multispeed objects, these modifier curves are specific to the compressor speed to which they are applied, so each speed will have its own set of curves. They are described as follows.
1. **Energy input ratio (EIR) as a function of part load ratio** – uses the calculated part load ratio to determine an EIR modifier from compressor cycling, which is multiplied against the full-load EIR for the stage (Fig. 4). Note that EIR is the inverse of COP, so decreasing the EIR increases the realized efficiency. For the multispeed units modeled in this work, this curve is only used for the lowest compressor speed where cycling losses may occur.

2. **Capacity as a function of temperature** – uses outdoor drybulb and indoor wetbulb temperatures to predict a capacity modifying factor that is multiplied against the rated capacity for each stage (Fig. 5). For heat pumps, the available capacity decreases with temperature.

3. **EIR as a function of temperature** – uses outdoor and indoor drybulb temperatures to determine an EIR (1/COP) modifying factor that is multiplied against the rated EIR for each stage for the time step (Fig. 6). Note that other modifier functions can also affect the final COP.

4. **Capacity as a function of flow** – modifies capacity based on the determined flow rate for a time step. This curve is not used since capacity is already accounted for in the speed level.

5. **EIR as a function of flow** – modifies EIR based on the determined flow rate for a time step. This curve is not used since the EIR is already accounted for in the speed level.

The cooling performance maps for EIR as a function of part load ratio, COP as a function of temperature, and capacity as a function of temperature are shown Fig. 4, Fig. 5, and Fig. 6, respectively.

![Fig. 4](image.png) **Fig. 4.** Heating and cooling energy input ratio modifier as a function of part load ratio for all speed levels. This curve primarily captures losses due to part-load cycling at compressor speed 1. This value is divided by the EIR for the time step, which effectively decreases efficiency at lower part load ratios.
2.3.3. Heat pump heating performance

The variable speed heat pump heating in the proposed HP-RTUs is modeled using the EnergyPlus “Coil:Heating:DXMultiSpeed” object using four speeds of heating [10], [11]. This object performs similarly to the “Coil:Cooling:DXMultiSpeed” object described previously. The rated efficiency values used for this
study are based on a 10-ton variable-speed RTU with a full-load COP of 3.42 at rated conditions (8.3°C outdoor air temperature entering the condenser and 21.1°C drybulb indoor air temperature entering the coil) [15]. Because the EnergyPlus COP input is compressor-only, and therefore removes supply fan energy, the model input is adjusted to 3.8 COP, using the methodology from PNNL’s study [15]. The parameters for each stage of heating are shown in Table 2. The capacity and COP fractions for each speed level were determined using manufacturer-provided data for a variable-speed central ducted forced air heat pump system (Table 2). The data is roughly 10 years old but is expected to be a reasonable representation of a variable speed system. The heating COP increases with lower speed levels similarly to what was described for the cooling COPs. Because the testing is based on residential central HP units rather than commercial RTUs, the values derived from the testing are normalized to the rated COP of 3.8 to better represent a commercially available HP-RTU for this study (Table 1) [15]. Variable speed HP-RTUs are capable of modulating to the specified fractions, but they may not do so in the same manner as the residential units the performance parameters are based on which emphasizes the need for additional research in this area [13]. The minimum operating temperature for the heat pumps is modeled at -17.8°C, which is the default setting for some manufacturers. The compressor will lock out below this temperature and only backup heat will be available.

Comparisons of modeled performance data versus alternative data sources were made, where possible, for validation that the performance data used is reasonable. Table 3 and Table 4 compare some key points on the modeled heat pump performance maps for COP and capacity retention as a function of outdoor air temperature, respectively, with other available data sources for validation. The first data source is for the variable speed Daikin Rebel HP-RTU, with specification sheet data specifying capacity and COP at 8.3°C (rated) and -8.3°C [11]. The second source is a Rheem two-stage HP-RTU with heating performance data at various outdoor air temperatures [16]. The last data source is from a study that performed lab testing on a Carrier cold climate variable speed HP-RTU, which provides COP values at various outdoor air temperatures [17].

The modeled HP-RTU outperforms the capacity retention of the reference units by 5 to 9%, with the largest difference occurring with the Rheem unit at -17.8°C (Table 3). For COP retention, the modeled HP-RTU outperforms the reference units by 3% to 14%, with the largest difference occurring with the Rheem unit at -17.8°C (Table 4). Although there are some notable differences between the modeled and reference unit performance, and the modeled HP-RTU outperforms the reference units in all cases, these comparisons still suggest the modeled HP-RTU performance is reasonably appropriate compared to other available data.

Similar to the DX multispeed cooling objects, five performance curve modifier types are used for modeling the DX multispeed heating objects. The descriptions of these are discussed in the cooling performance section of this document, with the only difference being that the heating coils use indoor air drybulb temperature as opposed to indoor air wetbulb temperature used for the cooling coils. The performance curves were derived from manufacturer-provided data for a central ducted variable speed heat pump system. The resulting performance maps for all speed levels are shown in Fig. 4, Fig. 7 and Fig. 8 for EIR as a function of part load ratio, COP, and capacity retention, respectively. As expected with heat pumps, heating COP and capacity generally reduce with outdoor air drybulb temperature.

Heat pump performance maps are especially impactful due to the general reduction of capacity and efficiency at lower outdoor air temperatures where increased heating loads often occur. This study attempts to utilize the best available data, as described previously, as this will notably impact the results. However, it should be emphasized that complete heat pump performance data is still scarce and available at the time of this study, especially for variable speed commercial RTUs and low temperature operation. This adds limitations to the understanding of heat pump performance and operation in this analysis. Further research on heat pump performance could increase confidence in heat pump modeling, and this study may be updated as more data becomes available.

Comparisons of modeled performance data versus alternative data sources were made, where possible, for validation that the performance data used is reasonable. Table 3 and Table 4 compare some key points on the modeled heat pump performance maps for COP and capacity retention as a function of outdoor air temperature, respectively, with other available data sources for validation. The first data source is for the variable speed Daikin Rebel HP-RTU, with specification sheet data specifying capacity and COP at 8.3°C (rated) and -8.3°C [11]. The second source is a Rheem two-stage HP-RTU with heating performance data at various outdoor air temperatures [16]. The last data source is from a study that performed lab testing on a Carrier cold climate variable speed HP-RTU, which provides COP values at various outdoor air temperatures [17].

The modeled HP-RTU outperforms the capacity retention of the reference units by 5 to 9%, with the largest difference occurring with the Rheem unit at -17.8°C (Table 3). For COP retention, the modeled HP-RTU outperforms the reference units by 3% to 14%, with the largest difference occurring with the Rheem unit at -17.8°C (Table 4). Although there are some notable differences between the modeled and reference unit performance, and the modeled HP-RTU outperforms the reference units in all cases, these comparisons still suggest the modeled HP-RTU performance is reasonably appropriate compared to other available data,
especially considering they are different units from different data sources. Note that no alternative data sources were found for comparing part-load performance or the impacts of cycling on variable speed heat pump units, further emphasizing the need for more research in this space to increase modeling confidence.

Fig. 7: COP as a function of temperature performance map for the four stages of heating. Note that these COP values are for the compressor only – adding in supply fan energy would decrease the values presented.

Fig. 8. Capacity as a function of temperature performance map for the four stages of heating. This value is multiplied by the nominal capacity for each time step to determine the actual available capacity for the time step.

2.3.4. Heat pump sizing & backup heating

The sizing of heat pumps is non-trivial since the same system is used for both heating and cooling. Heat pumps in colder climates usually require a source of supplemental heat, which today is often sized to meet the entirety of the heating load. This is because heat pump capacity is reduced as outdoor ambient temperatures decrease, which generally corresponds to the highest heating loads for the building. Furthermore, compressor lockout controls are often implemented in heat pump systems, which disable heat pump operation below a certain temperature [13]. This would require the supplemental heat source to be sized to meet loads below this temperature. Because the supplemental heat source in colder climates is then often sized to meet the design heating load, the system can then be sized based on the required cooling capacity with the assumption that the supplemental heat source will address any heating load beyond the corresponding capacity of the heat pump, avoiding the need to purchase a larger capacity unit. Supplemental heat is less of a concern in warmer climates where the design cooling load exceeds the design heating load, even when accounting for heat pump capacity degradation at lower temperatures, and where the design heating temperature is well above any minimum compressor lockout temperature.

The supplemental heat source is often electric resistance, which has an effective site COP of 1, while the heat pump system will often demonstrate a site COP much higher than this even at temperatures down to -17.8°C. Sizing heat pump systems to address more of the heating load is sometimes suggested since the heat pump heating is more efficient than electric resistance, so long as the sizing of heat pump system still enables effective operation for both heating and cooling [18], [19]. However, this analysis simply sizes the heat pump based on cooling load, and reserves studying the impact of other sizing approaches for future analyses. The
minimum outdoor air temperature for heat pump operation is modeled as -17.8°C, which aligns with the default minimum temperature for some manufacturers, noting that this default value can change between manufacturers and can be overridden, which would impact performance [13].

### 2.3.5. Defrost operation

Frost formation can occur on the outdoor unit during heat pump heating operation due to humidity in the outdoor air condensing and freezing on the cold outdoor coil. Frost needs to be periodically removed so the coil can function properly. This is generally done using either an electric resistance coil or by reversing the operating of the heat pump to remove the frost buildup, both of which result in additional energy consumption. This analysis uses reverse cycle as it is common in practice and does not require additional heating coils.

Reverse cycle defrost inhibits the heating capacity of the heat pump system which may require the use of lower-efficiency supplemental heating during these times. Additionally, reversing the cycle of the heat pump causes additional heating load in the RTU since the system is essentially in cooling mode, which EnergyPlus adds to the total effective heating load [10], [11].

Control of the defrost cycle can also vary. Some units use a set time fraction, where the unit operates in defrost mode for a specified time when outdoor air temperatures are below a specified temperature. This analysis uses EnergyPlus’ “on-demand” defrost operation, which estimates the amount of time needed for defrost based on a set of empirical calculations dependent on outdoor air wetbulb temperature, coil temperature, and other parameters; these calculations are described in detail in the EnergyPlus Documentation [10], [11].

### 2.3.6. Greenhouse gas emissions

Greenhouse gas (GHG) emissions savings are estimated in this work using similar methods to those presented in [9]. For direct fuel combustion, the impact of GHG emissions was estimated using emissions factors published by the ANSI/RESNET/ICCC: natural gas = 63.27 kg/GJ (147.3 lb/MMBtu), propane = 76.4 kg/GJ (177.8 lb/MMBtu), and fuel oil = (84.15 kg/GJ) 195.9 lb/MMBtu [20], [21].

Estimating GHG emission impacts due to electricity consumption is more complicated. It requires projecting the resource composition of the electric grid as a result of load increase, which may be substantial when electrifying commercial building HVAC equipment as is done in this study. This is important since the prevalence of cleaner grid resources will directly impact the GHG emissions per kWh of electricity used. Furthermore, the resources producing electricity on the electric grid vary based on location and time of day, which can impact GHG estimates if not accounted for properly [22], [23].

The choice of grid emissions scenario will impact emissions factors and therefore analysis results [24]. This analysis uses NREL’s Cambium dataset. The Cambium dataset provides emissions factors that vary based on time of day and U.S. grid region to capture geospatial and temporal variation in converting consumed kWh to GHG emissions [22], [23]. The Cambium dataset includes various grid scenarios to choose from: this analysis uses Cambium long-run marginal emissions rate “low renewable energy cost 15-year” scenario data [22], [23]. The timeseries grid emissions factors in this dataset are coupled with ComStock timeseries electricity consumption outputs for each model based on time of day and the location-based Cambium grid region to estimate the GHG emissions impacts of transitioning to HP-RTUs. The published emissions values represented a single year of emissions, which are calculated using a weighted average year over the levelization period.

### 2.3.7. Heat pump annual performance

For this analysis, annual effective heating COP is calculated for the ComStock simulations to understand the performance of the heat pump heating system, as shown in Equation 1.

\[
\text{COP}_{\text{effective}} = \frac{q_{hp} + q_{supp}}{E_{hp} + E_{supp} + E_{defrost}}
\]

- \( q_{hp} \) = annual heating output energy from heat pump
- \( q_{supp} \) = annual heating output from supplemental heating coil
- \( E_{hp} \) = annual heat pump heating electricity input
- \( E_{supp} \) = annual supplemental heating electricity input
\[ E_{\text{defrost}} = \text{annual reverse cycle defrost electricity input} \]

The effective annual COP calculation in Equation 1 includes performance and capacity degradation with temperature, heat pump sizing limitations, and heat pump defrost cycles and the associated supplemental heating coil operation. This calculation does not include supply fan energy, which is commonly included in product specification sheet values for rated COP values. It is also important to note that natural gas furnaces and boilers are often rated on thermal efficiency and exclude the delivery system (fans or pumps). Including supply fan energy in the COP calculation could lower the values presented in this study by 20–40%.

3. Results and Discussions

3.1. Annual energy and GHG savings

Ten percent (10%) total annual site energy savings (130 TWh) can be achieved for the modeled U.S. commercial buildings, including savings of 8% for electricity, 17% for natural gas, and 50% for other fuels (fuel oil and propane). Savings numbers reflect the 66% of the U.S. commercial building stock currently modeled in ComStock at the time of this analysis. The total site energy savings for just the 45% of buildings with RTUs is 21% (Fig. 9b). The site energy savings for electricity are primarily from fan energy savings from the single-zone VAV operation with high-efficiency fans and cooling savings from high-efficiency variable-speed compressor operation. Notably, these fan and cooling energy savings could also be achieved with high-performance non-heat-pump RTUs. The median fan and cooling energy savings are approximately 35% and 40%, respectively, which align with the results from a lab testing and modeling study performed by PNNL on variable-speed RTUs [15]. There are also substantial electricity savings in the heating end use from converting electric resistance RTUs (“PSZ-AC with electric coil”) in the baseline to HP-RTUs which have higher heating COPs. The electricity savings presented in this study would be reduced, possibly causing a net electricity penalty, if replacement of baseline electric resistance RTUs was omitted from the analysis.

![Fig. 9. Aggregate annual site energy consumption by fuel type for (a) the total U.S. commercial building stock modeled by ComStock and (b) the U.S. commercial building stock applicable to the HP-RTU scenario.](image)

The site energy savings from the combustion fuels (natural gas and other) can be attributed to transitioning the baseline gas-fired RTUs to electric heat pump heating. Switching from a gas heated system to an electric heated system will add electricity consumption to the building, although some of the increase in electricity may be offset by fan and cooling savings. HP-RTU replacement alone may not completely electrify applicable buildings if combustion fuels are still used for water heating, appliances, and non-RTU HVAC systems.

Nine percent (9%) total annual GHG emissions savings (32.4 MMT) can be achieved for the modeled U.S. commercial buildings by replacing all existing RTUs with HP-RTUs (Fig 10a). This represents 6.6% GHG emissions reduction for electricity consumed by these buildings, 16.6% GHG emissions reduction for natural gas, 66.7% for fuel oil, and 50% for propane. Similar to the site energy savings projections, these savings numbers reflect the 66% of the U.S. commercial building stock currently modeled in ComStock at the time of this analysis. The reductions in GHG emissions are primarily caused by net reduced energy consumption across all fuel types (Fig. 9). However, emissions for electricity are also impacted by temporal and geospatial variation in grid emissions factors informed by the Cambium dataset. Electricity consumption may be shifted to times
with higher or lower grid emissions factors based on the predicted grid resources for that time. As previously mentioned, this study chose a single Cambium scenario for grid emissions factors. The choice of scenario impacts emissions results [24]. Electrification will become more attractive from a GHG emissions standpoint as the grid continues to generate more electricity from lower GHG sources, effectively lowering grid emissions factors. Geospatial variation in emissions factors between grid regions will impact the GHG reductions from electrification in the particular region [22], [23].

The baseline ComStock model currently underestimates natural gas consumption by around 30% for the modeled buildings, as shown in Figure 193 of the technical report on calibration of ComStock [5]. The source of this error is unknown but may be attributable to some combination of underestimation of heating load, overestimation of primary combustion equipment efficiencies, or misrepresentation of inefficiencies in controlling or maintaining HVAC systems. Because the baseline natural gas consumption is used as a starting point for comparison, the savings potential for HP-RTUs may be higher than the results shown described above.

3.2. Heat pump annual performance

Simulation results show variation by state in average annual effective heating COP of the HP-RTUs, with lower values around 2 COP and the highest values above 5 COP (Fig. 11). This annual average heating COP includes performance and capacity degradation, heat pump sizing limitations, and heat pump defrost operation and associated supplemental heating coil operation, but does not include supply fan energy which would lower the COP. Note that some of these higher COPs are attributed to operating the HP-RTUs at lower compressor speeds during part-load conditions (Table 2; Fig. 7), which is possible with the variable speed units modeled in this study. These average COPs would likely be reduced with constant speed HP-RTUs that cycle the full compressor capacity to meet loads.

States with warmer climates generally show higher heating COPs for HP-RTUs than states with colder climates (Fig. 11). This behavior is expected since heat pumps have better performance in warmer conditions. Additionally, in warmer climates the design heating load is generally closer to or below the design cooling load. Since this study sizes heat pumps based on the cooling load, the heat pump heating capacity in warmer climates will naturally meet a larger portion of the design heating load compared to cooler climates, leading to higher annual average heating COP values. However, the heating energy use intensity (annual energy used for heating divided by floor area) in colder states can be more than 10 times higher than in the heating intensity in warmer climates, which stresses the importance of cold climate performance (Fig. 12).

State average percentage of total heating electricity used by the supplementary system ranges from 6% to 56% (Fig. 13). This is due to the reduced capacity of heat pumps under cold ambient conditions, as well as the fact that the heat pumps are generally being sized to a smaller fraction of the design heating load (when sized to design cooling load, as is done in this study). States with higher fraction of supplementary heating generally correspond to lower COPs as expected (Fig. 11 & Fig. 13). Note that supplementary heating can also be induced by reverse-cycle defrost operation which temporarily disables heat pump from heating.

Fig 10, Aggregate GHG emissions by fuel type for (a) the total U.S. commercial building stock and (b) the U.S. commercial building stock applicable to the HP-RTU scenario.
Fig. 11. Stock annual average effective heating COP by state. Effective heating COP is the total heating energy output divided by total heating energy input. Heating energy output includes heating from the heat pump and supplemental heating. Heating energy input includes heat pump compressor and outdoor fans, supplemental heating, and defrost. The heating energy input does not include associated supply fan energy use. Including supply fan energy use would reduce COPs.

Fig. 12. ComStock baseline stock annual average heating energy use intensity (EUI; kWh/m²/year) by state.
Fig. 13. Stock annual average percent heating electricity input used for supplement heating by state. Note that supplemental heating occurs due to insufficient heating capacity of the heat pump which can be further exacerbated from defrost operation.

Most states have multiple climate zones represented and therefore state average values do not tell the whole story. Fig. 14 shows the distribution of annual heating COPs for two different states. The average for South Carolina is 4.2, but the distribution extends from a COP of 3.1 up to 5.7, while the distribution for Michigan is more closely distributed to its average heating COP of 3.2. One question is why the range of annual heating COPs is so large in a single climate zone. A full analysis and discussion of the reasons for this range is outside the scope of this paper, but generally includes sizing considerations, particularly for buildings with either very unbalanced heating and cooling capacity requirements, heating energy consumption, or both. In some cases, climate can vary substantially within it state which could also cause wider COP distributions.

Fig. 14. Distribution of annual effective heating COPs for models in South Carolina (SC) and Michigan (MI)
4. Conclusion

Transcending the existing RTUs (gas fired and electric resistance) in the U.S. commercial stock to high-performance HP-RTUs is a promising pathway toward electrification and reducing GHG emissions. Comstock energy modeling results show 10% total site energy savings (130 TWh) for the modeled building stock from this transition, noting that ComStock currently models 66% of the building stock at this time. GHG emissions also showed savings totaling around 9% (32.4 MMT CO2) for the modeled building stock, noting that this analysis uses a single reference scenario from the Cambium dataset for grid emissions factors, the choice of which can impact these estimates. GHG and site energy and savings are achieved by transitioning from gas furnace and electric resistance heating to high-efficiency heat pump heating, and from fan and cooling savings by converting the older, less efficient RTUs currently in the U.S. commercial stock to high-performance variable speed RTUs. Note that the fan and cooling savings could also be achieved with high-performance non-heat-pump RTUs. GHG savings would be expected to increase from electrification pathways as the U.S. electric grid becomes less carbon intensive, therefore reducing the carbon contribution per kWh of electricity.

This analysis also presents average annual heating system COPs by state from the ComStock simulations, which demonstrates the effective COP that can be expected when factoring in impactful heat pump considerations such as supplementary heat, defrost cycles, realistic/economical sizing practices, and efficiency/capacity degradation at lower temperatures. ComStock modeling results suggest annual effective heating COP averages vary considerably by state, with a low of 2.1 and a high of 5.6, and even within a state. As expected, states with warmer climates generally show higher COPs, noting that states in colder climates generally require substantially more energy for heating, which increases the importance of cold climate performance.

Future research could analyze the impact of transitioning existing RTUs to HP-RTUs on electric peak demand, as well as the impact of adding air side energy recovery or utilizing different fuel sources for supplemental heat. Furthermore, although this study attempts to utilize the best available heat pump performance data and makes comparisons to alternative data sources where possible, limitations exist due to the small amount of performance data available for commercial variable speed HP-RTUs. Heat pump energy modeling can be sensitive to performance assumptions such as the variation in COP and available capacity under different operating conditions, which can impact analysis results. Future research could expand this body of knowledge through additional lab testing and field evaluation of HP-RTUs to increase confidence in heat pump modeling, which this work could be updated to include.

Abstract

One of the greatest challenges in US electrification efforts to reduce carbon emissions is to utilize electric heat pumps for space and water heating rather than fossil fuels. Although the number of heat pumps for space conditioning is growing, they still represent only 35\% of sales and only 12\% of installed base. While it has been over forty years since one of the first heat pump water heaters was introduced, they only account for 2\% of sales and less than 1\% of the installed base.

Several barriers exist that impede the widespread adoption of heat pump technology for space and water heating in the US, especially for retrofit applications. This paper will examine the various barriers and identify potential solutions and strategies to address those barriers, including various research activities related to equipment, and potential cost reduction strategies, both for the product and installation. Also included will be a discussion of programs and incentives by utilities and efficiency organizations.

1. Introduction

The United States (US) has set an ambitious goal to reduce greenhouse gas (GHG) emissions by at least 50\% by 2030. Achieving this goal would put the United States on a path to limit global warming to 1.5 degrees Celsius, the target scientists say is required to avoid the worst consequences of the climate crisis.

A recent study by a team of scientists and policy analysts from across the nation indicates there are multiple pathways to achieve this goal. However, commitments to the actions need to be made as soon as possible. The study consolidates findings from six recently published techno-economic models that simulate U.S. energy system operations. According to the authors, the separate models all agree on four major points:

- The majority of the country’s greenhouse gas emissions come from power generation and transportation, so to reduce overall emissions by 50\%, the electricity grid needs to run on 80\% clean energy (up from today’s 40\%), and the majority of vehicles sold by 2030 need to be electric. Other important sources of GHG emissions reduction include electrification of buildings and industries.
- The primary barrier to increased alternative energy use will not be cost, it will be enacting new policies. A coordinated policy response between states and the federal government will be necessary to succeed.
• Thanks to advances in wind, solar, and energy storage technologies, powering the electric grid with renewables will not be more expensive; and electric vehicles could save every household up to $1,000 per year in net benefits.

• A clean-energy transition would reduce air pollution, prevent up to 200,000 premature deaths, and avoid up to $800 billion in environmental and health costs through 2050. Many of the health benefits will occur in communities of color and frontline communities that are disproportionately exposed to vehicle, power plant, and industrial pollution. [1]

The US Department of Energy (DOE) is one of the primary US government agencies involved with ensuring America’s security and prosperity by addressing its energy, environmental and nuclear challenges through transformative science and technology solutions.

DOE’s analysis of greenhouse gas pollution reductions from the clean energy provisions of the Inflation Reduction Act and Bipartisan Infrastructure Law finds that the combined impact of both laws could reduce emissions by approximately 1,000 million metric tons (MMT) in 2030, with a total of nearly 1,150 MMT when considering other provisions of each law. The expected emissions reduction from these measures is equivalent to the approximate combined annual emissions released from every home in the U.S. [2]

“The Inflation Reduction Act (IRA) is a triumph of historic scope and ambition that will enable a whopping 40% reduction in greenhouse gas emissions below 2005 levels. Combined with President Biden’s Bipartisan Infrastructure Law and the CHIPS and Science Act, these investments will transform our economy and bring us closer to achieving our nation’s climate goal,” said U.S. Secretary of Energy Jennifer M. Granholm. “These historic legislative accomplishments are delivering on the President’s promise to build a new American clean energy economy that creates millions of good jobs while lowering energy bills for families and combating the climate crisis.” [2]

In support of the IRA, the Building Technologies Office in DOE’s Office of Energy Efficiency and Renewable Energy develops, demonstrates, and accelerates the adoption of cost-effective technologies, techniques, tools and services that enable high-performing, energy-efficient and demand-flexible residential and commercial buildings in both the new & existing buildings markets, in support of an equitable transition to a decarbonized energy system by 2050, starting with a decarbonized power sector by 2035.

2. Carbon Dioxide Emissions

As shown in Figure 1, the transportation sector has the highest percentage CO₂ emissions (37%), followed closely by the combined emissions (35%) from the buildings sector [3]. Electricity used to power equipment in the residential and commercial sector comprises the largest source of CO₂ emissions (67%), followed by natural gas (26%).

Fig. 1. U.S. CO₂ Emissions from Energy Consumption by Source and Sector.
One of the strategies to address decarbonization in the buildings sector is to increase the use of renewables to replace existing fossil-fueled power plants and address future growth. An additional strategy is to replace natural gas equipment, such as furnaces and water heaters, with heat pumps. As shown in Figure 2, space heating with natural gas is the largest contributor to direct emissions in both residential and commercial buildings [4]. Natural gas water heating is the next largest contributor in residential buildings. Together, space and water heating with natural gas account for over 90% of the direct emissions in the residential buildings and approximately 60% in commercial buildings.

Fig. 2. U.S. CO\textsubscript{2} Emissions from Energy Consumption by End Use.

The number of heat pumps in the US for space conditioning is growing (Figure 3) [5]. Since 2000, sales have increased 20%. However, they still represent only 35% of sales and 12% of the installed base. The highest saturation is in the south, accounting for 24% of the installed base (Figure 4) [6].

Fig. 3. US Heat Pump Annual Sales.
Heat pump water heaters are the future of water heating, with local jurisdictions promoting all-electric buildings and a new national effort to accelerate market transformation. Numerous reputable water heating manufacturers have released their own models, and by 2017-2018, HPWH shipments totalled about 70,000 on average (Figure 5) with an estimated market penetration of almost 2% [7]. Factors driving the future growth of the heat pump water heater market include their efficiency relative to electric resistance coupled with the ability to use renewable sources of energy to power the unit, which requires three to four times less energy. In addition, supportive regulations and incentives are also expected to play a key role in the growth of this market [8].

4. Barriers to Heating Electrification

As shown in Figure 6, all states are not equal in the amount of carbon emissions [9]. The main contributors, highlighted in green, are some of the most populous states, such as California, Texas, and Florida. However, population alone doesn’t impact carbon emissions. Other factors, such as the fuel used for building equipment (natural gas, electricity, fuel oil), the energy source for power generation (natural gas, nuclear, hydropower, coal), and the climate all influence the amount of carbon released from buildings to the atmosphere.
To significantly reduce carbon emissions in the buildings sector, the US must concentrate on addressing some of the main barriers to electrification of building equipment in the ten states, many of which are also problematic in the other states. Following are the major barriers encountered when consumers consider replacing their fossil-fired equipment with an electric heat pump.

4.1 Heat pump barriers

Several barriers exist that inhibit greater numbers of heat pumps being installed in the US. Among these are installed cost, operational cost, space constraints, panel upgrades required when replacing natural gas equipment, installer familiarity, shortage of trained installers, product availability, and consumer acceptance. These barriers can be generally grouped by 1) cost; 2) installation challenges; 3) consumer issues; 4) workforce issues; and 5) capacity. Most of these barriers apply to both retrofit and new installations in residential and commercial markets. However, there are some differences which are unique to the building type, especially for multifamily housing, which will be highlighted in section 4.1.6.

4.1.1 Cost

Installation costs are one of the main barriers to increasing the number of heat pumps, especially in northeastern regions where the present equipment is a natural gas or oil-fired furnace. In the Northeast, natural gas fuels 55% of homes; this is broken down by 75% of New Jersey homes, 61% of New York's, and 51% of Pennsylvania's [10]. In Figure 7, installation costs were estimated in New York for an air-source heat pump compared to a gas furnace with an air-conditioning (3-ton unit) [11]. Estimated costs were based on an average from Long Island, New York City, and the Hudson Valley/Upstate/Western New York region databases and vetted through stakeholder conversations. The average shows the cost difference between an air-source heat pump versus a furnace/electric air-conditioner is $4584, an increase of 55% over the cost for the furnace/electric air-conditioner.

</tbody>
</table>

Fig. 7. Installation Cost Estimates for New York.
One of the main drivers for the higher installed cost is that heat pumps in colder climates require larger units to provide sufficient heating at lower temperatures (capacity drops at lower temperatures) and variable-speed compressors and fans to reduce capacity in the summer to prevent frequent cycling that would otherwise result from oversizing the units for winter operation.

Another factor is that in some areas where contractors are unfamiliar with heat pumps, they charge a premium to install a heat pump system versus a natural gas or oil furnace since they will need to spend more time properly designing the system. In addition, they may be concerned about call backs if the customer is unhappy with their new system due to cooler temperatures leaving the register. This would result in less profit for the installer due to the increased cost for labor and vehicle charges (gas and maintenance) to address the issue with the consumer.

In addition to installation costs, operating costs must also be considered to evaluate the overall life-cycle cost for an electric heat pump versus a natural gas/electric air-conditioner. The American Council for an Energy Efficient Economy investigated the life-cycle costs in all regions of the US [12]. The results, shown in Figure 8, indicate that, in general, heat pumps have lower life-cycle costs in states with lower rates for electricity versus natural gas (Southern, Pacific Northwest) and higher life-cycle costs in states with higher rates for electricity versus natural gas (Northeast and Midwest). The higher installed costs in those regions are also a large factor in the differences.

![Fig. 8. Life-Cycle Cost Estimates for Various Equipment Types.](image)

**4.1.2 Installation challenges**

According to new research from residential electricity research group Pecan Street, electric panels in up to 48 million U.S. single-family homes will need to be upgraded to fully transition away from fossil fuels and use electricity for space and water heating, and other applications. Most older homes have a 100-amp breaker panel and heat pumps require a circuit breaker up to 60 amps. With an average cost of $2,000 for an upgraded panel, that represents a nearly $100 billion impediment to residential electrification [13]. This can be problematic when replacing a natural gas furnace to a heat pump in some states, especially California, where natural gas is the most popular residential heating fuel type. Some 64 percent of occupied housing units in the state rely on natural gas for heating in 2020 [14].

**4.1.3 Consumer issues**

The majority of consumers don’t evaluate the total cost of ownership when purchasing a heat pump. They gravitate towards the lowest cost product which is usually minimum standard efficiency. However, it was shown in section 4.1.1 that a higher cost product, such as the cold climate heat pump, can save enough money in energy costs over its lifetime such that the life-cycle costs that are lower than a 97% AFUE furnace in St. Louis.
Consumers are also reactive, meaning they don’t plan replacements of heating and cooling equipment ahead of time, but only replace in emergency situations (failure). In addition, they typically replace like for like, e.g., a natural gas furnace is replaced with another natural gas furnace.

4.1.4 Work force issues

Contractors are a key stakeholder in electrification retrofits because they are the main point of contact for home and building owners. In many parts of the US, there are simply not enough contractors trained to properly install heat pumps, particularly in retrofit situations. At the same time, many trained contractors are retiring and not enough people are entering the contractor workforce to replace them. This gap can severely limit the number of electrification retrofits in each area [15].

Contractors may also be hesitant to learn about new equipment because they have limited resources for training and they may worry that there is not enough market demand to justify retraining and changing their business model.

4.1.5 Capacity

Heat pump capacity drops as the outdoor temperature gets colder. The capacity for single-speed heat pumps at low outdoor temperatures can be roughly half of what it is at the rated condition. One remedy for this is to equip heat pumps with electric resistance heaters to maintain the set-point temperature in the house. However, this increases the operating cost since electric resistance heaters only have an efficiency of 1 versus heat pump efficiencies as high as 4. Another remedy is to use variable-speed motors to increase the capacity at low temperatures by increasing the speed (moving more refrigerant through the system) to better match the house load. Unfortunately, variable-speed designs tend to be more expensive than single-speed. Thus, trade-offs must be made when deciding on which heat pump design is most cost-effective.

4.1.6 Multifamily applications

Multi-family housing is a large portion of the U.S. housing stock, with 26% of total housing units located in multifamily buildings [15]. Space constraints are one of the major barriers to heating electrification in multifamily housing since many apartments and condo buildings do not have sufficient space for heat pumps, especially the associated ductwork necessary to distribute conditioned air evenly throughout the space. The locations where electric heat pumps are installed may result in noise complaints, particularly if located in common spaces, balconies or other locations that could disrupt tenants.

Multifamily buildings can also face market barriers with respect to renter occupied units, which comprise the majority (86%) of multifamily units. The large number of renters in multifamily buildings leads to the issue of split incentives which refers to building owners being unwilling to invest energy upgrades for tenants who pay for their own utility costs. Because the value of energy efficiency upgrades benefits the tenant, property owners see little to no return which creates a motivational barrier to the installation of heat pumps [15].

4.2 Heat pump water heater barriers

Barriers for heat pump water heaters are similar to those for heat pumps, such as cost, installation challenges, consumer issues, and capacity. For heat pump water heaters, there are a few barriers that are unique or more pronounced, such as space constraints, location of the unit, and availability of units. As in the case with heat pumps, most of these barriers apply to both retrofit and new installations in residential and commercial markets. However, there are some differences, which will be highlighted in section 4.2.6.

4.2.1 Cost

Installation costs for heat pump water heaters can be approximately $1000 higher when replacing an existing natural gas water heater with a heat pump water heater. This is a 65% increase and for homeowners that base their decisions on first cost, it is difficult hurdle to overcome [16]. Replacing an existing electric resistance water heater with a heat pump water heater may seem to be an easier upsell, especially with paybacks
of around 3 years for a family of four [17]. However, the first cost difference is even higher than that for a gas water heater scenario (approximately $1300) [16].

4.2.2 Installation challenges

Heat pump water heaters face the same electrical panel upgrade challenge as heat pumps when replacing an existing gas unit. Although the breaker required is only 30 amps versus 60 amps for a heat pump, this still can be a difficult hurdle to overcome, especially if there is no wiring in the vicinity of the gas water heater to provide power to the unit. The additional labor and materials for wiring and condensate piping further increase the cost by approximately $500 [16]. This issue can be extremely problematic for states like California where 90% of water heating is supplied by natural gas [18].

4.2.2.1 Space constraints

In residential applications where the water heater is located in a closet, the installation space requirements for heat pump water heaters are much different than for the existing water heater (electric resistance or natural gas) they will replace. The National Building Code requirements for a gas water heater are: 1) it should have a minimal 1-inch clearance between it and any combustible material, such as wall framing or wall finish; 2) it must have a self-closing gasketed door that prevents carbon monoxide or other products of combustion from entering the home; and 3) fresh air needed for combustion must be drawn from outside the home using double wall metal pipe [19]. On the other hand, electric water heaters don’t require even a minimal clearance space. This is because, unlike their gas-powered counterparts, they don’t release exhaust. The main difference when locating a heat pump water heater in a closet is that it has to have adequate ventilation from the indoor space. In order to run efficiently, heat pump water heaters need 700 to 800 cubic feet of available space (air in the room) to operate properly, which requires louvered doors when this space is not available [20].

4.2.2.2 Location

Another issue regarding the installation space concerns the ambient temperature at which the heat pump water heater must operate. Since it is a heat pump, the efficiency and capacity get worse as the surrounding air temperature gets colder. Therefore, for a northern climate, locating the heat pump water heater in a garage or attic will severely degrade its performance during the winter.

4.2.3 Consumer issues

Heat pump water heaters are an unfamiliar technology to most consumers. When it comes to replacing their water heater, consumers typically replace in kind because of their familiarity with what has been working for them. One complaint from consumers is that heat pump water heaters are perceived as being noisy. Although they make about as much noise as a refrigerator, consumers are not used to hearing a noise from their electric resistance water heater [18]. Also, for consumers replacing a fossil-fired water heater, they may expect a heat pump water heater to be less noisy than their existing unit.

Because heat pump water heaters transfer heat from ambient air, they do not work well, or sometimes at all, in colder temperatures. For this reason, it may be difficult to utilize a heat pump water heater in certain regions due to a loss in capacity [21]. If hot water recovery is limited to the heat pump alone, it will take a lot longer to reheat the tank after a long draw. Electric resistance heat can hasten the recovery, but at the price of eliminating much of the savings [22].

4.2.4 Capacity

Heat pump water heaters take a relatively long time to heat a volume of water to the pre-set temperature, approximately 3 to 4 hours when running in compressor-only mode for a 40-gallon tank. For comparison, an electric resistance water heater takes 40 to 60 minutes and a natural gas water heater takes 30 to 45 minutes. In order to keep up with the hot water demand, particularly at peak times, most heat pump water heaters are equipped with electric heating elements which would enable them to match the recovery performance of an electric resistance water heater. When properly installed, a heat pump water heater rarely needs to revert to its less efficient backup mode where the heating elements are energized [23]. One strategy for reducing the
amount of time a heat pump water heater avoids turning on the back-up electric resistance heaters is to install a larger tank, 50- to 80-gallon versus a traditional 40 gallon.

4.2.5 Product availability

Another main drawback to heat pump water heaters is the availability of residential products both in big box stores and stocked by plumbers. Plumbers install 43% of all residential water heaters. Homeowners (26%) and retailers (17%) account for another 43% of installations (Figure 9) [24]. Typically, water heaters are an emergency installation following a catastrophic tank failure. Thus, product availability is critical. The majority of plumbers and retailers don’t routinely stock heat pump water heaters, thus the only type of water heater available is a standard natural gas or electric resistance version. The reason availability is limited is due to the market demand. Since heat pump water heaters represent 2% of all water heaters sold, there is no incentive for retailers and plumbers to stock them.

4.2.6 Multifamily and large commercial applications

For multifamily housing, two options are commonly used: 1) a central domestic hot water system with one or more commercial storage water heaters or one or more boilers coupled with a storage tank to serve the entire building, or 2) alternatively, water heaters are installed in each dwelling unit (similar to single-family). The availability of large heat pump water heater models for central systems is limited compared to residential products. This is especially true for applications that require higher temperatures, such as boiler applications and in large buildings where recirculation losses would require electric resistance boosters. For applications where a single heater services each unit, tankless and low boy water heaters are more popular due to their ability to be located in small spaces. However, this becomes an impediment for replacing with a heat pump water heater since they necessitate more space due to their size and ventilation requirements.

5.1 Incentives

Financial incentives, whether provided through utility programs or by state agencies, can spur market development. Incentives directly to consumers for heat pumps for space and water heating can aid in mitigating
barriers associated with upfront cost. Incentives to distributors and retailers (rather than through customer rebates) can also be tied to the sale of high-efficiency electric equipment. Incentives can also encourage distributors and plumbers to keep heat pump water heaters in stock for use in emergency replacement situations.

Beginning in 2023 and through the end of 2032, all homeowners will be eligible for a 30% federal tax credit on the total cost of buying and installing their new heat pump, with a maximum credit of $2,000. For heat pumps installed in 2022, there is currently a smaller tax credit of 10% of the cost up to $500 or a specific amount from $50-$300 [25].

The High-Efficiency Electric Home Rebate Act, part of the Inflation Reduction Act, can also help offset the cost of purchasing a heat pump, depending on your income. Homeowners could be eligible for up to $1,750 for a heat-pump water heater and $8,000 for a heat pump if household income is less than 150% of their state’s median income. If household income is less than 80% of their state’s median household income, then homeowners qualify for the full rebate; meaning if both the heat pump and heat pump water heater are purchased, the homeowner could get $9,750 back. If income is between 80 to 150% of their state’s median income, the homeowner would be eligible for 50% of the rebate, and they could receive up to $4,875 back [25].

One potential drawback to incentives is that once they are removed, the market may return to pre-incentive levels. The aftereffects could be that manufacturers would have to absorb the excess inventory as a result of scale-up during periods of higher demand and contractors may have to lay off workers. A better approach would be to create demand for high efficiency space and water heating equipment that is sustainable without the need for incentives.

5.2 Installation challenges

In an older home or a home with a natural gas for heating and water heating, installing a heat pump or heat pump water heater might require a panel upgrade. Several water heater manufacturers are responding to this issue by introducing 120v heat pump water heaters in the market. Presently, at least four manufacturers have brought products to the market that operate on 120v electrical power and others will soon follow. The 120v heat pump water heaters are available in both shared circuit and dedicated circuit models [26]. Field tests are ongoing in California that will provide useful information on the performance of 120v water heaters.

Tall, slim, natural gas water heaters typically found in manufactured homes where space is limited. The market for these units is limited. However, there is a project underway by a national laboratory to develop a 120v heat pump water heater with equivalent first hour rating that can be replace water heaters of this type.

More demonstrations of multi-split heat pump water heaters (i.e., one outdoor unit tied to multiple indoor storage tanks) are needed to prove the technology and facilitate their use to displace electric resistance and fossil-fired water heaters for medium-sized commercial and multi-family buildings. Replacing low-boy water heaters in multi-family buildings is a prime candidate for a demonstration of this type.

5.3 Consumer education

Lack of awareness is one of the key barriers to adoption of this clean energy technology. Programs to raise awareness and educate on a heat pump technology’s availability, financial, health, safety, and comfort benefits would help consumers to make informed decisions when it comes time to replace their existing space conditioning or water heating equipment.

The National Resources Defense Council details three successful program designs used by Efficiency Vermont, Association for Energy Affordability in California, and Efficiency Maine [27]. To summarize, the features of currently-successful programs are:

• A midstream/upstream design with incentives that bring costs into parity or better
• Customer education through mass market and targeted outreach
• Strong engagement of supply chain participants
• Trade ally networks that provide a range of benefits to contractor and distributors
• Positive referrals by word of mouth
• Planned and emergency replacements can be installed within one day if panel upgrade isn’t required

5.4 Reduce costs

Beyond incentives, several ways to reduce installation/product/operating costs for heat pumps and heat pump water heaters have been proposed. Among these are modular designs that enable homeowners to install the units, reducing installation costs with better tools for right-sizing and smart diagnostic tools to reduce installation time, increasing the efficiency of to reduce operating costs, and reducing the manufacturing cost.

Developing modular designs that enable homeowners to install the units themselves is a novel idea that has merit. Recently, two companies were awarded contracts to develop a window unit heat pump for multifamily housing that operates in cold climates, only requires 120v electrical power, and can be installed by the consumer [28]. One of the main benefits of modular designs is that they are portable and can be taken with the consumer when moving to another location. This is especially beneficial for tenants that live in apartments. It also helps to solve the split incentive issue by shifting the responsibility for the cost of the unit to the tenant rather than the building owner.

Improved tools for sizing heat pumps help to avoid over-sizing which could result in a smaller, lower cost unit being specified. Smart diagnostic tools, comprised of wirelessly connected digital measuring probes, enable real-time fault detection and diagnostics during installation and can reduce costs by reducing the time it takes to verify units are correctly installed.

Increasing the efficiency of the units to reduce operating costs seems to be a reasonable idea. However, this usually comes at a higher unit cost which is then passed down through the value chain, resulting in multiplying the difference in the manufacturer’s cost of the unit by three times. The higher unit cost needs to be evaluated to determine if the reduction in operating cost over the life of the product justifies the higher cost.

Reducing manufacturing cost is challenging. However, research is presently being funded by the DOE to reduce costs through lower cost, more compact heat exchangers and compressors. More compact heat exchangers also have the added benefit of reducing the refrigerant charge to enable the possible use of lower GWP refrigerants that are flammable.

5.5 Work force development

Work force training on how to build and maintain equipment for low-carbon buildings is a promising candidate for public-private partnerships. Such training aligns the interests of the public (emissions reduction and safe and comfortable buildings), the building trades (quality installations with high customer satisfaction), and equipment suppliers (having their products installed correctly in homes and businesses).

While consumer awareness is important to drive demand, it is equally necessary to train installers to be able to support and fulfil the demand. There is a focus within the Advanced Water Heating Initiative to develop training and tools to support both contractors and designers. Several hours of training material and videos have been developed and more are planned to support the central systems [29].

Abstract

As industrial heat production is responsible for about 20% of total GHG emissions in Europe, shifting to sustainable sources is inevitable in achieving Paris Agreement goals. This paper focuses on two decarbonisation technologies for industrial process heat supply for multiple locations a) Electricity-driven high-temperature heat pumps powered with photovoltaic (HTHP+PV), as an advanced efficient technology in generating steam, and b) parabolic trough collectors (PTC), which produces heat economically with minimal carbon footprint. The aim of this paper is to evaluate the levelized cost of heat (LCOH) of these technologies to fulfil a comparative techno-economic analysis. A maximum PTC collector's solar fraction limit (SF\textsubscript{limit}) is defined to indicate when the LCOH for these two technologies is equal. The evaluation is carried out through the annual energy yield using TRNSYS and MATLAB. The result shows that the design of a PTC system with optimal SF can reach cost parity with hybrid system of HTHP and PV for the locations with medium to high direct normal irradiation locations.

1. Introduction

"Heat is half" of the global primary energy consumption [1]. The generation of heat from various fuel sources results in nearly 40% of the global CO2 emissions. Decarbonizing the heating supply is the "elephant in the room" and needs significant attention from policymakers to promote the right technological solution to facilitate the rapid replacement of gas, coal, and other fossil fuels.

Heat is consumed in buildings for space heating, domestic hot water, and industries to generate steam or hot water. The major focus regarding technical solutions for clean heating is often on electrification using electrical heaters or heat pumps (HPs). Residential heating demand can be decarbonized using commercial HPs, and their significance is further emphasized in Repower EU, which aims to deploy 60 million HPs by 2030, a projected 4-fold increase from current numbers [2].

It is important to note that industrial process heating demand constitutes 66% of the EU's overall heating demand [3]. In addition, the concepts of positive energy district (PED) and climate-neutral city are promising nowadays, but they have not yet included industrial heating demand within their boundaries. With the ongoing challenges in gas supply, natural gas prices have increased exponentially in the past few years, thus creating an energy-tense situation in the EU [4]. This implies that a less price-volatile and reliable supply of fuels for industrial process heat should be prioritized. The process heat required in most industries is in the medium temperature range (i.e., 80 to 250 °C). Several technologies in the market can achieve this temperature with low carbon emissions, such as solar thermal (ST) collectors, high-temperature heat pumps (HTHP), and boilers utilizing green fuels such as waste biomass or biogas, or renewable electricity.
Industries typically use fossil fuel boilers to generate steam, which is used as a heat transfer fluid to carry out several processes. Retrofitting any new technology in an existing boiler system requires a detailed understanding of system boundary conditions. Economic feasibility is a crucial decisive criterion for industries to evaluate any technology. From market experience, it is realized that large multinationals can facilitate the capital expenditure (CAPEX) for an efficiency improvement process (such as the implementation of ST, HTHP) only if the payback is less than 5 years.

An indicative pre-feasibility assessment using economic key performance indicators (KPIs) can facilitate industries toward quick decision-making for a go/no-go decision concerning a detailed evaluation of any technology. Therefore, this paper is themed around doing a comparative techno-economic analysis for heat generation using typical boundary conditions encountered in industries. The focus is on two technologies to generate steam, i.e., (a) steam-generating HTHPs and (b) Parabolic trough collector (PTC), which is a type of concentrating ST collector. The sections provide a literature review and the current development status of using these technologies for industrial applications.

1.1. Hybridization of solar thermal with heat pumps

Terrestrial irradiation has daily and seasonal variations. For a typical solar PV system, the grid acts as a large battery that balances the production and demand with minimal waste of electricity. However, the solar heating systems are often retrofitted with individual/stand-alone boilers to continue the operation for non-sunny hours.

As most industries have constant heating demand throughout the day (and year). ST System design with a low SF allows the solar production to always be less than the user's heat demand, thus increasing the system's utilization. Therefore, SHIP systems are typically designed with low solar fraction and backup systems. However, if an ST is designed without thermal storage, the fraction of the overall heat demand met with solar collectors be limited.

To achieve high solar fraction, steam storage is often a limiting component restricting the cost feasibility of the system. Due to its very low density, steam storage is not economical. It is usually stored as sensible heat in solid media or liquid using oil or pressurized hot water. It is observed that for a given constant load profile, the economic feasibility of the solar thermal installation decreases after a threshold solar fraction due to the need for high thermal storage capacity. As the specific heat cost of a pressurized thermal storage is higher than that of a solar thermal collector, thus large tank volumes in the system result in a relatively high cost of heating. This situation puts a financial limit on the maximum solar fraction achievable.

As industries are looking for nearly 100% renewable heating systems, solar thermal has the opportunity to collaborate with other technological alternatives to compensate for the solar irradiation lack or fluctuation during the night and day to reach high renewable heating fractions using a concept involving several technologies, such as thermal storage and a heat pump driven by green electricity. The existing boiler use can be minimised if the system components are sized optimally.

Previous studies have shown that hybridizing the heat pump with solar thermal collector results in the lowest levelized cost of heating (LCOH) compared when these technologies are used individually [5]. Therefore, more research is needed to understand the techno-economic boundaries of solar thermal and HTHP in stand-alone and hybrid modes. This paper takes a step by looking into a comparative analysis of these two technologies. The current study is a base to investigate the combined hybrid systems in future applications.

2. Objectives

The central objective of this paper is a comparative analysis of both HTHP+PV and PTC systems for steam applications using industrial boundary conditions. Previous studies have performed a general feasibility analysis for solar thermal technologies or heat pumps. However, only a few have investigated comparing these technologies on with techno-economic boundaries. The most relevant work to the current paper is by Meyers et al. (2018), where the authors have developed a techno-economic comparison method using maximum turnkey solar investment as an indicator. This method can be used as a criterion to quickly compare and select between solar thermal and heat pumps based on boundary conditions. However, the study did not consider the effect of SF on LCOH. This variation is critical to consider while comparing technologies, especially with high-temperature solar thermal, due to the lack of steam storage technologies. The LCOH of the ST system increases exponentially after a threshold SF due to the diminishing added value of heat storage. Therefore, when comparing other technologies with ST, the SF is a critical criterion to define and is not considered in
previous studies. Meanwhile, the LCOH of hybrid system of HTHP+PV would decrease in most cases while it is also dependant on many other factors such as: GHI, electricity prices and CAPEX. The current paper has overcome the limitations by using comprehensive variables as a comparison basis for both HTHP+PV and ST.

3. Method

This study aims to assess the energy and economic performances of Industrial PTC and HTHP+PV in four European climates. Figure 1 shows the flow chart of the method used for analysis. First, the evaluation is carried out through annual energy simulations performed with dynamic simulation software. After this, a systematic approach is followed to provide the reader with the information needed to understand the results. The analysis is carried out for two load profiles with constant peak demand to capture a broad range of industrial load conditions. However, the results obtained are parametrised to direct normal irradiation (DNI) and global horizontal irradiation (GHI) which can be used to assess the performance for any given location.

In Step 1, simulations for HTHP are conducted using TRNSYS for given load profiles to calculate the COP and thermal output [6]. The outputs are based on a performance map obtained from an HTHP supplier for a broad range of operating conditions. For PV part the annual yield have been simulated based on the results from renewable ninja while in calculating LCOH of hybrid HTHP+PV, the balance of PV yield and power consumption of HP has been considered. It is also assumed that all excess production over consumption been wasted.

In Step 2, dynamic simulations for PTC collectors are done. The product chosen for this study is restricted to a PTC manufactured by a Swedish company named Absolicon solar collector AB [7]. The product is designed for industrial applications and fits this study well. Simulation of the PTC system is done in two sub-steps. The component performance is analysed using TRNSED, and the system performance is simulated using the developed model in OCTAVE. Storage sizing optimization obtains each location's SF vs. LCOH curve. The LCOH calculations for ST and HTHP+PV are done using Excel spreadsheet.

Finally, in Step 3, based on the results obtained, the LCOH of both technologies is compared to provide boundary conditions to identify the strong economic hold of each technology. An indicator SFlimit is introduced to distinguish the economic advantage and to generalize the results.
4. System boundaries and Model

4.1. Load profiles and heating demand

The heat demand in the industries depends on the process characteristics and varies, which is difficult to capture by one study. However, the selection of load profiles to represent a significant share of industries is the focus of this paper. Two different load demand profiles are considered for the analysis. The peak heat demand is fixed at 500 kWth (steam flow of 0.8 tonnes per hour), typical of many process industries. As ST and HTHP are subjected to the same load constraints, the comparative results are not affected by the selection of peak load value. The steam demand is assumed at a constant temperature of 140 °C (saturation pressure 3.7 bara). The steam temperature range is commonly used in many food processing industries and fits well with temperature constraints for both medium-scale PTC and HTHP products. The two chosen load profiles are explained as follows:

- **Continuous demand**: Uniform demand throughout the year with 8760 annual operational hours, which results in annual heat demand of 4380 MWh/year. Such load profiles are prevalent in many large production factories, such as the pharmaceutical sector.

- **Daytime demand**: Uniform demand only during the day (10 hours per day starting 8:00 to 18:00 for whole week), resulting in an annual heat load of 1825 GWh/year. This load profile is typical for a small/medium production facility.

Weekly variation for considered load profiles is shown in Figure 2. The presented week pattern is repeated for a whole year to obtain the annual heat demand.
4.2. HTHP integration

After industrial boundary conditions, the next step is to design an HTHP system and evaluate the techno-economic conditions. HTHP can be integrated at several points, for example, central steam generation for the whole plant or a specific process. This integration type will decide the inlet temperature of the fluid stream at the sink of HTHP to further convert into steam. Steam generated by the HTHP will be fed to the steam line. Therefore, the sink inlet fluid can be tapped feed-water or de-aerator of the existing boiler system. The feedwater pump used for the boiler can be utilized to obtain the required flow in the HTHP. If integrated with the boiler steam header, HTHP must generate steam at slight overpressure to ensure that steam from HTHP is preferred over boiler steam.

The HTHP is designed for peak heating capacity in this study. Therefore, it is considered the sole heat source for the energy system without any backup boiler. On the source side, the available wastewater stream is considered at the inlet, which transfers heat to the HP refrigerant and exits at a lower temperature depending on the temperature glide. On the sink side, the feed water stream enters the inlet and receives heat from HP to convert to steam, which is fed to the process line. A commercial HTHP (Kobelco model SGH 165) capable of generating steam at a maximum temperature of 165 °C is used to meet the steam requirement [8].

4.3. HTHP model

The HTHP used for this study can produce steam up to maximum temperature and pressure of 165 °C and 0.8 MPa-gauge, respectively. The applied refrigerant in this HP is a mixture of R134a and R245fa. The heat pump utilizes a semi-hermetic inverter twin screw compressor. The rated COP of the modelled HTHP is 2.5, specified at source and sink temperatures of 70 °C and 165 °C, respectively. A performance map based on data from the commercial HTHP[8] is used to calculate the electricity consumption. The performance map consists of the COP of the HTHP for various temperature lifts. The temperature lift represents the difference between the fluid temperature at the heat source inlet and the heat sink outlet. The heat pump has a variable speed capacity to operate at the part load conditions. The electrical consumption derived from the annual simulations is then used to calculate the LCOH.

The design temperatures for the HP model are shown in Figure 3. The source for the HP evaporator is considered a wastewater stream with a fixed temperature of 40 °C, available throughout the year. A temperature glide of 6 K is considered on the evaporator. The resulting temperature lift of the HTHP is 100 °C, corresponding to steam temperature of 140 °C. The feed-water temperature entering the HTHP arrives at 110 °C, resulting in a 30 K temperature difference on the heat sink side. The flow rate in the source and sink are varied to obtain the designed temperature glide and thermal capacity, respectively.
Other than the electricity consumption of the HTHP, there are water pumps on the source and sink side, which also consume electricity and is important in LCOH calculations. The pumps are sized to provide the desired flow rate in the network. Pressure drop calculations are done to estimate the total head in the network using Serghide’s method [9]. The pump is designed for the total pressure drop of the network is 1 bar, assuming 20% safety factor while accounting for bends and joints, etc. Based on the flow and pressure drop, a commercial pump is selected from the manufacturer catalogue. The products are used to derive the pump curves (flow vs. head and efficiency vs. head) to simulate the working points of a given scenario and thus used for electricity consumption to calculate LCOH.

4.4. Economic inputs for HTHP

For the heat pump LCOH, it is necessary to include various costs. The analysis is done for three different capital expenditures (CAPEX) of 500, 1’000, and 1’500 Euro/kWth values derived from data based on implemented HTHP case studies [10]. The operational costs for HTHP consider the electricity to run the heat pump compressor and fluid pumps. The O&M costs for HTHP are usually higher than those for boilers and are set to 5% of the CAPEX value with the system degradation rate equal to 0.5%. The LCOH of both HTHP and PTC systems are compared for a time horizon of 15 years. The period is chosen to reflect the suitable timeline various multinational companies consider for energy-related investments. Three different electricity prices are chosen for analysis considering the range of industrial electricity tariffs in the EU.

For sensitivity analysis of LCOH, a total of 6 cases are analysed, accounting for three different cases with HP CAPEX and electricity prices for both load profiles (i.e., CAPEX, electricity price, and load profiles). The values of these variables are shown in

4.5. ST simulations - PTC product description

The ST product considered for analysis is a PTC collector manufactured by the Swedish company Absolicon solar AB. The product T160 is a concentrating parabolic trough collector that focuses direct solar irradiance onto an absorber tube that runs along the focal line of the concentrator and contains a working fluid that gets heated when solar radiation is concentrated on it. The collector works on single-axis tracking using the astronomical watch, which tracks the solar collectors, so they always face the sun. The product can generate steam and hot water from 60 °C to 160 °C, and is therefore suitable for many industrial sectors (e.g., dairy, brewery, chemical, etc.). The collector can be categorized as a small PTC type and is certified by solar Keymark. The optical efficiency of the collector is 76.6 % based on aperture area. The key technical specifications of the collector are shown in Table 2.

The main components of a collector consist of:
- Reflector, which reflects the incoming radiation onto the receiver.
- The receiver tube absorbs reflected radiation and converts it into heat; this heat is then dissipated by the agent fluid that is pumped through the receiver tube.
- The protective glass avoids heat losses and protects the collector from dust, snow etc.

4.6. Modelling PTC system

A dynamic simulation of the collector performance was carried out for a statistically normal year based on climate data from Meteonorm using time step of 15 minutes. Simulations are based on the Solar Keymark ISO 9806 collector parameters of the Absolicon T160.

The simulation approach for PTC is based on 2 steps. In the first step, the collector is modelled without interacting with the heating load. This can be considered as if the collector operates under infinite load, and thus all the heat generated by the collector is fully utilized. The simulations are done using TRNSED, which is an add-on to TRNSYS. The collector performance parameters based on the aperture area used in the TRNSED are shown in Table 3.

The output of the component analysis results in an hourly profile of collector output with other variables. The output is used in the system model for defined industrial boundaries. System simulations are done using the OCTAVE tool, on an hourly time-step basis for a year. The tool simulates the collector interaction with the load. Several iterations are performed to obtain the collector area and storage volume for a range of solar fractions for specific loss factors. The loss factor represents the maximum quantity of heat allowed to spill from the collector at any time step and is fixed at 20 % of the collector production. The loss factor is chosen based on previous experience. Based on the simulations, a curve representing the collector area and storage volume needed for a range of solar fractions is obtained. The range of SF is restricted from 1 % to 91 %. It is possible to run simulations for SF approaching 100 %. However, this is avoided so to reduce the computational effort.

Moreover, it is uncommon to design a solar thermal system for such high SF due to the excessive tank volume required, which negates the installation's economic gains. The power consumption of the PTC system due to tracking and fluid pumps is also derived from simulation results. The collector area and tank volumes required for various solar fractions are then used to calculate the LCOH of the system, as explained in the next section.

4.7. Economic boundaries & geographical inputs

The data for PTC economic analysis includes the capital and O&M cost. The economic input values are based on data collected from the PTC manufacturer as shown in Table 4.

5. Key performance indicators

_levelized cost of heating:_ LCOH is a comparative indicator representing the cost of heating from any system considering capital, operation, and maintenance costs during the system's lifetime [12]. If the LCOH of a new solution is lower than the LCOH of the existing system, it implies that the new system implementation will have positive returns. It is a suitable performance indicator to compare various heat generation technologies. The LCOH is calculated based on Equation 1.

\[
LCOH = \frac{\text{CAPEX} + \text{Price}_e \cdot \sum_{n=1}^{N} \left( \frac{W_{\text{Sys}}}{(1 + DR)^n} \right) + \sum_{n=1}^{N} \left( \frac{\text{EX}_{\text{O&M}}}{(1 + DR)^n} \right)}{\sum_{n=1}^{N} \left( \frac{Q_{\text{Yield}}(1 - SD)^n}{(1 + DR)^n} \right)}
\]

Where:

- \(\text{CAPEX}\) = Capital cost of technology used (including installation and commissioning) (€)
- \(W_{\text{Sys}}\) = Annual power consumption of technologies (Electricity for fluid pumps, heat pump, and collector tracking system) (kWh)
- \(\text{EX}_{\text{O&M}}\) = operation and maintenance cost per year (€/year)
- \(\text{Price}_e\) = Current unit price of grid electricity (€/MWh)
- \(\text{DR}\) = Discount rate (%)
SD=degradation rate (%) of each technology
N= Project lifetime (years)
\( Q_{yield} \) =Heat yield of the system (kWh/year)

\( SF_{lima} \): To compare the cost of heating between HTHP+PV and ST based on location-specific characteristics such as annual DNI, a new comparative indicator \( SF_{lima} \) is defined for the analysis. The \( SF_{lima} \) refers to the point on the SF-LCOH curve of a PTC when the LCOH of HTHP for the analyzed condition becomes equal to the LCOH of ST. Therefore, if a PTC system is designed for an SF which exceeds the \( SF_{lima} \), then the LCOH of PTC at the designed SF will be higher than HTHP. In other words, below the SF limit value, the LCOH of the ST system will always remain below the HTHP+PV LCOH. Therefore, a higher value of \( SF_{lima} \) would represent better cost feasibility and favorable conditions for PTC installation.

6. Results

6.1. HTHP simulation results

Table 5 shows the results for LCOH calculations for HTHP for 6 simulated scenarios representing load profiles, investment cost, and electricity price variation. For any specific load profile, the CAP-ELP represents the LCOH of HTHP assuming CAPEX 1 (500 €/kWth), and Electricity prices 1 (70 €/MW), as shown previously in

Table 5: HTHP LCOH [€/MWh] for simulated scenarios

6.2. PTC simulation results

The results from PTC simulations suggest that LCOH has a higher variation than HTHP. The reason can be attributed to a wide range of solar irradiation variations across simulated European locations. Furthermore, the LCOH also varies with solar fraction for any specific location.

The range of LCOH obtained from PTC varies is huge depending on the solar fraction. The minimum LCOH obtained is obtained for high DNI regions and at a lower solar fraction. A decreasing trend of LCOH with increasing DNI is due to high collector output. Furthermore, for the same DNI, the LCOH increases with an increase in solar fraction due to lower utilization of heat.

It is also important to consider that LCOH depends not only on the absolute annual DNI value but also on the temporal variation. The high temporal variation makes it difficult to achieve large SF due to the large tank volume needed, thus increasing the LCOH.

Then while comparing the LCOH of PTC or any ST product with other technologies, it is important to specify the SF at which the comparison is made.

The simulation results are used to generate SF-LCOH curve for a location, the LCOH will have a minimum constant value up to a certain SF, till all the collector heat is utilized by the system resulting in no excess heat and no storage tank. However, after a threshold solar fraction, the thermal production of the collector exceeds the load demand, bringing the need for thermal storage. The introduction of thermal storage adds additional
cost to the system, increasing the LCOH. After this point on the curve, the LCOH increases exponentially as the thermal storage size required is very high with an increase in SF. Increasing collector areas/tank volumes would diminish the returns for utilized heat, increasing the LCOH. This curve is obtained for all the simulated locations and for two different load profiles. It is then compared with HTHP’s LCOH to obtain the corresponding SF limit.

Figure 4[a] illustrates the LCOH comparison for both technologies for the Spain-Seville location. The curves show the variation of PTC LCOH with SF for two different load profiles. For sake of comparison, the two horizontal lines in the graphs represent the minimum and maximum LCOH of HTHP for all simulated cases. Due to the high DNI in Spain, the minimum LCOH of PTC is always lower than HTHP for all simulated cases. It has been shown that for such a location for LPR 1, even with low CAPEX and OPEX of HTHP (bottom horizontal line), the SF limit is at 37%. SF limit increases up to 65% if the highest value of CAPEX and OPEX for HTHP are considered (top horizontal line).

The minimum LCOH of HTHP in LPR 2 is higher than in LPR 1. The reason is a lower number of operational hours while having the same CAPEX of HTHP, which results in high LCOH.

Comparative results are shown for a low DNI location (Czech-Prague) in Figure 4[b]. As can be seen, the PTC LCOH for Prague in LPR 1 are even higher than the worst case of HTHP LCOH (CAP3-ELP3). This implies that for such a case and under the analysed boundaries, HTHP would be more cost-effective option for heat generation than PTC. However, there would be a change by considering LPR 2, where PTC has lower LCOH up to SF of 15% compared to CAP3-ELP3 scenarios. The SF limit for this case is at 15.6%.

6.3. Comparative analysis using SF limit

Based on the analysis in PTC simulation results section, the values of SF limit for simulated cases is shown in Table 6. The locations where no value of SF limit is defined (such as in UK-London) indicate that LCOH of ST is always higher than LCOH of HTHP in all simulated cases. These countries often have very low annual DNI, resulting in lower economic feasibility for PTC.
Table 6  Summary of SF limit (%) of ABSOLICON PTC (T-160) and HTHP with and without PV for LPR.1 and LPR.2. Empty values indicate that LCOH of ST is higher than LCOH of HTHP or HTHP+PV

7. Discussions

The cost aspects of any technology for low-carbon process heat assessment are extremely case-sensitive. The developed method serves as a valuable guide to quickly determine a preferred lower carbon heat solution just by looking at the annual DNI of any location and finding the optimal SF limit for that location. The analysis is comprehensive but restricted by the absolute values of the variables assumed. Several other aspects can change the techno-economic results in the near future. For example, the carbon tax can play a significant role in reducing the cost of heating. ST technologies consume significantly low electricity compared to HTHP technologies. If the CO2 emission cost is accounted for, the results will favour ST technologies and HTHP
with PV. Also, as the electricity grid will have more renewable penetrations, the HTHP will keep getting attractive from a cost and emission perspective.

The land usage for HTHP is much smaller compared to solar thermal collectors. This is a big advantage for HTHP, especially if the industries have limited ground or roof space for solar collector installations. HTHP, on the other hand, needs more developments for low-GWP refrigerants.

A way forward could be to use both technologies in conjunction where ST is designed up to the SFLimit, and HTHP is used to meet the rest of the load. A hybrid system of optimized solar thermal collectors with a small tank volume and HTHP can produce process heat at lower LCOH compared to the technologies used individually. Technology combination is imperative to reach clean and economical industrial heat ambitions. Such a hybrid system could have significant potential to decrease the cost and emission and will be of focus for future studies and publications. For new energy system planning, a bivalent system where only PTC and HTHP are used together, there is a possibility to reach 100% renewable heating fraction if the electricity for HTHP is renewable. Such system can run without any need for boiler backups. In case of retrofitting with existing boiler system, ST can be used as a starting point to cover part heat demand. Then HTHP can be introduced in the system designed for peak heat load demand to phase off the boiler completely.

In addition, to accelerate the decarbonisation aims, the EU has set an ambition to build 100 positive energy districts and smart cities (climate-neutral cities) by the year 2025. However, the focus of current PEDs is mainly on residential and commercial buildings. The PED boundary unfortunately does not include industrial energy system at the moment. Nevertheless, there is a strong need to factuality the industrial decarbonisation and include industrial energy system in the PED development since it belongs to whole city energy infrastructure. If a city wants to achieve the climate-neutral goal, it must consider industrial segment. On the other hand, industry segment fits high synergies if it is considered in PED concept. For instance, the low temperature waste heat can be recovered from industries to meet space heating and DHW demand through 5th generation district heating network. In return, when PED produces extra energy, it can be exported to industries through above-addressed district heating via heat pumps to upgrade heat to the required temperature level. Therefore, to address the technologies for industrial heat is critical to fulfil the PED and climate-neutral city goals, such as HTHP and PTC, which can be the key technologies for a fully decarbonised urban energy system.

8. Conclusions

This paper compares the techno-economic aspects of HTHPs and PTC collectors for various industrial boundary conditions. The focus is on steam generation at 140 °C (3.6 bara), commonly used in many process heating industries. The characteristics of commercial HTHP and PTC products are used as input in the simulation model to obtain energetic results. For LCOH calculation, an excel spreadsheet is used. Finally, results are generalized using SFLimit as an indicator to distinguish the economic advantage of each technology.

The major conclusions of the study are as follows:

- The LCOH of HTHP for the analysed boundary conditions ranges from 45 to 130 €/MWh. There is a clear trend of increasing LCOH with higher electricity prices and specific CAPEX costs. As the HTHP was sized for a peak load capacity of 500 kW, the total CAPEX is the same for both load profiles. However, the LCOH can be lowered by operating the HTHP for more hours. Therefore, the LCOH in scenario LPR1 is always lower than in LPR2 for the same cost of electricity prices.

- The least obtained LCOH comes from the PTC collector for high DNI regions and low solar fractions. If the meteorological conditions are suitable, PTC is a cheaper alternative to generate steam compared to HTHP. The LCOH range obtained from PTC simulations is 28 to 160 €/MWh up to 50% SF. Lower values of LCOH can be observed for high DNI regions and vice versa. High DNI regions are, for example, Spain, Portugal, and Southern Italy. Furthermore, LCOH has an increasing variation with SF. The SF-LCOH curve is not dependent on the absolute DNI but on the distribution of the DNI on a temporal basis, which decides the storage volume needed to increase the SF.

- As the LCOH increases with SF, a specific SFLimit exists when producing heat from ST gets more expensive compared to HTHP. This limit is higher for high DNI regions and lower for low DNI regions. The limit increases with higher ELP and CAP for the HP. In low CAPEX and electricity cost situations for an HTHP, a threshold DNI of 764 kWh/m² is needed for PTC to produce heat at a cheaper rate. In the high CAPEX scenario, this threshold DNI changes to 1200 kWh/m², and the average SF limit varies from 25% to 55%. In high DNI locations (1'500 to 2'000 kWh/m²), 15% to 30% for medium DNI (1'001 to 1'499 kWh/m²), and 0% to 10% for low DNI locations (0 to 999 kWh/m²).
The decrease in PTC CAPEX results in lower LCOH for any given solar fraction, eventually leading to high SF limit. When the CAPEX of PTC is lower and load profiles are favorable, a solar fraction limit of 32% is obtained, even for the lowest DNI location. This situation indicates that cost decrease can result in PTC as the most economic heating source for low DNI locations.

The industry segment fits high synergies if considered in the PED concept, while both HTHP and PTC can be the key technologies for a fully decarbonized urban energy system.

Abstract

Existing high-temperature heat pumps were investigated by means of life cycle assessment with thermal outputs of 0.19, 0.66, 1.2 and 10 MW. Scale up was performed linearly, due to a better fit than other methods presented in the literature. It was shown that the electricity consumed during the usage phase has a greater impact in the majority of damage categories rather than manufacturing or the production/leakage of the working fluid. The European grid mix was compared to the French and Spanish one, showing that a low-carbon power source is vital. Finally, a benchmark with other common steam sources was done in terms of global warming potential, showing the substitution of fossil-based steam sources is the biggest lever when implementing heat pumps for better sustainability.

Keywords: High temperature heat pumps, scale-up, Life Cycle Assessment, LCA, Environmental assessment

1. Introduction

When it comes to assessing sustainability of technologies and their development, life cycle assessment (LCA) is an apt tool to assess environmental impacts on a multidimensional level. Hence, heat pumps (HPs) are no exception and have been the target of several studies. [1] – [4] However, most studies only target residential HPs and/or low temperature systems with larger, high-temperature systems being more of an exception. When it comes to the roll-out of “green” technologies, investors and policy makers face a “hen-or-egg” type of question. Subsequently, potential investors want reliable information concerning economic & environmental implications, this data is hard to generate as hands-on cases are hardly found. While there are already profound approaches for other technologies such as for power-to-gas [5], [6], biorefineries [7], [8], or chemical conversions [9], High-Temperature Heat Pumps (HTHPs) are lacking in this area.

While it is common in LCA-modelling to omit the material needed for the plant as impacts are mostly of a minor nature, this notion will be put to the test in this study, as modelling of a material balance will be investigated. Caduff et al. [10] developed a scale-up framework of domestic HPs based upon exponential power laws. The applicability of this framework will be tested for commercial HPs, with its data being based upon results of IEA Task Annex 58. [11] Data gaps were filled by literature research and discussions with experts on the field. The final results were objected to an LCA with the functional unit to produce 1 GJ of steam.
2. Materials and methods

2.1 LCA

LCA has been described numerous times in literature, thus for an introductory reading, the authors would like to refer the reader to the following standard works. [12]–[14]. Yet, LCA will be performed following ISO 14044, with its 4 phases being:

- Definition of Goal and Scope
- Life Cycle Inventory (LCI) analysis
- Life Cycle Impact Assessment (LCIA)
- Interpretation and Discussion

2.1.1 Definition of Goal and Scope

The goal of the LCA case study in this paper is the modelling of a HTHP, located in Europe producing steam from low-temperature heat sources, mainly water. The four cases have an output of thermal energy of 0.19, 0.66, 1.2 and 10 MW. The cases are exemplarily conducted for France, Spain and the EU-28, which means the respective electrical grid is considered. The system boundary is cradle-to-gate, as no assumptions about the steam usage are made, with the functional unit of 1 GJ of steam produced. The system entails the production of the machinery and the usage phase, which is assumed to be 15-30 years. The machines are all assumed to operate 8000 hours per year and the End-Of-Life operations were not modelled in this study.

2.1.2 Life Cycle Inventory (LCI) analysis

Life cycle inventory is mostly based upon the Ecoinvent process “Heat Pump Production, brine-water, 10kW”. [15] Other inputs came from manufacturers of the featured HPs. The full inventory is presented in Table 4.

2.1.3. Life Cycle Impact Assessment (LCIA)

The damage impacts will be assessed by the CML-method [13], utilizing the standardized midpoint categories shown in Table 1.

Table 1: Midpoint categories used in this study as introduced by Guinée et al. [13]

2.2. Modelling of scaling laws

In the past, researchers found that the cost and material balance of scaling up process equipment does not show linear behavior, as in fact they follow a power law, as presented in Equation 1. With $C$ being the cost/material need of interest, $a$ being the normalization factor, $X$ the capacity/scale of interest and $b$ the scaling factor. If this factor is 1 the relationship is linear, however empirical data did show a value of 0.6 being best suited for many different applications.
Equation 1: The power law found for scale up of process equipment.
\[ C = a \times X^b \] (1)

As mentioned in the introduction, Caduff et al., [10] applied this approach to HPs and biomass boilers. They tried to correlate HP’s mass, working fluid use and coefficient of performance (COP) to the respective masses, by transforming Equation 1 logarithmically, as shown in Equation 2. In this case \( i \) is the property of interest, mass, COP, or working fluid, while \( a \) & \( b \) are scaling factors.

Equation 2: Equation 1 transformed logarithmically to allow for linear regression.
\[ \log(i) = \log a_i + b_i \log (X) \] (2)

3. Results and Discussion

3.1.1. Scale-Up of the HP

As in the original manuscript by Caduff et al., [10] the regressions for COP and the mass of working fluids had quite bad correlation, those were omitted for further analysis. For the material balance, the regression slope for the water/water HP was chosen. Two other additional slopes were drawn, based upon the standard-deviation in the 95% confidence interval. Thus, the following slopes were plotted, as shown in Table 2.

Table 2: Linear regressions found by Caduff et al., [10] and the case studies on our study.

As shown in the LCI (Table 4), the mass of a 10 kW HP was determined to be 128 kg of materials. Thus, a linear scale up was plotted as reference too. Table 3 shows the heat pumps of Annex 58 and their consecutive masses.

*0.3 MW Heating & 0.15 MW Cooling
The results of the linear regressions in Table 2 and the data presented in Table 3 are plotted in Figure 1. Apparently, the fitting done in the work by Caduff et al., [10] was futile in the case at hand, as the HTPh mass data follows a linear trend line in the closest manner. Thus, linear trendlines are explored further in the right part of Figure 1. In this comparison, a good fit for masses of HPs up to 0.7 MW was found, which quickly deteriorates as higher masses are also included. This finding is confirmed by the fact that for HPs with a power output > 1 MW their masses are not outlined and are commonly described with phrases such as “depends heavily on the installation and the parameters at the specific site”.

![Figure 1: The left part of the figure shows the scaling results by Caduff et al., also taking into account the boundaries of the confidentiality interval, in comparison with the HP data collected in IEA Annex 58 (Task) 1. The right part of the figure shows only the IEA data and two fits, one encompassing the entire data set, the other one only the ones with lower outputs.](image)

### 3.1.2. Life Cycle Inventory

The LCI was compiled for four HTPhs. The full inventory pertaining to mass for the machinery of the HPs is presented in Table 4. The original Ecoinvent process is shown with the linear scaling results for the selected case studies. On the right part, the four different case studies are presented. All processes were modelled after the Ecoinvent database, except for Copper where a process by Sphera was used [16].

Moreover, the LCI consisted of a part containing the working fluid and the power consumed/generated. Those results are found in Table 5 and Table 6. Due to the limited availability of steam-generating heat pumps on the market not all heat pumps in Table 5 are capable of producing steam on their own. This applies to cases 1 –
DryFiciency Wienerberger and Combitherm. To overcome this issue the COPs of these water-to-water heat pumps were considered and for steam production a flash tank was connected downstream. The internal mechanism of a flash tank only evaporates a relatively small portion of water at the flash valve. The percentage of the mass flow that is converted into steam depends on the pressure difference the fluid experiences at expansion. This added resistance requires more power to pump the sink stream. To take these effects into account circulation pumps were included in the calculation. Their electrical power consumption is estimated based on similar heat pump configurations that use flash tanks. The reference application was based on the design power of the pump. Therefore, the presented estimates for circulation pump power in Table 5 can be seen as an upper bound. The COPs for case studies 1 and 3 include the extra power consumption of the circulation pumps. Documentation of the different HTHP models is given in the citations.

* Expert’s estimate
*The manufacturer told the authors that the two WF are in a secret mixture, but for the sake of calculation 100 % R245fa should be assumed.

** The value was assumed to be similar for both enantiomers.

The original inventory from Ecoinvent listed significant amount of working fluid (WF) needed for the initial fillings and nearly 20 % of loss during production and decommissioning. [15]. After having talks with experts, it was concluded, that those values were too high for state-of-the-art processes. A leakage of 1 % per year and a refilling was hence assumed and modelled.

3.1.3. Transforming the inventory to the model

As presented in Table 4, the production of the HP features also the production of a WF. As R134a is not used in any of the model cases, production data had to be found for the remaining WFs. Literature shows that synthesis routes are manifold, mostly too complicated for LCA studies, as non-standard chemicals and rare element catalysts are used. [24], [25] As a process was found in the Ecoinvent database for R134a, which outlines a GWP of 17.6 kg CO\textsubscript{2}-eq. / kg R134a, it was decided to use it as a proxy [26]. The reason was that literature only lists values for GWP and ODP and we wanted the other midpoint categories to be accounted for, too. Chemical structures of the different WF’s Table 7.

For modelling the mass balance, the Ecoinvent standard processes were used given in the documentation of the process describing the 10 kW HP, if not stated else. Exceptions include the supply for thermal energy, which was modelled with the Sphera process “EU-28: Thermal energy from natural gas” [27], or the plastic waste mixture which was assumed to be treated with the “EU-28: Plastic packaging in waste treatment plant” [28] Sphera process. As for incineration, steam and power are produced, substitution had to be modelled. For the thermal energy, the beeforementioned process was taken; while for the grid, the grid used in the scenario was chosen. According to the country selections, the grid mixes featured the Sphera processes for “1KV-60KV grid mix” in the EU-28, France and Spain. [29], [30], [31]. To further clarify matters from chapter 3.1.2, the proxy production of the working fluids was modelled with Ecoinvent process given in the 10kW HP process, but connected to “use phase”.

3.2. LCIA results

As a first group of results, the base cases of the four heat pumps are presented. For those the EU:28 electricity mix was used. The absolute values results are listed in Table 8, as well as percentual impacts which were normalized to the 10 MW case, case 4.

</table>
Generally speaking, the results are relatively uniform throughout the impact categories. The 0.66 MW machine yields the lowest results, owing to the high COP, especially compared to 0.2 and 1.2 MW. While the 10 MW HTHP exhibits a COP of 4.2, one must not forget that this figure comes from a heat source of > 100°C. Moreover, case study 1 and 3 need the circulating pump, thus higher emissions due to the power used were found. However, lower emissions due to scaling effects were not found. Moreover, the impacts were grouped into the three different stages of the life cycle of the HTHPs. The results are shown in Figure 2.

Upon reviewing the percentual contributions it becomes clear the influences are very similar among the different HTHP systems. Except for ADP elements, FAETP, and ODP, the usage phase of HPs was responsible for the majority of the impacts. The leakage was only noticeable in the case of the 10 MW case, which resulted in a 7 % contribution to ODP, which was again based on very low overall numbers. Especially for GWP, HP production and leakage’s impacts were under 1 %, thus confirming the hypothesis that in energy-intensive operations the plant plays only a minor role. Interestingly enough, when comparing case studies 2 & 3, case study 2 featuring a working fluid with a GWP > 20,000, no difference is visible to case study 3 which uses a WF with a GWP of 43, thus indicating that over the lifetime of one HP the GWP of the working fluid should not influence decision making too much.

As mandated by ISO 14044, sensitivity analysis should be used in comparative LCA in order to account for weak spots in the analysis and to further insights into the comparative model. For this, the grid mixes were changed to the Spanish and French one, as well as material balances were changed by + 50 % and reduced by – 50 %. Results for the CML midpoint categories are presented in Figure 3.
Figure 2: Percentual contributions to the midpoint categories by the three different life style changes.
The findings of Figure 3 match the ones made in Figure 2. The increased/decreased material demands altered ADP and FAETP by less than 50%, while leaving the majority of other categories, including GWP, largely unaltered. Due to the linear scaling, the tornado chart is highly symmetrical. This once again highlights, that if GWP is the main focus of a HTHP study, the material balance plays a minor role at most. For toxicity related impacts however, the scaling effects are of interest. Acidification and eutrophication were also only influenced on a minor level. If only the electricity grid mixes were changed from the EU-28 mix to the Spanish or French one, the results turned out very different. The influence is mostly indirectly proportional to the previous analysis, as categories change more drastically. I.e., the French grid provided significant reductions of 77% in the ADP elements category as well as -78% for GWP, which was due to its low carbon intensity. AP and EP show similar behaviour, as they are also hardly influenced by the material balance’s scaling. The Spanish mix does provide some reductions, yet its influence is notably smaller than the French one. However, in a direct comparison, the Spanish grid provided little improvement over the French one, only in the FAETP category it yielded minuscule better results.

As it was shown, when aiming for an improved carbon balance, the usage phase provides the biggest lever. Aiming for a high efficiency and clean energy can help to significantly reduce the GWP. While this is one part of the equation, the other side in LCA is the energy provision, which will be replaced using a HTHP. Therefore, a last case study was prepared, comparing the 1 GJ produced by the HTHP to common other technologies such as solid biomass, biogas, light fuel oil (LFO) and natural gas. Data was obtained from Sphera’s Professional database and is presented in Figure 4. [32], [33], [34], [35]
When assessing the GWPs of the different steam generating technologies it becomes clear that the differences between the different HTHPs, their production and usage parameters are negligible when compared to the figures obtained by different steam generating technologies. This means if one of the HTHPs is implemented, the largest lever to lower the carbon balance is the technology which is replaced. The best case for example, the 0.66 MW design, powered by a French grid, replacing steam from LFO would yield a reduction of emissions by over 97%. The real case would probably be not as straight-forward, as 1:1 replacement is a very optimistic assumption, and it all comes down to the case at hand and its thermodynamic and process properties. But even replacing smaller fossil steam sources can provide significant emissions savings due to the emission’s slope’s sizes.

4. Conclusion, final remarks and further outlook

While the power-laws used for scaling up equipment/cost in process engineering have come in handy many times in the past, this was not true in this case of industrial sized HTHPs. It was shown that the power-law was not applicable to the HTHP case, as the scaling behaved mostly in a linear fashion. Especially in the range between 0.1 and 0.7 MW a good linear correlation was found. However, those results were of methodological interest only as it was shown that manufacturing is not as influential as the usage when it comes to life cycle impacts, especially GWP. This was confirmed in the sensitivity analysis. The usage/choice of working fluid also was shown to be not as influential as assumed, as no considerable difference was observed between cases with a WF with high and low GWPs. Therefore, it is recommended that manufacturers should care about thermodynamic properties foremost, which are mostly met by working fluids with low GWPs in the HTHP area anyways. In the case studies, it was shown that a grid with low carbon intensity can help significantly in decreasing environmental impacts. This effect can be further amplified if carbon-intensive steam sources are replaced. If e.g., a HTHP powered by the French grid replaces steam from LFO GWP savings of over 97% could be achieved. However, one must not forget that as of now the HTHPs can only supply lower temperature and lower pressure steam, while the fossil sources are not limited in that sense. Moreover, biogenic carbon CO₂ emissions are not further considered in this work as Sphera’s modelling approach assumes a full cycle from uptake in biomass, to the release when generating thermal power. [36] This is accurate for the system boundary in this case but may change drastically if different system boundary in terms of biomass is applied.

Development and Evaluation of Ammonia Vapor Compression Coupled to a CO₂ Convection Loop

Ron Domitrovic, Ethan Tornstrom, Troy Davis, Jerine Ahmed

Abstract

A novel approach to the application of zero GWP refrigerants for commercial space cooling was demonstrated using ammonia vapor compression chilling coupled to pumped carbon dioxide convection. Following the lead of emerging supermarket refrigeration systems, this approach is both modeled after and meant to substitute halocarbon-based pumped chilled water cooling. Compared to pumped chilled water, the use of CO₂ coupled with ammonia-based chilling could provide a system targeting multiple paths of optimization: reduced cost, increased efficiency, lower GWP potential, improved flexibility. Potential cost reduction may come from reduced piping cost, reduced installation cost, reduced physical building load and reduced pumping cost. These are all derivatives of the higher heat capacity of phase-changing CO₂ as compared to pumped water. Furthermore, low-charge ammonia provides a cheaper alternative to high GWP refrigerants. Efficiency gains potentially come from the use of ammonia as the vapor compression refrigerant—a fluid with inherently favorable thermodynamic properties as an HVAC refrigerant. Additionally, power may be reduced in pumping liquid CO₂ compared to pumping water. GWP reduction potential comes from eliminating the use of halocarbon refrigerants and from higher system efficiency. There is also potential for reduction related to embedded manufacturing cost, though this study did not evaluate those possibilities. In this first prototype system, the concept was proven to be technically feasible. The ability to operate a convection loop at a wide range of temperatures, including below water’s freezing point, allows for design and operational flexibility that isn’t possible with a water loop. Cooling coils may be operated colder in order to adjust the sensible heat ratio (SHR) and thus have flexibility for greater dehumidification without energy intensive re-heat. This paper summarizes the technical approach to design and shares testing results of the prototype 8-ton system.

1. Introduction

In California 14.9% of electricity is used for cooling applications (high temperature applications, not refrigeration). California commercial building cooling energy consumption was estimated to be 10,017 GWh in 2004. The majority of the existing stationary HVAC systems use R22, R410A, R134a, or R407C as the working fluid (refrigerant). R22, a very common HCFC has ozone depleting potential (ODP) as well as GWP. HFCs such as R134a have zero ODP, but still have high GWP.¹

Environmental concerns have drawn the attention of many regulatory bodies which have undertaken various initiatives to reduce the effect of HCFC’s and CFC’s. The most famous legislative action in this area is the Montreal Protocol, which mandated the phasedown first of CFCs, and more gradually of HCFCs such as R22. This action was primarily focused on preventing ozone depletion. Later legislation such as the Kyoto Protocol targets global warming, and with that, sets goals for HFC phase-down. The Montreal Protocol was signed by the US, and the Clean Air Act includes actions relating to this protocol. The US did not sign the Kyoto Protocol, but the US EPA is authorized to act through the Significant New Alternatives Policy (SNAP) Program, also under the Clean Air Act, and is doing so to phase down the usage of many high-GWP refrigerants. On a state level, California’s Air Resources Board (CARB) has a Refrigerant Management Program (RMP)² which institutes requirements for leak checking, reporting, and logging of usage of
refrigerants, first for heavy users (such as supermarkets and refrigerated warehouses), and later for smaller equipment.

Abroad, the European Union’s “F-Gas” bans include aggressive requirements to phase down production, and eventually recovery and use of refrigerants with “high GWP” (150–2000, depending on application). Some European nations further have specific taxes targeting refrigerants. In Europe, these legislative actions are significant enough that alternative refrigerant adoption is considerably higher than in the US. ³

Some promising, low GWP refrigerants may have other considerations, like toxicity or high pressure, making requiring specific protocols for safe operation. The above concerns – safety and environmental considerations – must be considered in parallel to equally important fundamental thermodynamic behavior of the fluid, which determines component sizing, operating pressures, efficiency and capacity, and so on. Combining all of these factors leads to a challenge, as no substance provides the ultimate combination of traits for all applications.

A long-term objective is to provide HVAC&R solutions using natural refrigerants. Natural refrigerants are defined as compounds that are naturally occurring and have thermo-physical properties suitable to be used in a refrigeration cycle with zero ODP and zero or near-zero GWP. Natural refrigerants like ammonia (NH₃) and carbon dioxide (CO₂) which are environmentally benign are possible alternatives but introduce certain other considerations that require tradeoffs. For NH₃, flammability and toxicity are primary concerns whereas CO₂ has challenges in high-ambient cooling operation and system operating pressures. Another potentially attractive option is the use of hydrocarbons, such as propane, which have high efficiency, but are restricted in how they may be applied because of flammability.

This paper describes the construction and evaluation of a first-of-its-kind ammonia to carbon dioxide chiller and convection loop. It is designed as a potential replacement for traditional chiller/hydronic HVAC systems. The system was shown to reliably and safely operate through a range of typical operating condition. The system has some inherent adjustability, allowing flexibility in the sensible heat ratio. Efficiency was reasonable with coefficients of performance ranging from ~2 – 3, considering that components were mostly taken from other, low temperature refrigeration applications, and the system was not fully optimized for HVAC operation. There is likely room for improvement in further designs.

There is potential for reducing material and installation cost because of the smaller (and lighter) piping requirements for pumped carbon dioxide compared to traditional pumped chilled-water. Simple economic analysis shows install cost may be reduced by a factor of 2-3.

Future development in this area should focus on optimizing for HVAC temperatures to push efficiency higher, design systems that incorporate heating or dual-purpose systems and field testing prototype systems.

2. System Design

A system was designed and constructed that uses natural refrigerants with low to zero GWP. The system is comprised of a low-charge Ammonia (NH₃) based direct-exchange (DX) vapor compression air-cooled chiller coupled to a pumped Carbon Dioxide (CO₂) convection loop. Refrigerant charge was less than 1 pound NH₃ per ton. This arrangement is aligned with traditional systems for space cooling using halocarbon based chillers coupled to chilled-water pumped loops. The evaluation is a hybrid between laboratory and field setup, using the EPRI, Knoxville laboratory space as the “field” installation, but taking measures such that indoor conditions could be held reasonably fixed. Figure 1 shows a schematic for the NH₃/CO₂ system.

The chiller is a nominal 8-ton semi-hermetic chiller with ammonia as the working fluid. It was a beta prototype unit at the time of evaluation, designed to exchange heat on the source (cooling) side through an ammonia to carbon dioxide plate heat exchanger.

Carbon dioxide was piped in a separate convection loop, coupled to the chiller, much as a chilled water loop would be coupled in traditional systems. CO₂ remained in a saturated state throughout evaluation, maintained at pressures between ~3.1–3.8 MPa (450 – 550 psig). A central receiver tank acted as the repository for CO₂. Vapor from the top of the receiver entered the chiller heat exchanger, condensed while flowing through it and returned to the receiver through gravity—there was no pumping for the chiller-CO₂ heat exchange.
3. Evaluation Approach

The objective was to evaluate overall system operation, with a focus on measuring cooling capacity, power draw characteristics and system efficiency as functions of ambient temperature conditions. Other system characteristics were observed and measured as appropriate. Such other characteristics may include part-load dynamics, standby pressure conditions and cycling behavior.

The system can be viewed with multiple control volumes:

- Control volume around the entire system, measuring overall system input (electrical power) and output (cooling capacity). This approach gives insight on the overall system efficiency for comparison to other comparable approaches (e.g. halocarbon chiller with pumped chilled water).
- Separate control volumes around the NH₃ chiller and the pumped CO₂ loop. This approach isolates each subsystem so that capacity, power draw details and efficiency can be measured for each.

Instrumentation of the setup is designed to accommodate both approaches.

3.1. System Control Volume Approach

Referencing the system control volume in Figure 2, overall system capacity is determined through air-side measurement on the indoor air handlers. Capacity is calculated by:

\[
\dot{Q}_{air\ capacity} = \sum_{i=1}^{4} \dot{m}_{air,i} [h_{air,\text{out},i} - h_{air,\text{in},i}]
\]  

where:

\( \dot{m}_{air} \) is the mass flow rate of air discharged from each air handler. \( h \) is air enthalpy.
System power is measured at five points, summing to the total power use of the system:

- Chiller unit power
- CO₂ pump rack and controls power
- 3-6 -> Air handler 1-3 power

\[ \text{Total Power} = \sum_{i=1}^{6} \text{Power}_i \quad [2] \]

Overall system efficiency, termed the Coefficient of Performance (COP) is thus defined as:

\[ \text{Overall system efficiency (COP)} = \frac{\dot{Q}}{\dot{Power}} \quad [3] \]

These three quantities constitute the primary metrics of system performance. All three are functions of operating conditions, namely the outdoor and indoor dry bulb temperature and the indoor relative humidity.

\[ \dot{Q}, \dot{Power},\text{COP} \sim f(T_{\text{out}}, T_{\text{in}}, RH_{\text{in}}) \quad [4] \]

Air side capacity measurement is an industry accepted method for determining total delivered system capacity. It captures the heat transfer usefully delivered to the space and does not capture otherwise lost heat—losses. In a true building arrangement, there may be additional losses associated with the details of ducting. These are not captured in a laboratory style evaluation. The method of test is generally guided by AHRI 340/360 approaches and methods of measurement, though strict ambient air conditions are not maintained with psychrometric-style testing).

Air temperature is measured with type T thermocouple arrays; relative humidity is measured with capacitive RH sensors and air volume flow is measured via a pitot tube array. Air mass flow is calculated from air density, via measured static air pressure, temperature and relative humidity.

3.2. Subsystem Control Volume Approach

Referencing Error! Reference source not found., an additional control volume is shown around the air-cooled chiller. With both the full system CV and the chiller CV, then three overall sets of output metrics (capacity, power draw and efficiency) can be calculated:

- Full system
- Air-cooled chiller
- Convection loop

Because of complexities of measurement, only the full system CV was used for analysis of the experiment. Following is a discussion of some of the associated complexities for sub-component measurement, owing primarily to the nature of 2-phase CO₂ flow.

Convection loop metrics are then the difference between the full system and the chiller. For example:

\[ \dot{Q}_{\text{conv loop}} = \dot{Q}_{\text{system}} - \dot{Q}_{\text{chiller}} \quad [5] \]

\( \dot{Q}_{\text{conv loop}} \) is expected to be negative, indicating losses in the piping network.

3.2.1. Chiller CV Measurement

Measuring the chiller capacity is somewhat challenging. An air side approach can be used, though accurately measuring air volume flow is difficult on the type of low-static fans that move air through the condensing coil. The act of measuring can substantially change the volume flow rate, so some method of boosting airflow, with a secondary fan, back to its non-disturbed state, is necessary. This approach is sometimes also employed for indoor unit testing, if air flow is significantly affected by the act of measuring.
A more direct method of measuring chiller cooling output is to measure the convection loop heat transfer. In water cooled chillers this is straightforward as the product of mass flow, specific heat of water and temperature differential:

\[ \dot{Q}_{\text{chilled water}} = \dot{m}_{\text{water}} [h_{\text{in}} - h_{\text{out}}] \]  

Which can be simplified to:

\[ \dot{Q}_{\text{chilled water}} = \dot{m}_{\text{water}} \cdot c_{\text{water}} (T_{\text{in}} - T_{\text{out}}) \]

Since enthalpy is a direct function of temperature for liquid water (a sub-cooled liquid). For the NH\(_3\) system, using pumped CO\(_2\) as the convection fluid, the method is not as simple. The CO\(_2\) undergoes condensation in the heat exchange process with the chiller and is therefore usually in a 2-phase state—shown by the green line in Error! Reference source not found. Though equation [6] still governs the heat exchange process experienced by the CO\(_2\), there is no effective way to measure the enthalpy of 2-phase CO\(_2\) with only temperature and pressure measurements.

![Figure 3. Illustration of Possible CO\(_2\) State Points (Green→ Chiller-to-Receiver Loop; Red → Receiver-to-AHU Loop)](image)

For this evaluation, it was not possible to measure the enthalpy change across the chiller CO\(_2\) loop. The \(h_{\text{in}}\) (the enthalpy of CO\(_2\) returning to the chiller) is saturated or slightly superheated vapor, because of the geometry of its draw from the top of the receiver tank, enabling enthalpy to be calculated from measured temperature and pressure. \(h_{\text{out}}\) is a different matter, it can be 2-phase, saturated or sub-cooled. An enthalpy calculation is only possible if it is reliably saturated or sub-cooled (though there is no way to confirm saturation, so some small amount of sub-cooling is required).

4. Test Set Up

The test performed in this report was set up as a hybrid laboratory/field installation, where the laboratory space could be conditioned with reasonable control over the indoor ambient conditions. The chiller, CO\(_2\) receiver, and the CO\(_2\) pump were positioned outside and were subject to the outdoor ambient conditions of the summer testing period. The three indoor units were positioned in a horizontal orientation and stacked on top of each other in parallel so that temperature and humidity could be easily controlled. Supplemental heating load to the conditioned space could be adjusted to any wattage, up to \(~30\) kW. A variety of fans and deflectors were used to de-stratify the air and to ensure uniform entrance temperature to the three air handlers.

Humidity was supplied through manually controlled steam injection. Steam flow was adjusted to reach a rough target, return air, relative humidity of \(>40\%\). In steady-state operation of the tested system, return air conditions could be held reasonably stable (\(\pm 1.1\)C and 5\%RH). Each indoor unit was assembled and setup to accommodate air-side capacity measurements.
5. Testing Results

In addition to some general break-in and operational familiarity testing, five general tests were performed on the system:

- Low Ambient (~21-26°C)
- Moderate Ambient (~28-31°C)
- High Ambient (~32+°C)
- Standby Operation
- Power Failure

5.1. Low Ambient

Low ambient testing was performed with an outdoor ambient range of 21°C to 26°C as the outdoor temperature increased over the course of the test. The system was initially started with all three air handlers on and was then allowed to equilibrate. Air handlers 1 and 2 were successively turned off which is represented in Figure 4 as the test stepped down from three, to two, to one IDUs operating. Figure 4 shows cooling capacity versus time, and shows that with two and three IDUs operating, the chiller runs continuously, whereas with only one IDU operating, the chiller cycles. Figure 5, a graph of the chiller power consumption as a function of time, also shows the cycling where the power drops significantly during the cycling period and drops to zero when an IDU is turned off (transition effect). The data collected below is an average across a pseudo steady state temperature during that portion of the test. This low ambient test produced an operating COP range from 2.45-3.14.

![Figure 4. Cooling capacity vs time (low ambient test)](image)

5.2. Moderate Ambient Test

Medium ambient testing was performed with a steady-state outdoor ambient temperature of approximately 30°C. The system was initially started with all three IDUs turned on and was then allowed to equilibrate. The indoor temperature was held constant at approximately 27°C as the system reached equilibrium. After collecting the data in the steady-state, IDUs 1 and 2 were successively turned off similarly to the Low Ambient test. The moderate ambient test produced lower cooling capacity while increasing the ODU power. This moderate ambient test produced an operating COP range from 2.01-2.55 as shown in Table 1.

5.3. High Ambient Test

High ambient testing was performed by adding supplemental electric heat to the condenser inlet in addition to the ~29°C ambient outdoor air at the time of testing. This additional heat boosted the condenser inlet air temperature to approximately 33°C. All three IDUs were in operation throughout the entire test. The high ambient temperature with three IDUs running consumed total power around 12.6 kW. Total air-side cooling capacity was 28.84 kW (~8.2 tons), which operated at a COP of 2.14 (Table 2). Figure 6 shows the relationship between the ambient temperature with additional resistive heat and the cooling capacity of the system. The data observed was taken from operating temperatures of ~91°F which are featured in Figure 6. CO₂ tank pressure remained stable between ~3.4-3.6 MPa (500-525 psig).

</tbody>
</table>
5.4. Standby Operation

A standby test was performed to observe how the chiller operates when there is no cooling load imposed on the system. The chiller periodically cycles on to cool the CO2 receiver tank as shown in Figure 7—as CO2 tank pressure and Chiller power as a function of time. The pressure in the tank oscillates between ~3.27-3.59 MPa (475–520 psig) over a period of approximately 20 minutes. The time between intervals decreases slightly as the ambient outdoor temperature increases over the course of the test.

5.5. Simulated Power Failure

This test was performed to ensure that the system would properly re-energize and reset after a power outage or power failure. The system was initially fully turned on with all three IDUs in operation. All power was then cut from the system by de-energizing the main circuit breakers. After a 10-minute standby, the power was re-applied to the system and observations regarding the test were as follows:

- When power was off, CO2 tank pressure naturally drifted up ~0.007 MPa/min (1 psi/minute)
- When power was re-applied, the chiller began its restart sequence.
- After 5-minute built-in delay, the compressor and ancillary systems restarted.
- CO2 tank temperature dropped accordingly, and the system began cycling normally.
The test setup required the CO₂ pump and the three IDUs to be manually restarted after a power failure to restart the cooling process. This was a design choice for this particular experimental setup and is not necessarily indicative of how a system would actually be set up in a field deployment. Automatic restart of pumping and cooling could be easily accommodated with proper control strategies.

6. Economic Analysis of Aspects of Installation

There is potential installation cost savings from using phase-change CO₂ as the convection fluid instead of water. CO₂ is used in some refrigeration systems because it can provide low-temperature (sub-freezing) convection. For HVAC applications where the convection temperature can remain above freezing, CO₂ still may offer an advantage of smaller pipe size and, in turn, lower installation cost. The following is an example per-unit calculation of relative material and installation cost for CO₂ convection. This analysis is focused on the CO₂ convection loop, not the ammonia chiller. It is assumed that capital cost per unit of installed capacity of an ammonia or halocarbon chiller is roughly equivalent, leaving any difference in cost to the convection loop only.

The boiling heat capacity of CO₂ at ~3.44 MPa (500 psig), is approximately 416 kJ/kgK (99.3 Btu/lbm °F), while for water, the heat capacity is ~4.19 kJ/kgK (1 Btu/lbm °F). If typical chilled water applications undergo a 5.5°C-temperature change, then phase-changing CO₂ can provide up to 10 times the convection heat transfer per unit mass of pumped fluid. This 10x heat transfer is the key point of exploration for potential installation cost reduction. The full 10x may not be realized in actual systems because full phase transition may not occur as systems may be designed to return a partially boiled mixture of liquid and vapor CO₂ from the evaporator.

Chilled water is typically piped in welded steel or grooved connected steel pipe. CO₂ for HVAC applications can be piped in braised high-pressure copper alloy which is a variant of standard ACR type K copper refrigerant tubing. The 8-ton system under test used 7/8” (22mm) O.D. braised copper/iron tubing for the CO₂ supply line and 1-1/8” (28.5mm) for the return. A similarly sized chilled water convection loop would use ~1.5”-4.0” (38-102mm) steel pipe. The CO₂ system with its respective hardware would accommodate ~7.95 lpm (2.1 gpm) of CO₂ flow compared ~72.7lpm (19.2 gpm) of water flow for the similar-sized chilled water convection loop. For an 8-ton system, as described in this report, the CO₂ copper piping would cost 2.67 times less to install than the chilled water steel pipe. Table 30 shows a comparison of installation costs of variously sized ACR copper and welded steel pipe in price per linear foot.

7. **Summary and Conclusions**

A first-of-its-kind, natural refrigerant based HVAC system was constructed and evaluated. The system uses ammonia (NH$_3$) in a low-charge packaged chiller as the primary refrigerant for vapor compression, and carbon dioxide (CO$_2$) as the convection fluid to distribute cooling to remote indoor air handlers. This combination takes advantage of the high efficiency of NH$_3$ and the high heat capacity of CO$_2$ to provide an environmentally friendly option for medium to large HVAC applications. The technology builds on advances made in the supermarket refrigeration sector where refrigerant management is highly important and the shift toward zero GWP refrigerants is already underway.

The general workability of the system approach was demonstrated successfully. Cooling capacity and efficiency were reasonable, with limited effort to optimize the component selection and system controls, likely leaving room for substantial improvement in future designs.

This system was only designed and tested for cooling operation. The concept can be extended to include heating with additional consideration and componentry to accommodate high-pressure CO$_2$ for heat convection.

The smaller size of piping required for CO$_2$ convection (compared to hydronic convection) offers potential for material and installation cost savings, that could help to offset any capital premium for this new type of equipment.

Abstract

Using low-GWP refrigerants can reduce the Green House Gas (GHG) emission of heat pump systems. Heat exchangers and compressors are the key components and have a prominent impact on system performance, significant research is devoted to reducing the cost of the heat exchangers while achieving the same or better system performance with refrigerant charge reduction.

To better understand the environmental impacts of optimized systems with low-GWP refrigerants, Life Cycle Climate Performance (LCCP) evaluation method was used to evaluate the direct and indirect emissions of the system over the course of its lifetime from manufacturing to disposal. The DOE/ORNL Heat Pump Design Model (HPDM) is used to evaluate the performance of heat pumps. Multi-objective optimizations using Particle Swarm Optimization (PSO) algorithm are performed on a 3-ton R410A residential air source heat pump on market. Seven R410A alternatives, i.e., R32, R454B, R454C, R455A, R457A, and R1234ze(E) are investigated. The last five fluids have GWP lower than 150.

As a result, 5.5%-12.8% seasonal energy efficiency ratio 2 (SEER2) improvement is achieved, and the optimized systems reduce life cycle CO\textsubscript{2} emission by 8.5%-28.6% with GWP lower than 150 refrigerants. The optimal heat exchangers can fit into the original R410A fan-coil units; therefore, the proposed design method establishes a production and installation path to produce cost-effective low-GWP heat pumps easily accepted by end users.

1. Introduction

Modern cooling technologies are significant sources of greenhouse gas emissions (GHGs) with total CO\textsubscript{2} equivalent emissions from the HVAC sector accounting for 7.8% of global GHG emissions ([1]. Considering the commitment to reduce the impact of GHGs on climate in the HVAC&R sector, a transition from fluorinated substances to alternative refrigerants with reduced global warming potential (GWP) values is supported by F-gas Regulation ([2], the Montreal Protocol with the Kigali Amendment ([3] of which 146 countries have not ratified, and the Paris Agreement ([4] and the US AIM ACT. The requirements as set forth by the F-gas Regulation banned the use of refrigerants with a GWP of 2500 or greater for high refrigerant charge stationary HVAC equipment in 2020. Beginning in 2022, a GWP limit of 150 has been set for multi-circuit cascade...
systems for commercial use with a nominal capacity of 40 kW or more, and for 2025, the GWP limit for single
split AC on the European Union (EU) market is set as 750. This ban will not permit the use of R410A (2088
as GWP value) in small charge system applications. In this regard, much research has been conducted to find
alternative low-GWP refrigerants.
Reducing the environmental impacts of HVAC&R systems has been an important research topic due to
recent severe global climate changes. In residential buildings, space heating and cooling are the main energy
consumers, which are relying on vapor compression-based heat pumps. The HVAC&R industry has moved to
phase out refrigerants with high global warming potentials (GWP), e.g., R410A, R22, R134a, R404A, etc. The
next-generation refrigerants are mostly mixtures of HFO (Hydrofluoroolefins) refrigerants, e.g., R1234yf and
R1234ze(E) combined with the HFC (Hydrofluorocarbons) refrigerant, e.g., R32. Since most of these low-
GWP mixtures are in the new A2L lower flammability, research [5] has shown that promoting the use of
smaller diameter tubes in heat pump systems is an effective way to reduce refrigerant charge and avoid
explosion risk. But it may cause performance degradation.
One characteristic of these low-GWP alternative refrigerants is their high glide, i.e., temperature glides from
the bubble point to the dew point at one pressure. High-glide refrigerants prefer multi-row, counter-flow heat
exchanger configurations for a single-mode operation. If switching mode, the counter-flow heat exchanger
(HX) becomes a parallel-flow heat exchanger. The reversed flow causes significant efficiency degradation.
Therefore, improvements in components and system configurations are needed to make the high-glide
refrigerants work for both cooling and heating modes to achieve good energy efficiency and protect the
environment.
This study demonstrates a low-GWP heat pump design method with a particular focus on the use of a new
system configuration for dual-mode reversible heat pumps and 5-mm, 7-mm, and 9-mm tube optimized heat
exchangers and required modification in compressors. The goals of the study include:
- Investigate the effect of a new system configuration to maintain heat exchanger flow configuration
  under both cooling and heating modes.
- Optimize multi-row 5-mm, 7-mm, and 9-mm tube coils with low-GWP refrigerants and compressors
to determine the performance improvements.
- Analyze the annual performance indices of optimal heat pumps and access their life cycle climate
  performance (LCCP) to assess carbon footprints.

2. Methodology

2.1. System Model
The DOE/ORNL Heat Pump Design Model (HPDM) [6] is used to model the performance of heat pumps.
HPDM is a public-domain HVAC equipment and system modeling and design tool, which supports a free web
interface and a desktop version for public use. A finite volume (segment-to-segment) tube-finned HX model is
used to simulate the performance of the heat exchanger with different circuits. This model has been validated
by the experimental data [7]. The dehumidification model used in the evaporator simulation is an heat & mass
transfer effectiveness-based model [8]. More details of HPDM can be found in [9]. In HPDM, REFPROP 100
[10] is used to produce performance look-up tables and simulate the refrigerant properties.

2.2. Selection of Refrigerants
In literature [11], near-term refrigerant candidates have GWP<750 and R32 and R454B can be good drop-
in options. Long-term options require GWP×150, and those fluids usually do not match the incumbent fluid
(R410A) properties. For fluids with GWP lower than 150 such as R454C, R455A and R457A, they require
significant changes in heat exchanger structure to address the high temperature glide (temperature rise from
the refrigerant bubble point to dew point at constant pressure) and redesign of the compressor to compensate
the capacity and efficiency degradation. R1234yf and R1234ze(E) have ultra low GWP values and they are of
interest in long term. Table 1 shows the characteristics of R410A and its low-GWP alternatives for a typical
residential air source heat pump. The temperature glides are evaluated at saturation pressure corresponding to
8 °C dew-point temperature.

2.3. Heat Pump System Configuration and Heat Exchanger Structural Parameters

In this study, a 3-ton R410A residential single-stage heat pump product on market is modelled. Fig. 1 shows the schematic of the baseline heat pump operating under cooling mode and heating mode. The refrigerant direction inside the heat exchangers is reversed between mode switching.

![Fig. 1. R410A Baseline Heat Pump System: (a) Cooling Mode Operation; (b) Heating Mode Operation.](image)

To model the baseline system, HPDM has been closely calibrated against experimental data. Table 2 lists the structural parameters of the baseline heat exchangers. The condenser fan moves 2876 CFM of airflow across the outdoor HX and consumes 263 W of power; the indoor blower provides 1205 CFM of supply airflow and consumes 435 W of power. The fan/blower powers and flow rates were the same among all refrigerants.

Table 3 lists the empirical correlations used for local heat transfer and pressure drop. For air-to-refrigerant heat exchangers, the thermal resistance is mostly dominated by airside, therefore, it is crucial to model the airside heat transfer coefficient accurately. Different correlations are used according to its suitable application range to improve the prediction of small diameter tube and large diameter tube heat exchangers.

Fig. 2 illustrates 3 typical circuitry patterns by a simple six-tube HX. For the conventional system configuration as used in the baseline system, if the heat exchanger has counter-flow configuration (Fig. 3 (a)) in cooling mode, after the refrigerant flow is reversed in heating mode, the circuitry will become parallel-flow (Fig. 3(c)). And this yields undesirable performance degradation in heating mode.

![Counterflow](a)
![Mixed Flow](b)
![Parallel Flow](c)

Fig. 2. Heat exchanger circuitry patterns: (a) counterflow, (b) mixed flow, (c) parallel flow

To mitigate the heating performance degradation, the heat exchanger in baseline system is designed as mixed-flow configuration (Fig. 3 (b)) as a compromise solution to balance between cooling and heating modes. The detailed circuitries of the baseline indoor and outdoor heat exchangers are shown in Fig. 3. The indoor HX has 60 tubes per row and 2 tube rows and is divided into 6 mixed flow circuits. The outdoor HX has 24 tubes and 1 tube rows and is divided into 3 circuits. Different colors represent different circuits. The baseline indoor heat exchanger uses 7.95 mm diameter tubes, and the outdoor heat exchanger uses 9.52 mm diameter tubes.

![Baseline Indoor HX](a)
![Baseline Outdoor HX](b)

Fig. 3. Baseline tube-fins heat exchanger circuitries: (a) Indoor HX with 7 mm tube; (b) Outdoor HX with 9 mm tube.
As mentioned in the previous section, research has shown that for low-GWP zeotropic mixtures, the counter flow configuration has the most efficient heat transfer performance due to significant saturation temperature glide [5]. With this consideration, one goal of this research is to develop a new system configuration to maintain the same refrigerant flow direction inside the heat exchangers between cooling and heating mode switching. Fig. 4 shows the proposed reversible heat pump system configuration evaluated in the study as the optimized systems. The new configuration has 4 one-way check-valves at the inlet of indoor and outdoor heat exchangers and the heat exchangers have bi-directional distributors. Under both heating and cooling modes, this system configuration can maintain the same heat exchanger circuitry pattern.

Fig. 4. New System Configuration with Check-valves and Bi-directional distributors Maintaining Counter-flow HXs in Dual Modes

2.4. Optimization Problem Formulation

Shen et al. (2012) [19] developed an optimization framework that integrates HPDM with GenOpt ([20]), a public domain optimization package. In this research, the Particle Swarm Optimization (PSO) algorithm implemented in GenOpt is used to optimize the heat pump system. Regarding PSO setting, the optimization runs use 100 as population size and 200 as number of generations.

Equation (1) shows the optimization problem formulation. The objective is to maximize the Energy Efficient Ratio (EER) of the heat pump under AHRI Standard 210/240 [21] cooling test A condition (95 °F). In Equation (1), the number of circuits for indoor and outdoor heat exchangers are two design variables, which varies between 1 and the number of tubes in each row of the heat exchangers. The number of circuits has an adaptive upper limit to coordinate with the number of tubes in each row.

Maximize : EER

Subject to:

\[ \text{Heat exchanger tube diameter varies among 5 mm, 7 mm, 9 mm} \]
\[ 1 \leq N_{\text{circuits evaporator}} \leq N_{\text{tubes per bank of evaporator}} \]
\[ 1 \leq N_{\text{circuits condenser}} \leq N_{\text{tubes per bank of condenser}} \]
\[ \Delta T_{\text{superheat evaporator outlet}} = 10 - \frac{\Delta T_{\text{subcool condenser outlet}}}{2} \text{ [R]} \]
\[ 2 \text{ [R]} \leq \Delta T_{\text{subcool condenser outlet}} \leq 15 \text{ [R]} \]
\[ Q_{\text{evaporator}} = 10.55 \text{ kW} \]
\[ |\text{SHR}_{\text{evaporator}} - \text{SHR}_{\text{baseline evaporator}}| \leq 1\% \]
\[ \text{Height}_{\text{evaporator}} = \text{Height}_{\text{baseline}} \]
\[ \text{Length}_{\text{evaporator}} = \text{Length}_{\text{baseline}} \]
\[ \text{Height}_{\text{condenser}} = \text{Height}_{\text{baseline}} \]
\[ \text{Length}_{\text{condenser}} = \text{Length}_{\text{baseline}} \]
In terms of constraints on operating conditions, the evaporator outlet superheat degree is specified based on the temperature glide of refrigerants as recommended by refrigerant OEM. The condenser outlet subcooling degree is automatically adjusted, but it is constrained between 2 R to 15 R. The cooling capacity of evaporator is a HPDM solving target and set to be the same as the baseline 3-ton R410A heat pump. The compressor displacement volume is altered in HPDM to meet the target evaporator cooling capacity. When modeling the optimized systems using low-GWP refrigerant other than R410A, the compressor isentropic efficiency is fixed as 0.74 and the volumetric efficiency is fixed as 0.98 to be consistent with the baseline R410A system. The goal is to investigate the required displacement volume of the compressor to meet the system capacity for low-GWP refrigerants.

In terms of constraints on heat exchanger dimensions, the last four constraints in Equation (1) guarantee that the optimized indoor and outdoor heat exchangers have the same frontal shapes as the baseline heat exchangers, i.e., the optimal heat exchangers can fit into the original indoor and outdoor fan-coil unit perfectly. This can ease the retrofit effort of upgrading the R410A heat pump to the new low-GWP system by minimizing the change in manufacturing and installation processes and guarantee that the optimized systems have the best compatibility with end-users’ house structure. As a result, the new products can be easily accepted by manufacturers and end-users.

The staggered tube layout and tube spacings are shown in Fig. 5. These tube layout and spacings are off-the-shelf designs from a heat exchanger manufacturer. The heat exchanger circuitry pattern is fixed as counter flow configuration, since counter-flow pattern has the most efficient heat transfer for high-glide zeotropic mixtures [5].

Fig. 5. Horizontal spacing and vertical spacing in inch for (a) 5-mm tube HX; (b) 7-mm tube HX; (c) 9-mm tube HX.

3. Results

3.1. Drop-in Performances

Fig. 6 (a)), R32 induces a capacity increase by 8.3% and R454B shows 1.48% capacity decrease compared with the R410A baseline. If the baseline R410A heat exchangers and compressor are used, R454C, R455A, R457A, R1234yf and R1234ze(E) induce 29.4%, 26.8%, 32.9%, 46.9% and 55.5% capacity degradation, respectively, without changing any component.

In terms of EER, the variation is very small. R32, R454B, R457A and R1234yf induces EER increases by 2.2%, 3.2%, 1% and 3.3%, while R454C, R455A and R1234ze(E) induces EER decreases by 0.7%, 2.6% and 0.4%, respectively.

For the drop-in test, the compressor isentropic efficiency and volumetric efficiency are predicted by 10-coefficient compressor map provided by the compressor manufacturer. Despite the compressor map is regressed for R410A test data, a scaling method assuming the same isentropic and volumetric efficiencies at the same suction and discharge saturation temperatures for R410A is used to predict the compressor performance when other refrigerants are used. This compressor scaling method is validated against experiment data [11] and demonstrates good prediction accuracy.
Fig. 6. Baseline System Drop-in Cooling Performance at 95 °F (a) Cooling Capacity; (b) EER

Fig. 7 shows the drop-in performance for heating operation under AHRI 210/240 heating condition at 47 °F. R32 shows a 6.7% capacity increase and 0.03% COP increase. R454B shows comparable performance to R410A, i.e., a 3.9% capacity decrease and 1.72% COP increases. R454C, R455A, R457A, R1234yf, R1234ze and induces 6.5%, 27.6%, 38.9%, 52.3% and 62.5% capacity degradation, respectively.

Fig. 7. Baseline System Drop-in Heating Performance at 47 °F (a) Heating Capacity; (b) COP

As a conclusion, these results show that R32 and R454B are good drop-in candidates. However, GWP<150 refrigerants cannot be directly drop-in due to the significant capacity degradation. For low-GWP refrigerants, it is necessary to redesign the system configuration and components to meet the performance metrics. One required change for the compressor is to increase the displacement volume to increase capacity.

3.2. Optimization Results

The previous section shows the drop-in test results, which demonstrates the system efficiency and capacity degrade with drop-in of low-GWP refrigerants. This section shows the results after conducting design optimization of the components and adopting the new system configuration. For all optimization cases, the suction line is sized such that the saturation temperature drop of the suction line for different refrigerants is the same as that of the baseline R410A system. The goal is to investigate the required displacement volume of the compressor to match the R410A system capacity and efficiency requirements.

All cooling-optimized systems using 5-mm capacity requirements (i.e., 36000 BTU/hr) to using 5 mm tube HXs attributes to the increase shown in Table 4. Despite the optimized heat baseline coils, 5-mm tube heat exchangers consist horizontal and vertical tube spacing as shown in Fig. 5.
Fig. 8 shows the cooling performance comparison at 95 °F. For R410A, R32, R454B, R455A and R457A, the optimized 5-mm tube heat exchangers yield 9.4%, 11.6%, 9.4%, 5.5% and 5.1% EER improvements, respectively. Except R32 and R454B, using 7-mm tube and 9-mm tube with GWP less than 150 refrigerants yields performance degradation compared with the baseline drop-in test. For refrigerants with GWP less than 150, heat exchangers with optimal design show a tendency to improve system performance. In this study, increased heat transfer area and reduced mass flux in heat exchangers have the same coil width and coil consist of more tubes in each row and more tube rows due to smaller horizontal and vertical tube spacing as shown in Fig. 5.

![Staggered Heat Exchanger Layouts](image)

**Fig. 5.**

![Cooling Performance Comparison](image)

**Fig. 8.** Cooling Performance Comparison of Baseline and Optimal Systems at 95 °F (a) Cooling Capacity; (b) EER

The cooling optimized designs are evaluated under heating mode at 47 °F. Their performances are depicted in Fig. 9. As shown in Fig. 9(a), the optimal systems using most refrigerants fluids can satisfy the heating capacity of R410A baseline, except R1234ze(E) which induces significant capacity degradation.

In terms of COP, Fig. 9(b), systems using 5-mm tube optimized heat exchangers show the most performance improvements, i.e., 11.4%, 12.7%, 10.2%, 0.05%, 1.2%, 6.5%, 1.0% and 10.0% for R410A, R32, R454B, R455A, R457A, R1234yf and R1234ze(E), respectively. The performance of optimized 7-mm tube HX is close to the baseline system and the performances of system using 9-mm tube HXs are better than the baseline for R32, R454B, R454C, R457A and R1234ze(E), but worse than the baseline for R455A and R1234yf.
Fig. 9. Heating Performance Comparison of Baseline and Optimal Systems at 47°F (a) Heating Capacity; (b) COP

Fig. 10 (a) shows the refrigerant charge of the optimized systems. Use of 5-mm tube heat exchanger yields charge reduction. The charge reductions range from 28.4% to 43.7%. While 7-mm tube heat exchangers increase the system charge, and 9-mm tube heat exchangers have the comparable charge amount compared with the baseline system.

Fig. 10 (b) shows the redesigned compressor displacement volumes for each refrigerant to match the baseline cooling capacity. The required compressor displacement volume is not sensitive to the tube diameters used in the heat exchanger, rather, it is sensitive to the property of fluids. In general, R32 induces displacement volume decreases by 15.8% while R454B, R455A, R457A, R1234yf and R1234ze(E) induce increased displacement volume increases by 4.7%, 40.2%, 50.7%, 62.2%, 152.6% and 224.2%. These results demonstrate the importance of compressor redesign for low-GWP heat pumps. In general, systems using low-GWP refrigerants require larger compressors than systems using R410A.

Fig. 11 (a), the SEER2 of the baseline R410A system is 11.42. R32 and R454B optimized coils can satisfy the baseline SEER2 criteria. Among the five GWP less than 150 refrigerants, the three fluids which overperform baseline is R454C, R457A and R455A using 5-mm tube heat exchangers. The optimized system using R1234yf and R1234ze(E) shows smaller SEER2 after dimension-constrained heat exchanger optimization and compressor sizing.

Fig. 11 (b) shows the HSPF2 of the baseline and optimal systems. The HSPF2 of the baseline R410A system is 7.17. R32 and R454B can satisfy the HSPF requirement regardless of the choice of heat exchanger tubes. When using 5-mm tube heat exchangers with GWP<150 refrigerants, HSPF2 of the optimized systems exceeds HSPF2 of the baseline.
To streamline the performance of different heat exchangers with different low-GWP refrigerants, the SEER2 and HSPF2 are shown in Fig. 12. The marker shapes represent different system types, i.e., either the baseline system or optimal systems with different diameter tubes. And the marker colors show different refrigerants. The performance of the baseline R410A system (SEER2-11.4/HSPF2-7.2) is highlighted as the cross in the center. By comparing the baseline performance with optimized systems, the design space is divided into 4 regions. The system designs located in the upper right region have both cooling and heating performance superior to the baseline and the system designs located in the bottom left region has dual-mode performance inferior to the baseline. The other two regions have designs with only 1 mode better than the baseline. In the upper right region. The best performances are achieved using R32 (SEER2-13.1/HSPF2-7.9), followed by R454B (SEER2-13.0/HSPF2-7.9) and R410A (SEER2-12.6/HSPF2-8.0). For the GWP <150 fluids, three design candidates using R457A (SEER2-12.0/HSPF2-7.5), R454C (SEER2-11.8/HSPF2-7.2) and R455A (SEER2-11.7/HSPF2-7.7) satisfy both heating and cooling performance requirements.

Table 4 shows the heat exchanger structures for those optimal systems in Fig. 12. For brevity, the heat exchanger structure is denoted as Number of Tubes per Row x Number of Rows - Number of circuits. For example, the 7-mm tube indoor baseline heat exchanger in Fig. 3 has 60 tubes per row, 2 rows and has 6 circuits, so its structure is 60x2-6, and the 9-mm tube outdoor baseline heat exchanger has 24 tubes per row, 1 row and 3 circuits, so its structure is 24x1-3. Following this convention, the heat exchanger structures of the optimized system are listed in Table 4.

</table>

From Table 4, the optimal 5-mm tube indoor HX has two structures depending on the fluids, either 64x3-16 or 64x3-32. The optimal 5-mm tube outdoor HXs regardless of fluids have the same structure, i.e., 32x2-16. Compared with the baseline indoor 7-mm tube HX (60x2-6) and baseline outdoor 9-mm tube HX (24x1-3), the number of circuits are significantly increased for optimal HXs using 5-mm tube. The optimizer increases number of circuits to distribute refrigerant mass flow such that the refrigerant pressure drop in the heat exchangers can be reduced and the effect caused by the decreased tube cross sectional area is mitigated.

3.3. Life cycle climate performance analysis

To understand the environmental impacts of optimized heat pumps using the new system configuration and the optimal HX structures with low-GWP refrigerants, life cycle climate performance (LCCP) evaluation is used to analyze the direct and indirect greenhouse gas (GHG) emissions of the system over the course of its lifetime from manufacturing to disposal. It is calculated as the sum of direct and indirect emissions generated over the lifetime of the system “from cradle to grave”. Direct emissions include all effects from the release of refrigerant into the atmosphere during the lifetime of the system. Direct emissions include:

- Annual refrigerant loss from gradual leaks
- Losses at the end-of-life disposal of the unit
- Large losses during operation of the unit
- Atmospheric reaction products from the breakdown of the refrigerant in the atmosphere

The indirect emissions include:

- Emissions from electricity generation
- Emission from the manufacturing of materials
- Emissions from the manufacturing of refrigerants
- Emissions from the disposal of the unit

More details about LCCP evaluation method can be referred to Wan et al. (2021) [22]. The input values used for evaluating the LCCP are shown in Table 5 including the cut-off outdoor temperature and the temperature at which the heat pump starts. A critical part of the LCCP is the assumed leak rate and end of life recovery. 2% leak rate per year with 18 years lifetime and 20% end of life recovery are specified based on ASHRAE 189.1. To compare systems using different low-GWP refrigerants, Chicago is selected for a case study and its TMY-3 weather data is used for annual performance evaluation.

Fig.15 shows the comparison of the direct and indirect emissions for systems. Compared to R410A baseline, systems using other refrigerants reduce direct emissions as shown in Fig.15 (a). This attributes to their lower GWP value and the reduced system charge as shown in Fig.10 (a).

Fig.15 (b) shows the comparison of the indirect emissions. The optimized systems have 10%–16% lower indirect emissions than the baseline system due to the improved EER (Fig.13 (a)) and improved COP (Fig.14). The 5-mm optimal designs with R454C and R457A induces significant indirect emission reductions. This indirect emission reduction attributes to improved SEER2 and HSPF2 as shown in Fig.11 and Fig.12. Since Chicago is a city in the heating climate region IV with both significant number of heating and cooling days, the indirect emissions are affected by both cooling and heating performance.

It is worthwhile to mention that the reduction potential is different in another climate zone. For example, in a location with warm or mild climate, the SEER2, i.e., the cooling efficiency plays a more dominant role since the heat pump is mostly operated in cooling mode.
Fig. 16 shows the comparison of the total emissions. In fact, 96%-98% of the total emission is comprised of indirect emissions. So indirect emission dominates the total emission. Although many designs using 7-mm tube and 9-mm tube heat exchangers show great emission reduction potential, they cannot meet the cooling and heating efficiency requirements as shown in Fig. 12. The three feasible designs satisfying the efficiency requirements are systems using 5-mm tube heat exchangers with R454C, R455A and R457A. The optimal 5-mm tube systems using R454C, R455A and R457A yields 28.6%, 8.5% and 16.5% lifetime emission reduction compared to the baseline R410A system.

4. Conclusion

This study presents heat exchanger and system development technologies to support the transition to refrigerants with GWP lower than 150. Higher than baseline R410A system efficiency levels in cooling and heating modes are achieved by a model-based design optimization approach based on simulation using detailed hardware information. The new reversible heat pump systems with low-GWP refrigerants adopt a new system configuration, the optimized indoor and outdoor heat exchangers, an optimized compressor. The potential of 5-mm, 7-mm and 9-mm tube in heat exchangers are investigated. The optimal systems using R454C, R455A and R457A with 5-mm tube heat exchangers outperform the baseline R410A heat pump product. Life cycle climate analysis shows that the optimized systems using GWP lower than 150 fluids reduce the lifetime CO2 emissions by 8.5%-28.6%, while guaranteeing the same or better capacity and efficiency performance than the baseline.

The optimal heat exchanger designs obtained from this research can fit into the original R410A heat exchanger ducts and chasses, which helps to minimize changes in manufacturing and installation. As a result, the system retrofit impacts on manufacturers and end users are minimized. The proposed design approach establishes a production and installation path to produce cost-effective high-performance low GWP reversible heat pumps.
